Chapter 32

Insulin and Drugs Used for the Treatment of Diabetes

Robin M. Zavod

Bruce L. Currie

Introduction

History and Epidemiology

The term “diabetes mellitus” is derived from the Greek word for siphon (diabetes) and the Latin word for sweet (mellitus). The Greek physician Arateus, in the first century AD, described diabetes as “the melting down of flesh and limbs into urine” (1). The term “mellitus” was added 1,000 years later in medieval times when physicians noticed the sweet taste of urine from some of their patients. Diabetes is not a single disease but, rather, is a group of metabolic diseases characterized by hyperglycemia caused by inadequate insulin secretion with or without a simultaneous decrease in hormone action at its receptor (2). The World Health Organization estimates that 177 million people worldwide have diabetes. It is predicted that by 2010, there will be a 50% increase in this number, with the most significant increases in Africa, Asia, and South America (3). In the United States, it is estimated that 18.2 million people have diabetes. During the last 40 years, the prevalence of this disease has increased sixfold (4). Currently, diabetes is the fifth deadliest disease, killing 400,000 annually.

In 1869, Paul Langerhans determined that the pancreas is comprised of two cell types: acinar cells, which secrete digestive enzymes, and cells clustered in islets with a different biological function (5). Twenty years later, in Strasbourg, France, Mehring and Minkowski induced diabetes in a dog by removing its pancreas. In doing this type of experiment, they determined that the pancreas is the origin of diabetes mellitus (6). By 1909, the German scientist Georg Zuelzer had created the first pancreatic extract; unfortunately, the side effects were too extreme for the extract to be of therapeutic benefit. In 1921, in a laboratory provided by John J. R. MacLeod, Frederick G. Banting (orthopaedic surgeon), and Charles H. Best (medical student) isolated insulin from the pancreas and initially tested it in dogs (7). On January 11, 1922, their pancreatic extract was administered to a 14-year-old diabetic boy, Leonard Thompson, who was near death, and he quickly recovered. On May 31, 1922, a bovine pancreatic extract was developed by William Sansum, M.D., and chief chemist Norman Blatterwick and was injected into 51-year-old Charles Cowan, who recovered and lived to age 90 (8). In 1922, insulin could be readily isolated and purified in large quantities from both cattle and pigs in Great Britain, so the British Medical Research Council introduced insulin as a therapeutic agent. In 1923, Eli Lilly made insulin available in the United States and Canada, and the Nobel Prize for Medicine or Physiology was given to Banting and MacLeod, who shared it with Collip and Best (7). By 1924, large companies in both the United States and Britain were producing insulin and marketing it worldwide. In 1960, the primary amino acid sequence of insulin was identified, and by 1963, the complete synthesis of insulin was possible. Hodgkin and coworkers determined the three-dimensional structure of insulin in 1972 (5).

Type 1 Diabetes

Type 1 diabetes, which represents the diagnosis for 5 to 10% of the diabetic population, is caused by an absolute deficiency in insulin secretion. This overt absence of insulin production results from immune system–mediated destruction of the insulin-producing pancreatic β cells. Without insulin, the body's primary source of energy and the brain's only source of energy, glucose, is unable to

enter cells. This ultimately leads to the cells being energy starved as well as to elevated plasma blood glucose levels (hyperglycemia). Administration of exogenous insulin currently is the only method to effectively resolve this hormone deficiency.

Clinical Significance

Diabetes is a condition wherein the body no longer produces insulin (β-cell dysfunction) or uses insulin efficiently (insulin resistance). Insulin is a hormone that is needed to convert carbohydrates and other food into energy needed for life. The cause of diabetes remains unknown, although genetics and environmental factors, such as obesity and a sedentary lifestyle, appear to play important roles.

More than 20.8 million Americans, or 7% of the population, have diabetes. Unfortunately, an estimated 6.2 million people remain unaware that they have the disease. Diabetes is the leading cause of new-onset blindness, kidney failure, and nontraumatic amputations and has a major role in the development of heart disease, hypertension, sexual dysfunction, and dental disease.

Many oral diabetes medications are available with different mechanisms of action. Combination therapy, using medications from the different classes to address the deficiencies causing diabetes, is standard in diabetes care. Secretagogues, such as the sulfonylureas and the meglitinides, increase pancreatic insulin secretion and usually are used early in the disease process, when pancreatic β cells still produce insulin. Sulfonylureas typically can reduce a patient's hemoglobin A_{1c} by 2%, whereas meglitinides can cause a reduction of approximately 1%. Metformin blocks hepatic output of glucose, is used throughout the disease spectrum, and can reduce hemoglobin A_{1c} by 2%. Metformin is particularly advantageous in its ability to delay the onset of diabetes and to promote weight loss in patients. Thiazolidinediones (TZDs) enhance insulin sensitivity and may have a role early in preserving β-cell function in diabetes. The initial concern about the hepatotoxicity of TZDs has been relaxed, with few cases being reported with available agents. The efficacy typically seen with TZDs is an approximately 1.0 to 1.5% decrease in hemoglobin A_{1c}.

When the β cells of the pancreas cease to make insulin suddenly (type 1) or over time (type 2), exogenous insulin must be administered. The overall goal of insulin is to mimic physiological insulin secretion. This is achieved by using a combination of basal and bolus insulin. Types of basal insulin include neutral protamine Hagedorn, glargine, and detemir. Their role as basal insulin is to provide a constant, relatively peakless supply of insulin throughout the day, regardless of meals. Types of bolus insulin include aspart, glulisine, lispro, and regular. The role of bolus insulins is to provide insulin coverage for meals.

With the introduction of incretin mimetics, the first new class of diabetes agents in nearly 20 years is now available. Incretins improve glucose control but also have the potential to improve insulin resistance and to restore β-cell function.

One important aspect of treating a patient with diabetes is not to focus on blood sugar alone. The leading cause of death for patients with diabetes is heart disease; therefore, health care providers need to assess cholesterol, blood pressure, and other risk factors for heart disease.

Assistant Professor of Pharmacy Practice, School of Pharmacy, Loma Linda University

Type 2 Diabetes

Type 2 diabetes, for which 800,000 new cases are diagnosed per year, is a more complex disease. If one parent has type 2 diabetes, the risk of developing it is 38%, whereas if both parents are affected then, the risk of developing diabetes before age 60 is 60% (3). Type 2 diabetes is characterized by end-organ insulin resistance and/or a relative deficiency in insulin secretion (9). Unlike the abrupt loss of β-cell function characteristic of type 1 diabetes, the pancreatic β cells in type 2 diabetes undergo progressive deterioration over a fairly long time. In many patients, insulin resistance causes an initial increase in plasma insulin levels as a result of a compensatory increase in insulin secretion. At this point, blood glucose levels likely appear normal and the patient is asymptomatic. As β-cell function falters and insulin resistance worsens, hyperglycemia results (2). For most patients with type 2 diabetes, resolution of their metabolic disease may occur with appropriate lifestyle changes, including a well balanced diet and regular exercise. For those type 2 patients who are unable to achieve normal blood glucose levels nonpharmacologically, several classes of oral agents are available that target various biochemical processes associated with insulin secretion and/or insulin receptor sensitivity.

Gestational Diabetes

Gestational diabetes (GDM) complicates approximately 4% of all pregnancies in the United States (135,000 cases annually) (9). It is classified as any degree of glucose intolerance that first occurs during pregnancy, typically during the third trimester. The risk factors associated with developing GDM include previous history of GDM, obesity, glycosuria, or a family history that includes diabetes (10). It is found more frequently in the following populations: African American, Hispanic American, Pacific Islander, and Native American (10). If GDM develops during pregnancy, then the woman has a 50% risk of developing type 2 diabetes in the future and a 50% risk of experiencing GDM in a subsequent pregnancy (10). Babies born to women with preexisting diabetes that is poorly controlled are two- to fourfold more likely

to have a serious birth defect (e.g., eye defects, respiratory tract defects, cleft palate, anal atresia/stenosis, urinary tract defects, and positional defects of the foot) (10). Whether the mother has preexisting diabetes or develops GDM, she is at risk for delivering a large baby (≥10 pounds). It therefore is recommended that those women with preexisting diabetes maintain tight blood glucose control for 3 to 6 months before conception and that insulin therapy replace all oral hypoglycemic medications during the pregnancy.

Table 32.1. Maturity-Onset Diabetes of the Young: Classifications and Genetic Loci (9,11)

Type	Genetic Loci	Biochemical Effect	Treatment
1	HNF-4α	Regulation of gene transcription in pancreatic β cells is abnormal. Defect in metabolic signaling of	Oral agent or

		insulin secretion results.	insulin
2	Glucokinase	Defective enzyme produced. Enzyme is required in conversion of glucose to glucose-6-phosphate (the rate limiting step in glucose metabolism). Defect in β-cell sensitivity to glucose and hepatic storage of glucose as glycogen results.	Diet and exercise
3	HNF-1α	Regulation of gene transcription in pancreatic β cells is abnormal. Defect in metabolic signaling of insulin secretion results.	Oral agent or insulin
4	IPF-1	Transcriptional regulation of β-cell development/function is abnormal.	Oral agent or insulin
5	HNF-1β	Regulation of gene transcription in pancreatic β-cells is abnormal. Defect in metabolic signaling of insulin secretion results.	Insulin
6	NeuroD1	Transcriptional regulation of β-cell development/function is abnormal.	Insulin

Maturity-Onset Diabetes of the Young

Maturity-onset diabetes of the young may account for 1 to 5% of all cases of diabetes in the United States. It is not a single disease but, rather, represents several types of genetic disorders. To date, there have been abnormalities detected at six genetic loci (Table 32.1). It generally is characterized by impaired insulin secretion with minimal or no defects in insulin action. In this scenario, the onset of hyperglycemia is early (<25 years) (9,11).

Metabolic Syndrome

Metabolic syndrome, also known as Syndrome X or the insulin resistance syndrome, was defined by the World Health Organization in 1999 as the presence of diabetes, impaired fasting glycemia, impaired glucose tolerance or insulin resistance, and two or more of the following: obesity, dyslipidemia, hypertension, or microalbuminuria (Table 32.2) (12). Somewhat similar definitions are used by other organizations. The prevalence of this syndrome is highly age dependent (7% in ages 20–29, 44% in ages 60–69, and 42% in ages ≥70). Individuals with this syndrome are predicted to develop cardiovascular disease and diabetes.

Drug-Induced Diabetes

A number of drugs impair insulin secretion or insulin action at its receptor (Table 32.3) and, potentially, cause drug-induced diabetes. Generally speaking, impairment in insulin secretion may not be sufficient to cause a patient to develop diabetes; however, it may be enough for those who are already predisposed to develop the disease or already experiencing insulin resistance (9). In a limited number of cases, patients develop diabetes and their blood glucose levels remain uncontrolled despite treatment with insulin, oral agents, and diet modification (13). The greatest likelihood of developing drug-induced diabetes is associated with the glucocorticoids.

Prediabetes: Impaired Fasting Glucose and Impaired Glucose Tolerance

Impaired fasting glucose (IFG; fasting blood glucose, ≥100 mg/dL and <126 mg/dL) and impaired glucose tolerance (IGT; 2-hour values for oral glucose tolerance, ≥140 mg/dL and <200 mg/dL) are two additional metabolic states that must be mentioned. In addition to those diagnosed with diabetes, 16 million Americans experience IGT (4). Patients with either IFG or IGT could be classified as prediabetic, because the disease has not yet progressed far enough to cause hyperglycemia yet the blood glucose levels are too high to be considered normal (9). Approximately 7% of those patients who present with IFG or IGT progress to overt diabetes annually (3).

Table 32.2. Clinical Measures Associated with Metabolic Syndrome (12)

Condition	Measurement	Gender Differences
Obesity	BMI >30	Waist to hip ratio: Males: >0.9 Females: >0.85
Dyslipidemia	Triglycerides ≥1.7 mmol/L	HDL cholesterol Males: <0.9 mmol/L Females: <1.0 mmol/L
Hypertension Microalbuminurea	BP >140/90 mm Hg Albumin excretion >20 µg/min	

BMI, body mass index; BP, blood pressure; HDL, high-density lipoprotein.

Table 32.3. Drugs that Impair Insulin Secretion or Insulin Action

Thyroid hormone	β-Adrenergic agonists
Nicotinic acid	Thiazides
Glucocorticoids	Dilantin
Atypical antipsychotic agents	α-Interferon

Biochemistry and Pathogenesis of Diabetes

Glucose Metabolism

After consuming a meal, complex carbohydrates are broken down into simpler sugars in the gastrointestinal (GI) tract. Glucose can then be absorbed and serve as the primary source of energy for the body as well as the only source of energy for the brain. If too much glucose is absorbed, then hyperglycemia can result. Normally, the liver is able to prevent hyperglycemia by storing up to two-thirds of the glucose absorbed from the intestines and releasing it when the body requires additional energy (2). In addition to glucose being taken up and converted by glucokinase (hexokinase IV) to glucose-6-phosphate (G6P) and then, ultimately, to glycogen in the liver, it can be taken up or used by several other types of cells. In the presence of insulin, glucose is taken up into muscle (heart, skeletal, and smooth) cells and serves as a source of energy for those cells. Glucose can be taken up by pancreatic β cells via the glucose transporter 2 (GLUT2) and is then, in the rate-limiting step, phosphorylated by glucokinase to G6P (3). In this reaction, glucokinase effectively serves as a glucose sensor for the pancreatic β cells, because it controls the rate of entry of glucose into the glycolytic pathway and the subsequent metabolism of G6P to adenosine triphosphate (ATP) (11). Then, depending on the resulting ratio of adenosine diphosphate to ATP in the pancreatic islet cell, activation of the sulfonylurea receptor 1 (SUR1) protein occurs, followed by a cascade of biochemical events (3). These events include initial closure of potassium channels, which alters the membrane potential of the cell. Calcium channels then open, allowing calcium to flow into the pancreatic islet cell. This increase in intracellular calcium concentration triggers the movement and ultimate release of preformed insulin granules from the islet cells (3).

Role of Insulin and Insulin Receptors

Insulin plays a vital role in a number of biochemical processes, including more than 100 examples of gene regulation. In the liver and muscle tissues, insulin promotes the storage of excess glucose as glycogen. Insulin suppresses hepatic glucose production and the breakdown of fats into fatty acids and glycerol (2). Insulin facilitates absorption of amino acids into cells and their conversion into proteins. Insulin converts excess carbohydrates, which cannot be used as glycogen, into fats and then promotes the storage of fat in adipose tissue (2). When bound to cell surface receptors, insulin initiates a cascade of

events that are integral to the transport of glucose into cells. The insulin receptor is a large, transmembrane glycoprotein composed of two α subunits and two β subunits linked by disulfide bonds (5). The α subunits, which possess the insulin binding domain, are located extracellularly. The β subunits are transmembrane proteins that also possess enzymatic activity. When insulin binds to and activates this receptor, intramolecular autophosphorylation of several β-subunit tyrosine residues occurs (2). This enhances the receptor's tyrosine kinase activity, which is responsible for phosphorylating insulin receptor substrates (IRS-1 to IRS-4). These phosphorylated proteins serve as intracellular signals for processes essential to cell survival and proliferation. This includes translocation of the glucose transporters to the cell surface and synthesis of glycogen, protein, mRNAs, and nuclear DNA (3).

Role of Glucose Transporters

Glucose transport into cells is regulated, in part, by glucose transporters. These integral membrane glycoproteins (~50,000 daltons) are comprised of 12 membrane- spanning α-helical domains (5). Several members of this family (GLUT1 to GLUT5) use a sodium-independent mechanism to facilitate glucose entry into the cell. When insulin binds to and activates its cell surface receptors, the intracellular vesicles, in which the GLUT1 and GLUT4 transporters normally reside, migrate toward the plasma membrane (5). This is an energy-dependent process. These vesicles fuse with the membrane, and the transporters orient themselves such that they become channels through which glucose can enter the cell. This process is reversible in that once insulin dissociates from the receptor, the intracellular vesicles re-form (via endocytosis), thereby moving the glucose transporters back into the intracellular pool. The rate-limiting step in glucose transport into muscle and adipose tissue is the initial translocation of intracellular vesicles toward the plasma membrane. Alteration of one or more steps in this sequence can lead to an insulin-resistant state. For example, a decrease in GLUT4 expression limits glucose entry into the cell (14).

Insulin Resistance

Insulin resistance often is a component of type 2 diabetes, IGT, and metabolic syndrome. It can be caused by obesity, physical inactivity, and aging, or it can be secondary to other disease states (e.g., Cushing's syndrome and pheochromocytoma) or medication usage (e.g., β-adrenergic blocking agents, glucocorticoids, oral contraceptives, and thiazide diuretics) (15). Clinically, insulin resistance presents itself as hyperglycemia because of a decrease in insulin-stimulated glucose transport into adipose tissue and skeletal muscle. There are many potential reasons for the development of resistance, including downregulation of GLUT4 expression (14), downregulation of GLUT4 translocation

to the cell membrane, a decrease in the number of available insulin receptors, and/or a decrease in the affinity of insulin for its receptor (15). It also is possible that downstream insulin signaling may be blocked. This may be caused by dephosphorylation of the β-subunit tyrosine side chains by cellular protein–tyrosine phosphatases; phosphorylation of IRS-1, which reduces its ability to act as a substrate for the β-subunit tyrosine kinase; and/or degradation of the IRS proteins (3).

Hemoglobin A_{1c} and Glucose Control

Hemoglobin normally undergoes glycosylation of its amino terminal valine residue. The product of this glycosylation, hemoglobin A_{1c} (HbA_{1c}), is a valuable endogenous marker for glycemic control over the previous 4 to 12 weeks (16). This endogenous substance has a half-life equivalent to that of an erythrocyte. Measurement of an individual's HbA_{1c} is an assessment of the concentration of plasma glucose and the length of time that hemoglobin was exposed to those glucose concentrations. Clinical trials (e.g., Diabetes Control and Complications Trial [DCCT] and UK Prospective Diabetes Study) have clearly demonstrated that if a patient's HbA_{1c} is maintained below 7%, the development and progression of neuropathy, nephropathy, and retinopathy in type 1 or 2 patients can be significantly decreased (17).

Diabetic Complications

Uncontrolled or poorly controlled plasma glucose levels will result in the development and progression of microvascular and macrovascular diabetic complications that involve the eyes (retinopathy), kidneys (nephropathy), nerves (neuropathy), heart, and blood vessels (9).

Diabetes is the leading cause of new blindness in adults (10,000 cases in diabetic patients per year) and represents 15% of all blindness (2,4). Typically asymptomatic in its earliest, most treatable stages, diabetic eye disease (e.g., retinopathy, glaucoma, and cataracts) represents the most common microvascular diabetic complication. Diabetic retinopathy begins to develop as early as 7 years before the diagnosis of type 2 diabetes. It is caused by the accumulation of polyols, the formation of advanced glycation end products, oxidative stress, and the activation of protein kinase C. These products or processes have adverse effects on cellular metabolism, cell signaling, and growth factors (18).

Diabetes is the leading cause of end-stage renal disease and represents 35% of all end-stage renal disease (2,4). This complication is experienced by approximately 40% of all patients with diabetes and is correlated with increased cardiovascular mortality. Diabetic nephropathy, which is caused by both tubular and interstitial changes in kidney structure, is characterized by stage. Microalbuminuria or incipient nephropathy is defined as increased urinary albumin excretion (>30 mg/24 hours and ≤299 mg/24 hours), whereas macroalbuminuria or overt neuropathy is defined as urinary albumin excretion

of more than 300 mg/24 hours (19). It is more prevalent in the African-American, Asian, and Native-American populations than in the Caucasian population. Even acute episodes of hyperglycemia can cause an increase in glomerular filtration rate or vascular damage resulting in glomerular dysfunction (12).

When plasma glucose levels remain high for an extended period of time, peripheral nerves are injured. Nerve damage, which can affect virtually every nerve fiber in the body, occurs in 60 to 70% of all diabetic patients (2). Peripheral neuropathy can lead to foot ulcerations, amputations, and Charcot joints (9). Cardiovascular autonomic neuropathy, a key cause of morbidity and mortality in the diabetic population, causes symptoms of orthostatic hypotension and decreased heart rate variability, contributes to exercise intolerance, and contributes to left ventricular dysfunction. Gastrointestinal autonomic neuropathy can result in gastroparesis, gastroesophageal reflux disease, delayed gastric emptying, and colon abnormalities. Genitourinary autonomic neuropathy can have adverse effects on both male and female sexual function and urinary continence. What most people associate with diabetic neuropathy actually is termed “sensorimotor neuropathy,” which is characterized by pain, abnormal sensations and sensory loss (20). The pathology of diabetic neuropathy is similar to that described for retinopathy. A staggering statistic is that diabetic neuropathy can be linked to between 50 and 75% of all nontraumatic amputations (4).

There are macrovascular complications to consider as well, including ischemic heart disease, cerebrovascular disease, and peripheral vascular disease. These complications are the primary cause of morbidity in type 2 patients. Diabetic patients have a two- to fourfold greater risk than the nondiabetic population of dying from a myocardial infarction or stroke (17). Insulin resistance has been shown to stifle the action of nitric oxide and increase the levels of prothrombotic factors (e.g., fibrinogen). Without nitric oxide an increase in vascular smooth muscle cell proliferation, an increase in platelet adhesiveness (as well as vasoconstriction) is likely. Insulin resistance also can interfere with the fibrinolytic process via an increase in the synthesis of plasminogen activator inhibitor-1 (PAI-1) (15).

Abnormalities in lipid metabolism also contribute to the macrovascular complications. When the body is unable to use glucose as its source of energy, it relies on the metabolism of fats and proteins for energy. Lipolysis results in the release of fatty acids and glycerol from adipose tissue into circulation. The liver converts excess fatty acids into cholesterol and phospholipids. Along with triglycerides, these substances are organized by the liver into lipoproteins and released into the circulation. This results in the development of hypercholesterolemia and atherosclerosis. When the body increases fat utilization, there is a corresponding increase in the formation and release of keto acids into the circulation, which can result in metabolic ketoacidosis (diabetic ketoacidosis) (2).

Diagnosis of Diabetes

Some, but not all, diabetic patients display the classic signs and symptoms of hyperglycemia before diagnosis. This includes polydipsia (excessive thirst), polyuria (excessive urination), as well as weight loss and a lack of energy despite the consumption of large amounts of food. The diagnosis of any of the previously discussed metabolic disorders, including type 1 and 2 diabetes, requires the measurement of fasting plasma glucose levels and/or plasma glucose levels after an oral glucose challenge. The clinical criteria for the diagnosis of diabetes mellitus are found in Table 32.4. Different clinical criteria exists for the clinical values associated with the diagnosis of IFG and IGT, as previously presented (9). This also is true for GDM in pregnant women when the fasting plasma glucose is greater than 126 mg/dL or the casual plasma glucose is greater than 200 mg/dL. If a patient's plasma level exceeds these thresholds, then a glucose challenge test typically is ordered on a subsequent day. This test, which does not require that the patient be fasting, involves consumption of a 50-g oral glucose load by the patient, followed by evaluation of their plasma glucose after 1 hour. A value of greater than 140 mg/dL indicates that the patient should undergo a subsequent 3-hour, 100-g oral glucose load on another day (10). A 3-hour postload plasma glucose level of 140 mg/dL or greater indicates that a provisional diagnosis of GDM should be made (9).

Role of Hormones Other than Insulin

In addition to insulin, the pancreas produces glucagon from α cells, somatostatin from δ cells, and amylin from β cells. Each of these hormones has an influence on blood glucose concentrations.

Glucagon

Glucagon stimulates glycogenolysis and gluconeogenesis through a receptor-mediated action in the liver. Hyperglycemia in patients with diabetes can be associated with elevated levels of glucagon in the blood. Thus, there is interest in developing glucagon antagonists as an approach to glycemic control (21).

Table 32.4. Diagnosis Criteria for Diabetes Mellitus (9)

Clinical Values	Symptoms
Non-fasting plasma glucose level ≥200	Polydipsia, polyuria, unexplained weight

mg/dL	loss
OR Fasting plasma glucose level ≥126 mg/dl OR 2-hour postload glucose ≥200 mg/dL after consumption of a 75-g oral glucose load	

Somatostatin

Originally isolated from hypothalamic tissue, somatostatin is characterized as an inhibitor of growth hormone (GH) release. The structure was determined in 1971. Subsequent investigations led to the recognition that somatostatin also was released from the pancreas and has a role of inhibiting the secretion of both insulin and glucagon. A total of five somatostatin receptor subtypes have been characterized and cloned (sst1 to sst5). Subtype sst4 is associated with the inhibition of insulin release, and an sst4-selective inhibitor has been reported (22). The somatostatin analogue SOM230 has exhibited selectivity for sst1, sst2, sst3, and sst5 in rats and effectively decreased plasma GH and insulin-like growth factor-1 (IGF-1) levels by 75% without significant effects on insulin or glucagon (23). Another analogue, PTR3173, with selectivity for recombinant human somatostatin receptor (hsst2, hsst4, hsst5) was substantially more effective in inhibiting GH secretion compared to glucagon and insulin release in rats (24). Nocturnal GH release and subsequent elevation of IGF-1 is thought to contribute to insulin resistance. Somatostatin analogues that can selectively control GH or glucagon release could be developed and aid in glycemic control (25). Recent investigations of somatostatin receptors in the retina have led to the proposed use of somatostatin or analogues for the treatment of diabetic retinopathy (26).

Amylin

Amylin normally is cosecreted with insulin from secretory granules in pancreatic β cells in response to meals and works with insulin to provide postprandial glucose control. Native amylin is a single-chain peptide of 37 amino acids. Observed deficiencies of amylin in both type 1 and type 2 patients treated with insulin have led to research and drug development related to amylin (27).

Glucagon-like Peptide-1

Glucagon-like peptide-1 (GLP-1) is an incretin, a natural peptide hormone secreted in response to food intake. Incretins have multiple physiological effects to lower blood sugar, including the stimulation of insulin release and the inhibition of glucagon release following meals (28).

Adiponectin

Adiponectin is a cytokine produced by adipocytes and is termed an “adipokine.” Adiponectin functions as an insulin sensitizer. Downregulation of adiponectin receptors and low levels of adiponectin have been associated with obesity-linked insulin resistance (29). Exercise and dietary changes have been shown to raise low levels of adiponectin in obese adolescents (30). Additionally, sarpogrelate hydrochloride, a 5-HT_{2A} antagonist, elevates low adiponectin levels and normalizes other factors associated with vascular changes seen in type 2 diabetes (31).

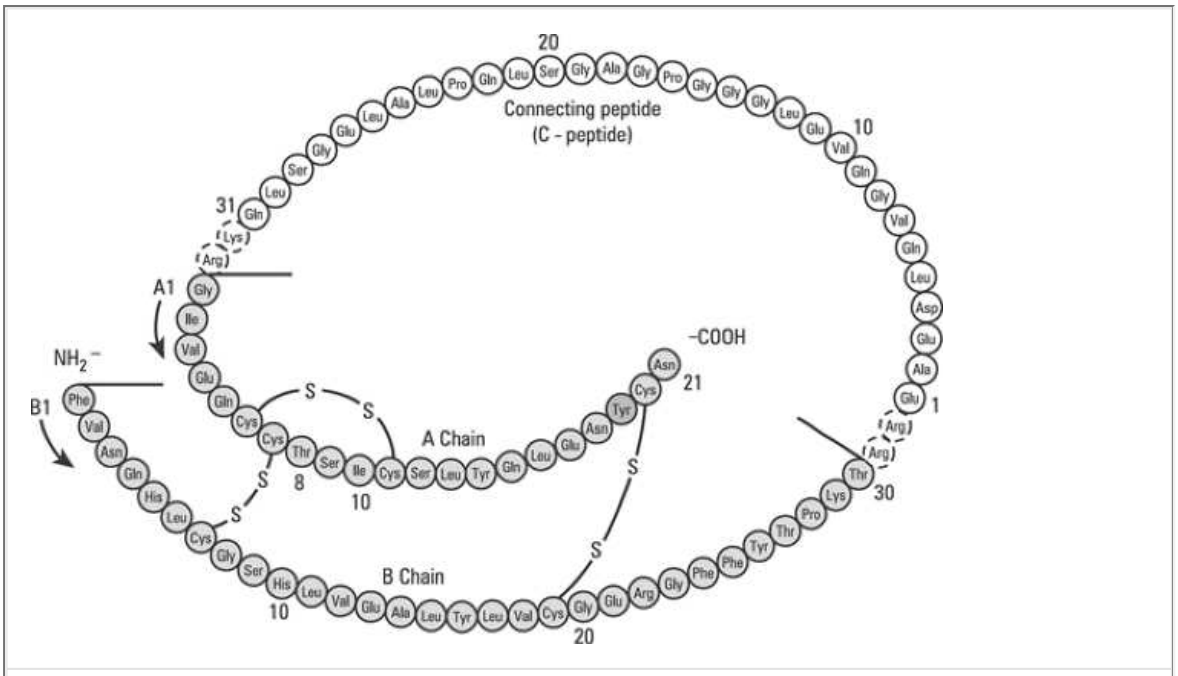

Fig. 32.1. Primary structure of proinsulin, showing cleavage sites to produce insulin.

Insulin

Biosynthesis of Insulin

Insulin has a place in the biochemistry "hall of fame" in that it was the first protein for which the chemical structure and molecular weight were determined and was the first genetically engineered drug approved by the U.S. Food and Drug Administration (7). The active insulin hormone is composed of a 21-amino-acid A chain and a 30-amino-acid B chain that are linked by two disulfide bonds. Separately, each chain is biologically inactive. Insulin is initially synthesized as a 110-amino-acid preprohormone in the pancreatic β cells. The preprohormone then undergoes translocation through the membrane of the rough endoplasmic reticulum. During this process, the cleavage of 24-amino-acids from the N-terminus of the B chain occurs to produce proinsulin. Inside the rough endoplasmic reticulum, the protein folds, and the three critical disulfide bonds form. In the Golgi complex, proinsulin undergoes additional modification that is catalyzed by calcium-dependent endopeptidases (PC2 and PC3). In this process, four basic amino acids as well as the connecting C-peptide are removed via proteolysis (Fig. 32.1). The resulting insulin protein represents the active form of the hormone found in the plasma. In solution, insulin can exist as a monomer, dimer, or hexamer. In the pancreas, insulin is stored in its hexameric form. In this form, two zinc ions are coordinated per insulin hexamer. The half-life of insulin is 5 to 6 minutes, whereas the half life of proinsulin is approximately 17 minutes (5).

Secretion of Insulin

Secretion of insulin from the pancreas is very tightly regulated. When glucose enters the β cell (GLUT-2–facilitated transport), it is phosphorylated by glucokinase to G6P. The G6P is used to generate ATP, thereby changing the ratio of ATP to adenosine diphosphate (ADP) and prevents an ATP-sensitive potassium channel from functioning, which in turn leads to depolarization of the β cells. This prompts activation of a voltage-gated calcium channel and calcium flows into the β cells. The elevated intracellular calcium concentrations causes activation of phospholipases A_2 and C, and levels of inositol triphosphate rise (5). Inositol triphosphate, an intracellular second messenger, facilitates additional release of calcium into the cytosol. The intracellular concentrations of calcium are now sufficiently high to promote insulin secretion from the β cells. Several classes of pharmacological agents alter the regulation of insulin release. A list of these agents and their respective effect on insulin secretion can be found in Table 32.5.

Insulin interacts with its cell surface receptor via key amino acid residues located along the N- and C-termini of the A chain of insulin and along the carboxy terminus of the B chain of insulin (Table 32.6). The binding of insulin occurs to amino acid residues located within the N- and C-terminal regions of the α subunit of the receptor, which includes a cysteine-rich region (5). Binding and activation of the insulin receptor results in a cascade of biochemical events previously described.

Table 32.5. Agents that Alter Insulin Secretion (5)

Pharmacological Class	Effect on Insulin Secretion
α_2-Adrenergic receptor agonist	Inhibits insulin secretion
α_2-Adrenergic receptor antagonist	Promotes insulin secretion
β_2-Adrenergic receptors agonists	Promotes insulin secretion
β_2-Adrenergic receptors antagonists	Inhibits insulin secretion

Table 32.6 Amino Acid Interactions with Insulin Receptor

Chain	N-terminus	C-terminus
A	Gly A1, Glu A4, Gln A5	Tyr A19, Asn A21
B	Val B12	Tyr B16, Gly B23, Phe B24, Phe B25, Tyr B26

Metabolism of Insulin

Insulin degradation occurs primarily in the liver and kidney. Of that which is secreted from the pancreatic islet cells, 50% reaches the liver via the portal vein and undergoes disulfide bond cleavage catalyzed by glutathione insulin transhydrogenase (insulinase). This is followed by proteolytic degradation before entry into the general circulation. Insulin is filtered by the renal glomeruli and can then be reabsorbed or degraded by the tubules (5). At the tissue level, insulin degradation occurs to a limited extent at the cell surface.

Sources of Insulin

Four types of cells are found within the islet of Langerhans, and each cell type secretes its own polypeptide hormone (Table 32.7). The β cells produce a basal level of endogenous insulin at the rate of 0.25 to 1.5 IU/hour. Consumption of a meal causes a biphasic bolus secretion of insulin. There is an immediate release of insulin, followed by an additional release 30 to 45 minutes after eating. Within 2 to 4 hours of a meal, insulin secretion returns to basal levels (8). Under fasting conditions (e.g., overnight), the pancreas produces 40 μg (1 IU)/hour.

In the treatment of all patients with type 1 or some type 2 diabetes, exogenous insulin must be administered to achieve a euglycemic state. Initially, patients only had the option of administering either bovine- or porcine-based insulins. Insulins derived from these animals were considered to be viable alternatives to human insulin, because the amino acid sequence homology between species was superb (Table 32.8). As early as the 1950s, it became obvious that there were limitations to these sources of insulin, because 100% of these patients developed both high- and low-affinity insulin antibodies. As a result, immunologic insulin resistance (a syndrome in and of itself) was reported in those patients with elevated levels of insulin antibodies that bound tightly to insulin (32).

Table 32.7. Polypeptides Secreted by Cells in the Islet of Langerhans

Type of Cell	Hormone Secreted
α	Glucagon

β	Insulin and amylin
δ	Somatostatin
PP or F cell	Pancreatic polypeptide

Table 32.8. Insulin Sequence Homology Between Species

	Insulin Amino Acid Substitutions		
	A Chain		B Chain
Source	Position 8	Position 10	Position 30
Beef	Alanine	Valine	Alanine
Pork	Threonine	Isoleucine	Alanine
Human	Threonine	Isoleucine	Threonine

Once the complete synthesis of human insulin was accomplished (1963), human insulin could be synthesized via two possible routes. One method involved the synthesis of each chain separately, followed by linkage of the chains to produce the active hormone (7). The other, more favored route involved the use of fermentation to synthesize the peptide hormone, followed by isolation of the pure substance. In 1978, Genentech and City of Hope National Medical Center were able to produce human insulin by recombinant DNA methods (7). This involved the insertion of synthesized genes for each of the two chains into *Escherichia coli* and then the use of fermentation methods developed by Eli Lilly to generate commercial quantities of human insulin. Clinical trials started in 1980, and by 1982, Humulin (regular insulin) became the first genetically engineered drug approved by the U.S. Food and Drug Administration (7). Once this recombinant technology was established, it was rapidly applied to the production of a variety of insulin analogues.

Solution Structure of Insulin

The secondary and tertiary structure is substantially the same for all insulins despite differences in the primary structure from various species. The A chain has two α-helices and the B-chain an α-helix and a β-turn, with the B21 to B30 region as a β-strand. This conformation buries a number of hydrophobic A-chain residues in the interior of the peptide, which improves water solubility and stability. The presence of phenol and cresol that often are used as preservatives in insulin formulations results in substantial changes in the insulin conformation. Phenol, in the presence of zinc ions, causes the formation of a B1-B8 helix, which involves movement of more than 25 Å in the B1 residue (33).

Only the insulin monomer is able to interact with insulin receptors, and native insulin exists as a monomer at low, physiological concentrations (<0.1 μM). Insulin dimerizes at the higher concentrations (0.6 mM) found in pharmaceutical preparations, and at neutral pH in the presence of zinc ions, hexamers form (34). These zinc-associated hexamers also are the storage form of insulin in β cells. At concentrations greater than 0.2 mM, hexamers form even in the absence of zinc ions.

Changes in the insulin concentration can profoundly change absorption after subcutaneous administration

(35). Insulin given at a concentration of 40 IU/mL (previously used commercially) is absorbed quite rapidly, but insulin at 100 IU/mL (now used commercially) is absorbed significantly more slowly. This apparently reflects the decrease in monomer concentration, the only absorbable form, as the concentration of insulin increases.

Stability of Insulin

The importance of zinc ions for stabilizing insulin preparations has been known since the first reported crystallization of insulin in the presence of zinc ions in 1934 (36). Suspensions of zinc insulin were used at that time. Presently, all pharmaceutical preparations are either solutions of zinc insulin or suspensions of insoluble forms of zinc insulin. A longer-acting and more stable form of insulin is protamine zinc insulin, which is prepared by precipitating insulin in the presence of zinc ions and protamine, a basic protein. This precipitate is known to contain two zinc ions per insulin hexamer. A somewhat shorter-acting and more useful preparation is neutral protamine Hagedorn (NPH) insulin, which includes m-cresol

as a preservative. This also is known as isophane insulin. Six m-cresol molecules occupy cavities in the hexamer involving the B1-B8 helix formed as a result of the presence of the m-cresol. Later, it was reported that when small additional amounts of zinc ions were added to hexameric two-zinc insulin in neutral acetate buffer, insulin could be made to crystallize in several forms with varying rates of dissolution in water. Thus, the rapidly soluble amorphous semilente insulin is a two-zinc insulin, and the crystalline, more slowly soluble ultralente insulin is a four-zinc form (37,38).

An additional form of insulin, partially unfolded insulin, can form a viscous or insoluble precipitates known as fibrils. Shielding of hydrophobic domains is the principal driving force for the aggregation. Further studies revealed that when the exposed hydrophobic domain (A2, A3, B11, and B15) interacts with the normally buried aliphatic residues (A13, B6, B14, and B18) in the hexameric structure, fibrils form (Fig. 32.1) (39). Fibrils also have been studied by electron microscopy, and packing considerations in the crystal lattice explain why fibril formation is accelerated when insulin is in the monomeric state (40). Insulin fibrils do not resuspend on shaking; thus, they are pharmaceutically inactive.

Insulin fibril formation is particularly important with the advent of infusion pumps to deliver insulin. In these devices, insulin is exposed to elevated temperatures, the presence of hydrophobic surfaces, and shear forces, all factors that increase insulin's tendency to aggregate. These problems can be overcome if the insulin is prepared with phosphate buffer or other additives. Another physical stability problem associated with insulin is adsorption to tubing and other surfaces. This normally occurs if the insulin concentration is less than 5 IU/mL (0.03 mM), and it can be prevented by adding albumin to the dosage form if a dilute insulin solution must be used (34).

There also are chemical instability issues associated with insulin. For 40 years, the only rapid-acting form of insulin was a solution of zinc insulin, with pH 2 to 3. If this insulin is stored at 4°C, deamidation of the asparagine at A21 occurs at a rate of 1 to 2% per month. The C-terminal Asn, under acidic conditions, undergoes cyclization to the anhydride, which in turn can react with water, leading to deamidation. The anhydride also can react with the N-terminal Phe of another chain to yield a cross-linked molecule. If stored at 25°C, the inactive deamidated derivative constitutes 90% of the total protein after 6 months (Fig. 32.2) (34).

If insulin is stored at neutral pH, a different reactions may occur. Deamidation occurs on the Asn at B3, and the products, the aspartate and isoaspartate-containing insulins, are equiactive with native insulin (Fig. 32.2). Deamidation is virtually undetectable in suspensions of bovine insulin zinc (37). More problematic transformations are possible, including chain cleavage between A8 Thr and A9 Ser and covalent cross-linking, either with a second insulin chain or with protamine, if present. These processes are relatively slow compared to the deamidations, but they have the potential of leading to products that may cause allergic reactions. Specific antibodies against insulin dimers have been found in 30% of diabetic patients receiving insulin (41).

Use of Insulin for Treatment of Diabetes

According to the DCCT and the UK Prospective Diabetes study, insulin and/or insulin analogues are the standard treatment for type 1, gestational, and some type 2 diabetes.

These drugs represented $9 billion in sales in 2006, with an anticipated $20 billion in sales by 2012. Although prescribing habits are different between and within countries, the most common factors that influence insulin selection generally include awareness and availability of insulin preparations as well as differences in eating habits and lifestyles (6). As with most medications that treat chronic conditions, the dosage and type of insulin and/or insulin analogue should be individualized and take into consideration the degree to which the patient adheres to recommended diet and exercise regimens. In the evaluation of which types of insulin to prescribe, a number of factors should be considered that affect the onset, degree, and duration of insulin activity. A list of these factors can be found in Table 32.9. These factors relate to the solubility and stability of insulin discussed above.

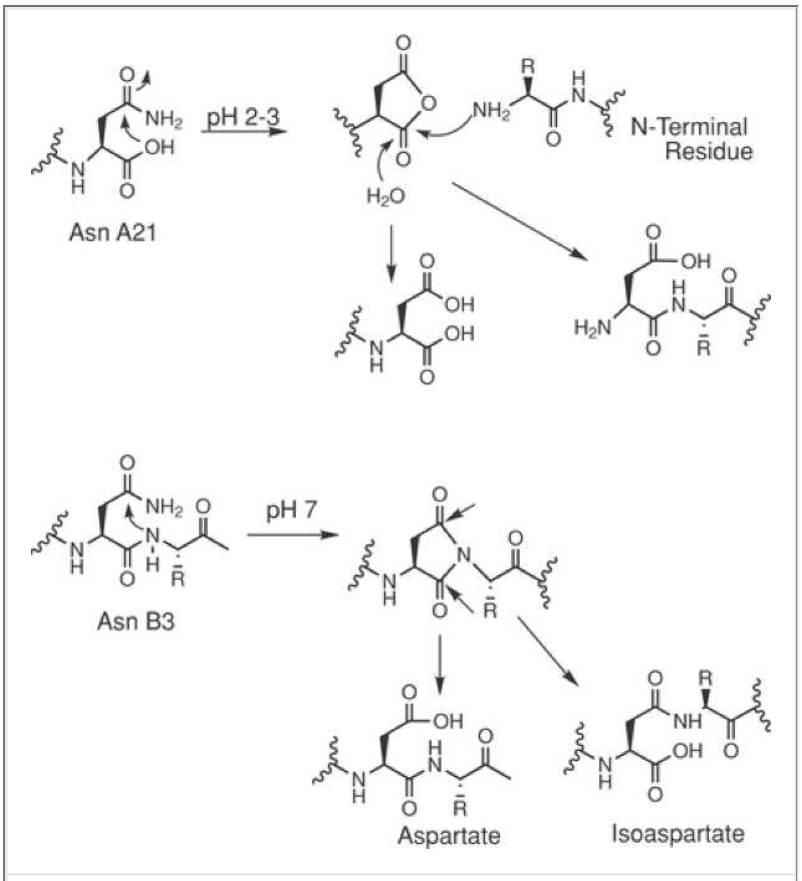

Fig. 32.2. Chemical degradation of insulin.

Table 32.9. Factors that Affect the Onset, Degree, and Duration of Insulin Activity (13)

Primary structure	Additions, deletions, insertions, modifications, and rearrangement of amino acid residues at the N- and/or C-terminus of the B chain
Insulin crystal type	soluble, amorphous, crystalline, microcrystalline
Concentration of zinc	
Presence of modifying protein	protamine
Site of injection	abdomen, upper arms, thighs, buttocks

Insulin Overdose and Diabetic Coma

The most common and serious reaction to insulin therapy is hypoglycemia. It is important that patients with diabetes, especially those receiving insulin therapy, be able to recognize the signs and symptoms of hypoglycemia. Symptoms of hypoglycemia may be evident with a plasma glucose level at 60 to 80 mg/dL. Severe hypoglycemia can lead to convulsions and coma. Patients that vigorously attempt to achieve euglycemia to avoid various vascular complications risk increased frequency of hypoglycemic episodes (42). In the DCCT, the incidence of severe hypoglycemic reactions was threefold

higher in the intensive insulin therapy group than in the conventional therapy group (43). It is now known that hypoglycemia kills neurons actively rather than by starvation from within. Thus, significant damage to regions of the brain can result from severe hypoglycemia (44). Because of these dangers, patients receiving insulin therapy should carry packets of sugar or candy to be used at the onset of the symptoms of hypoglycemia.

Insulin Analogues

Structure–activity relationship studies have been conducted over several years. These studies revealed that variations or removal of amino acid residues from the C-terminus of the insulin B chain did not drastically change the biological activity but could influence the rate of dimer formation or separation. If dimer formation can be inhibited, rapid-acting insulins may be obtained. Thus, the various insulin analogues that have been developed have substitutions in or additions to the C-terminus starting at residue B28. The resulting analogues have either a faster onset or a longer duration of action relative to native insulin. These analogues are all produced by recombinant DNA technology using a modified DNA template. Various analogues are summarized in Table 32.10.

Table 32.10. Insulin Analogues

Generic Name	Trade Name	Change in A Chain	Change in B Chain
Lispro	Humalog	None	B28 Pro → Lys; B29 Lys → Pro
Aspart	NovoLog	None	B28 Pro → Asp
Glulisine	Apidra	None	B3 Val → Lys; B29 Lys → Glu
Glargine	Lantus	A21 Asn → Gly	Add: B31 Arg and B32 Arg
Detemir	Levemir	None	Remove: B30 Thr Add: C14 fatty acid to B29 Lys

Faster-Acting Analogues

As indicated in Table 32.10, both insulin lispro and insulin aspart B28 Pro is replaced with a linear amino acid. This change also results in a conformational change at the C-terminus and, therefore, the ability of the insulin to dimerize. Both of these analogues dissociate into monomers faster, and this produces a faster onset of action. Both insulin lispro and insulin aspart can be injected immediately before meals providing for more convenient timing and more accurate calculation of appropriate dosing. These analogues also can be used in combination with regular or NPH insulin (45).

Longer-Acting Analogues

The first long-acting analogue to be introduced to the market was insulin glargine. This analogue results from the replacement of A21 Asn by Gly and the addition of two Arg amino acids to the C-terminus of the B chain, as indicated in Table 32.10. The resulting analogue has an isoelectric point close to seven, which results in precipitation on subcutaneous injection. The analogue is slowly released from the resulting depot. Insulin glargine produces minimal peak effects and has a duration of action of 22 ± 4 hours. It has been demonstrated to be comparable or slightly better than NPH insulin at maintaining or reducing HbA_{1c} levels without nocturnal hypoglycemia (45).

Insulin detemir is a long-acting analogue that was recently introduced to the market. This analogue results

from N-acylation of the B29 Lys with 14-carbon myristic acid (Table 32.10). The fatty acid side chain binds to plasma albumin to produce a depot and longer action. It is not as long-lasting as insulin glargine, and is injected twice daily by patients with type 1 and type 2 diabetes (45,46).

Drug Development Related to Other Hormones

Significant efforts are underway, in addition to those discussed earlier, to develop therapeutic approaches for the treatment of diabetes that are based on hormones other than insulin.

Glucagon Antagonists

Several nonpeptide glucagon antagonist are being investigated as potential agents for the treatment of diabetes (Fig. 32.3).

Presently, several of these drugs are in early clinical trials, whereas other antagonists of potential interest have not yet entered the clinic (47,48). BAY-27-9955 is an especially interesting antiglucagonemic agents. The drug is being investigated in patients with poorly controlled type 2 diabetes.

Amylin Agonists

Native amylin is a single-chain peptide of 37 amino acids. As previously discussed, amylin is cosecreted with insulin from the β cells in response to meals. Amylin has various actions, including a slowing of gastric emptying and a lowering of blood glucose levels by decreasing glucagon release. It has been reported that amylin levels are abnormally low in patients with type 1 diabetes and are insufficient at mealtime in insulin-using patients with type 2 diabetes. Amylin appears to produce these effects by binding to specific receptors in the central nervous system. The administration of amylin in patients with type 1 diabetes is unsuitable because of a physicochemical property of amylin, which is that the peptide is insoluble and aggregates in solution. Recently, an analogue of amylin has been approved for use in type 1 and type 2 diabetes.

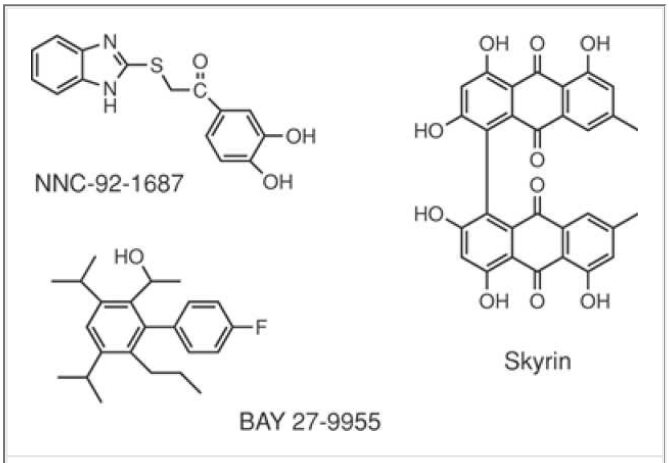

Fig. 32.3. Glucagon receptor antagonists.

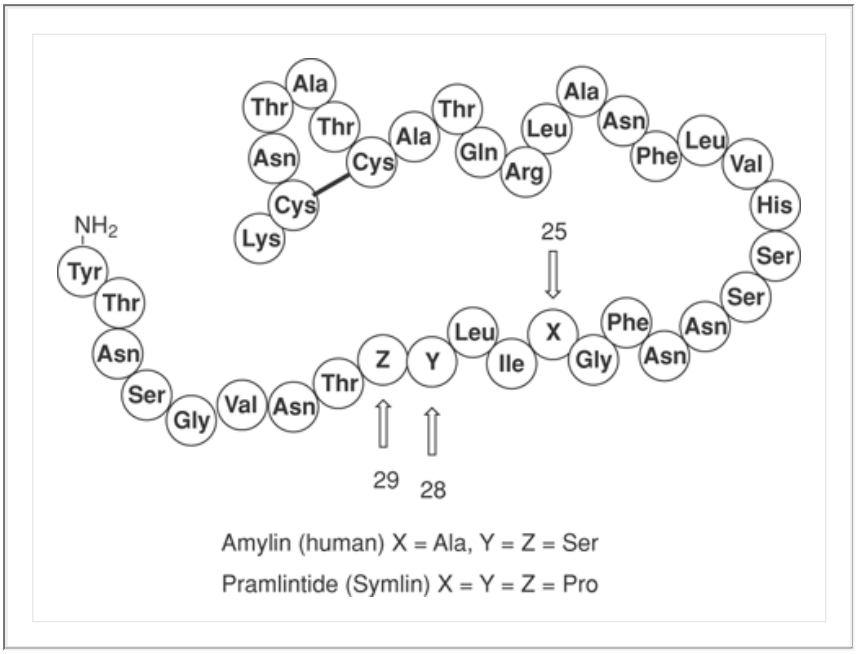


Pramlintide

Pramlintide is an analogue of amylin in which proline has replaced the normal amino acids at positions 25, 28, and 29, as indicated above. The result of these substitutions is an increase in water solubility and a reduced tendency for self-aggregation.

Pharmacokinetics

Pramlintide is administered via subcutaneous injection immediately before meals, reaches maximum circulating concentrations within 20 minutes, and has a half-life of 29 minutes. The drug is eliminated from the body primarily through the kidney. The plasma concentrations are similar to those seen with postprandial amylin. Because the drug is formulated at pH 4.0, it is potentially incompatible with insulin (pH 7.8) if administered within the same syringe, although one study of pramlintide combined with Novolin or Humulin did not show changes in the pharmacokinetics of either drugs (49,50).

Mechanism of action

Amylin receptors have been identified in distinct areas of the brain, including the nucleus accumbens and the dorsal vagal complex. Stimulation of these receptors reduces food intake and depresses GI motility. It is assumed that pranlintide stimulates these receptors, leading to the reported benefits of the drug in patients with diabetes, although the exact mechanism is still poorly understood. Pranlintide causes a moderate reduction in HbA_{1c} and postprandial glucose levels when used in combination with insulin, which has benefits in normalizing fluctuations of circulating glucose levels.

Side effects

The major side effects reported for pramlintide consist of mild to moderate nausea, with severe nausea appearing in patients using large doses of the drug. The nausea may decrease on continued use of the drug. The rate of hypoglycemia appears to be quite low.

Glucagon-like Peptide-1 Agonists

Glucagon-like peptide-1 (GLP-1), a mammalian incretin hormone, consists of two peptides secreted by the endocrine L cells located in the small intestine. The two forms of GLP-1 differ by one amino acid, with 80% of the GLP-1 possessing 30 amino acids (the minor peptide contains 31 amino acids). The role of GLP-1 appears to be to prepare the body for a glucose surge following a sudden rise in plasma glucose. The early insulin response (first-phase insulin secretion) appears to be lost in patients with type 2 diabetes. The GLP-1 stimulates the first-phase release of insulin from the pancreatic β cells and, additionally, inhibits the release of glucagon, thus controlling the release of glucose from the liver. In addition, GLP-1 slows stomach empting, causing a feeling of fullness that reduces additional food intake; it does this by binding to GLP-1–specific receptors in the β cells of the pancreas. The release of GLP-1 is only associated with elevated glucose levels; thus, its release drops when glucose serum levels drop. The GLP-1 itself would appear to have drug potential if not for the fact that GLP-1 has a half-life of 90 seconds. The enzyme dipeptidyl peptidase IV (DPP-IV) metabolizes GLP-1 by removal of two amino acids from the N-terminus of GLP-1. The resulting peptide has a half-life of less than 2 minutes. The enzyme DPP-IV is found in intestinal capillaries and in the liver. Diabetic patients in which GLP-1 was continuously administered exhibited a significant drop in HbA_{1c} (1.3%), a steady weight loss, and an improvement in pancreatic β-cells function. Although continuous administration GLP-1 is not practical, this work did suggest two potential drug avenues: the development of GLP-1 mimics, and the other DPP-IV inhibitors (51,52,53).

Exenatide

During the 1990s, it was discovered that saliva of Gila monsters contained a 39-amino-acid peptide, which had glucoregulatory activity. This peptide, exendin-4, has the ability to bind to the GLP-1 receptor and mimics the action of GLP-1. The synthetic version of exendin-4 is named exenatide. Exenatide shares 53% of the amino acid sequence with GLP-1 and also is a substrate for peptidase hydrolysis. Unlike GLP-1, however, exenatide has a half-life of 2 to 4 hours following subcutaneous injection. Exenatide is thought to exhibit its action via stimulation of GLP-1 receptors, resulting in the positive effects of improved insulin secretion, reduced glucagon release, reduced stomach emptying, as well as a reportedly slowing the loss of β cells and stimulating the differentiation and production of new β cells. The latter effect

appearing to be different from that experienced by GLP-1 release. Exenatide is approved for use in certain patients with type 2 diabetes that is not adequately controlled on metformin and/or a sulfonylurea. The drug is administered via subcutaneous administration in combination with metformin or a sulfonylurea. It has not been approved for use in patients with type 1 diabetes. Some patients have experienced desired weight loss with long-term exenatide use (54). The most commonly reported adverse effects include nausea, vomiting, diarrhea, jittery feelings, headaches, and dizziness. The drug should not be administered prior to marks, but after meals.

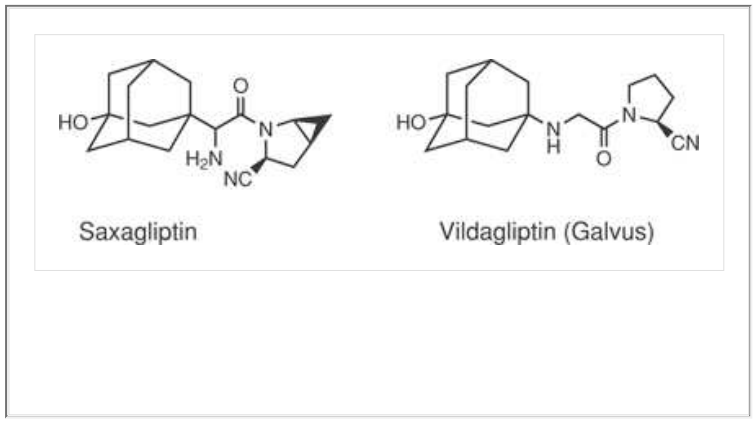
Additional Experimental Agents Affecting GLP-1

Liraglutide

Liraglutide is a GLP-1 derivative in which a 16-carbon fatty acid has been attached to 26-amino-acid lysine. The fatty acid side chain promotes binding to albumin and limits degradation by DPP-IV, resulting in a prolonged duration of action (55). The drug requires once-daily injection and leads to prolonged release of the GLP-1 derivative. The released drug has been shown in animal models to reduce food intake and body weight and, like exenatide, to increase insulin secretion, decrease gastric empting, and reduce blood glucose levels. In addition, glucagon secretion is inhibited. In humans, the half-life of liraglutide has been shown to be extended to 10 hours, with a bioavailability of 55%.

Dipetidyl peptidase iv inhibitors

A serine protease, DPP-IV is the primary protease responsible for degrading GLP-1. This enzyme is found in both intestinal capillaries and the liver. The enzyme removes two amino acids from GLP-1, thus inactivating GLP-1. Unfortunately, DPP-IV is not selective for GLP-1 and its derivatives, but it has protease activity on a variety of substrates, including neuropeptides and enzymes involved in the immune system. A number of pharmaceutical companies have DPP-IV inhibitors in various stages of clinical investigation. Two such agents are saxagliptin (56) and vildagliptin (57). A new drug application has been submitted for vildagliptin with approval expected in 2007.



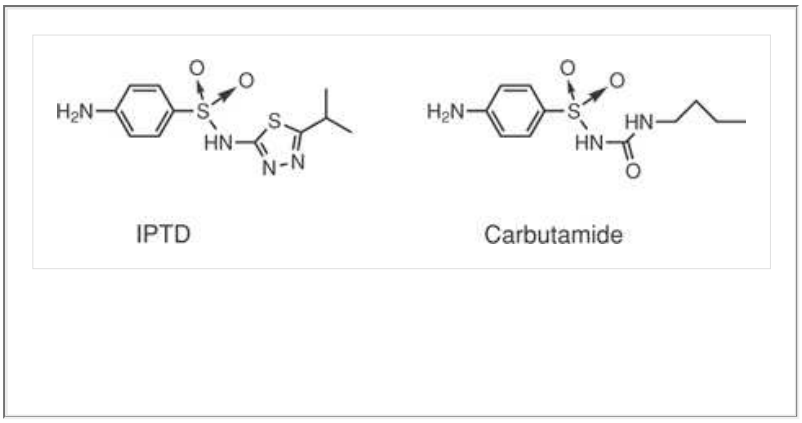
Oral Hypoglycemic Agents

First- and Second-Generation Sulfonylureas

History

In the 1940s, 2-(*p*-aminobenzenesulfonamide)-5-isopropylthiadiazole was used to treat typhoid fever but caused a number of deaths through prolonged hypoglycemia. About this same time, it was found that carbutamide was significantly more active and safer as a hypoglycemic agent. It became the first sulfonylurea hypoglycemic agent to be marketed but, because of effects on bone marrow, ultimately was withdrawn from the market.

After the discovery of carbutamide, many sulfonylureas were examined, and a number are still marketed today. Until 1994 they were the only oral hypoglycemic agents available (58).



Structure–Activity Relationships

The typical sulfonylurea is a mono substituted (usually para) aromatic sulfonylurea that has a bulky aliphatic substituent on the nonsulfonyl-attached nitrogen of the urea. Small alkyl groups, such as methyl or ethyl, are not active. In first-generation analogues, the aromatic substituent is a relatively simple atom or group of atoms (e.g., methyl, amino, acetyl, chloro, bromo, methylthio, or trifluoromethyl); however, the second-generation analogues have a larger *p*-(β-arylcarboxyamidoethyl) group that leads to significantly higher potency (Tables 32.11 and 32.12). Glimepiride typically is classified as a second-generation sulfonylurea, and it has a similar extended binding group like glyburide and glipizide; however, differences in its pharmacological profile may justify a separate classification.

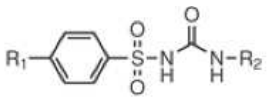
Sulfonylureas are weak acids, with pK_a values of approximately 5.0 with proton dissociation from the sulfonyl-attached nitrogen of the urea. Serum protein binding is high (Table 32.12), so care must be taken when administering with other highly protein bound drugs.

Mechanism of Action

The principal action of the sulfonylureas is to stimulate the release of insulin from β cells. They act by affecting the ATP-sensitive potassium channel. This channel is a hetero-octameric complex of two subunits: a sulfonylurea receptor (SUR1), and an inwardly rectifying potassium channel (Kir6.2). On binding to SUR1, potassium efflux is blocked, leading to depolarization of the membrane. This depolarization opens voltage-dependent calcium channels, resulting in an influx of calcium. At higher intracellular calcium concentrations, calcium-sensitive proteins act to promote the release of stored insulin from the cells. There are two phases to the release of insulin: The first phase involves the insulin granules at the plasma membrane, and a second phase involves newly formed insulin granules that migrate to the membrane (59). These drugs are effective in patients with type 2 diabetes whose insulin-secreting capacity is intact but whose ability to produce adequate insulin in the presence of elevated glucose has been lost. Sulfonylureas can cause hypoglycemia, because these drugs can stimulate insulin secretion even when glucose levels are low.

All sulfonylureas exhibit both insulin-secreting and extrapancreatic activities. Glimepiride relies on extrapancreatic effects for a greater proportion of its

hypoglycemic effect, and it is possibly because of this that it is considered less likely to produce unwanted hypoglycemia. Glimepiride binds well to not only SUR1 in β cells but also to SUR2A (as found in cardiac smooth muscle) and SUR2B (brain and smooth muscle). In contrast, tolbutamide is more selective for SUR1 (60).



Generic name	Trade name	R_1	R_2
1st Generation:			
Tolbutamide	Orinase	CH_3-	$-CH_2CH_2CH_2CH_3$
Chlorpropamide	Diabinese	$Cl-$	$-CH_2CH_2CH_3$
Tolazamide	Tolinase	CH_3-	
Acetohexamide	Dymelor		
2nd Generation:			
Glyburide (Glibenclamide)	Diabeta Micronase Glynase PresTab		
Glipizide	Glucotrol		
Glimepiride	Amaryl		
Table 32.11. First and Second Generation Sulfonylureas

Table 32.12. Pharmacokinetic Properties of the Sulfonylureas

Drug (Sulfonylureas)	Equivalent Dose (mg)	Serum Protein Binding (%)	t½ (hour)	Duration (hour)	Renal Excretion (%)
Tolbutamide	1000	95–97	4.5–6.5	6–12	100
Chlorpropamide	250	88–96	36	up to 60	80–90
Tolazamide	250	94	7	12–14	85
Acetohexamide	500	65–88	6–8	12–18	60
Glyburide	5	99	1.5–3.0	up to 24	50
Glipizide	5	92–97	4	up to 24	68
Glimepiride	2	99	2–3	up to 24	40

Pharmacokinetics and Metabolism

Sulfonylureas are highly protein bound, primarily to albumin, which leads to a large volume of distribution (~0.2 L/kg) (Table 32.12). Food can delay the absorption of these drugs but does not typically affect bioavailability. Metabolism takes

place in the liver, and the metabolites are renally excreted.

Chlorpropamide has a considerably longer half life than the other sulfonylureas, and as a result has a greater tendency for adverse effects. One explanation for the long half-life is that its metabolism (ω and ω-1 hydroxylation of the propyl group) is slow. A significant amount of the drug (~20%) is secreted unchanged.

In contrast, tolbutamide and tolazamide undergo a more rapid benzylic oxidation, leading to an inactive benzoic acid derivative (Fig. 32.4). An alternative hydroxylation of the aliphatic ring of tolazamide to an active metabolite results in a prolonged duration of action relative to tolbutamide.

The major metabolite of acetohexamide is reduction of the keto group, forming an alcohol. The hydroxy metabolite exhibits 2.5-fold the hypoglycemic activity of the parent molecule. An additional reported metabolite results from hydroxylation of the cyclohexyl group at the 4′-position, leading to inactivity.

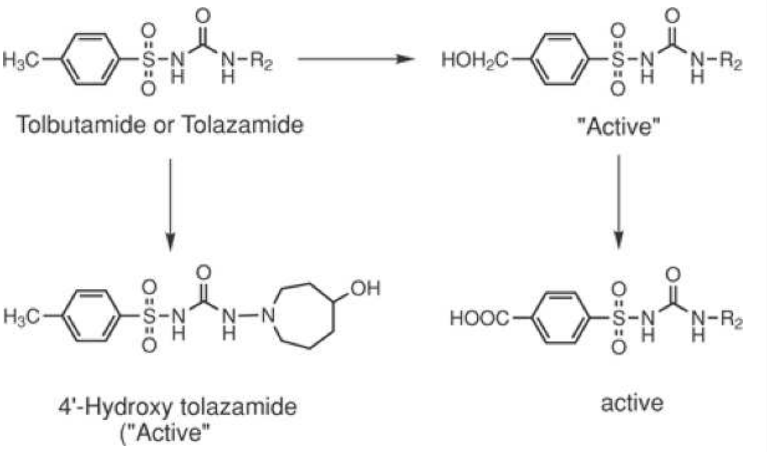


Fig. 32.4. Metabolism of tolbutamide and tolazamide.

Glipizide and glyburide are extensively metabolized (Fig. 32.5) to less active or inactive metabolites. Glipizide metabolites are excreted primarily in the urine, whereas glyburide's metabolites are excreted equally in the urine and bile.

Glimepiride is metabolized in the liver, primarily by CYP2C9, to the active metabolite M-1 (Fig. 32.6). It is then further metabolized to the inactive metabolite M-2.

Therapeutic Applications

Until the introduction of metformin and more recent antidiabetic treatments, sulfonylureas were the first line of pharmacological treatment. Both the first- and second-generation sulfonylureas appear to have the same clinical effectiveness, despite the large differences in potency. All produce a reliable glucose level reduction in patients with type 2 diabetes. These agents work best in patients whose type 2 diabetes is relatively mild (fasting serum glucose of <200 mg/dL or who can be controlled on ≤20 U of insulin daily). Frequency of administration varies among the compounds but is typically only once or twice daily.

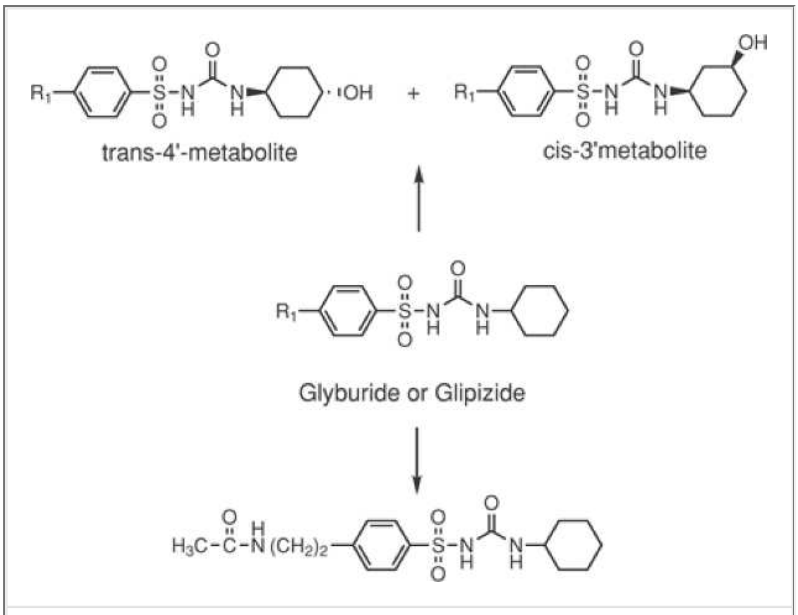

Fig. 32.5. Metabolism of glyburide and glipizide.

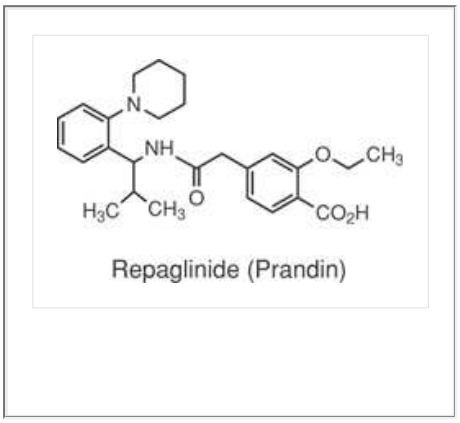
Meglitinides

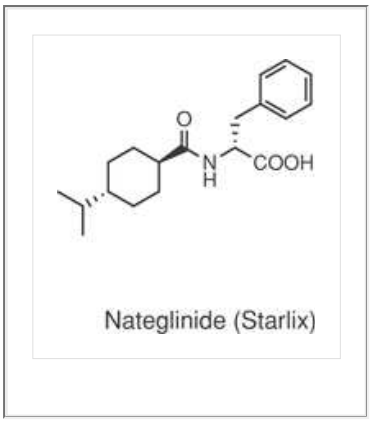
Repaglinide



Repaglinide is a nonsulfonylurea insulin secretagogue that was introduced in the United States in 1998 for type 2 diabetes. Like glimepiride described above, it binds well to SUR1, SUR2A, and SUR2B to block ATP-sensitive K^+ channels, resulting in insulin secretion from β cells in addition to having extrapancreatic effects (60). In an interesting conformational study, it was shown that repaglinide, several other active nonsulfonylurea hypoglycemics, as well as the sulfonylureas glyburide and glimepiride displayed a comparable "U"-shaped conformation, as indicated in molecular modeling studies. In this conformation, hydrophobic cycle groups were placed at the end of each branch, and a peptidic bond was at the bottom of the "U." Several inactive analogues of repaglinide and the poorly active drug meglitinide displayed a different conformation, with a greater distance between the hydrophobic cycle groups (61).

Repaglinide has a rapid onset and short duration of action compared to other hypoglycemic drugs. It is not associated with the prolonged hyperinsulinemia seen with the sulfonylureas, and possibly for this reason, it produces fewer side effects, including weight gain and potentially dangerous hypoglycemia. Repaglinide is at least fivefold more potent than glyburide on intravenous administration and nearly 10-fold more active on oral administration.

Nateglinide



Approved in the United States in late 2000, nateglinide is a rapidly absorbed insulin secretagogue that has a mechanism of action similar to that of repaglinide, with effects appearing within 20 minutes following oral dosing. Bioavailability is 73%, and it is 98% protein bound, primarily to albumin. Nateglinide is tissue selective, with low affinity for cardiac and skeletal muscle. It is metabolized in the liver, with 16% excreted in the urine unchanged. The major metabolites are hydroxyl derivatives (CYP2C9, 70%; CYP3A4, 30%) that are further conjugated to the glucuronide derivatives (Fig. 32.7). The drug has an elimination half-life of 1.5 hours.

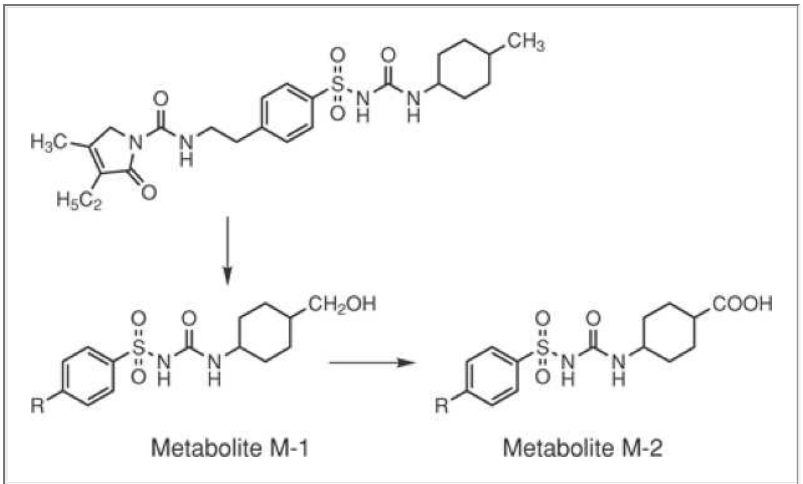


Fig. 32.6. Metabolism of glimepiride.

Like repaglinide, the insulin secretion produced by nateglinide is not as prolonged as that of the sulfonylureas and may result in less instances of hypoglycemia than other insulin-secreting agents. This also may be a result of the glucose-dependence of the insulin secretion caused by the drug. Low glucose levels lead to a diminished release of insulin.

Biguanides

Historically, goat's rue (*Galega officinalis*) had been used in Europe as a traditional remedy for diabetes (62). It was discovered that the active principle in this herb, galegine (isoamyleneguanidine), apparently also was the toxic principle in the plant, which caused the deaths of grazing animals. In 1918, guanidine itself was found to lower blood glucose levels in animals; however, it was too toxic for therapeutic use. In the 1950s, phenformin was found

to have antidiabetic properties and was used in the United States until 1977, when it was removed from the market because of patient deaths associated with lactic acidosis. Metformin was introduced in 1995 in the United States after a track record of safe and effective use for decades overseas, and it is currently in wide use.

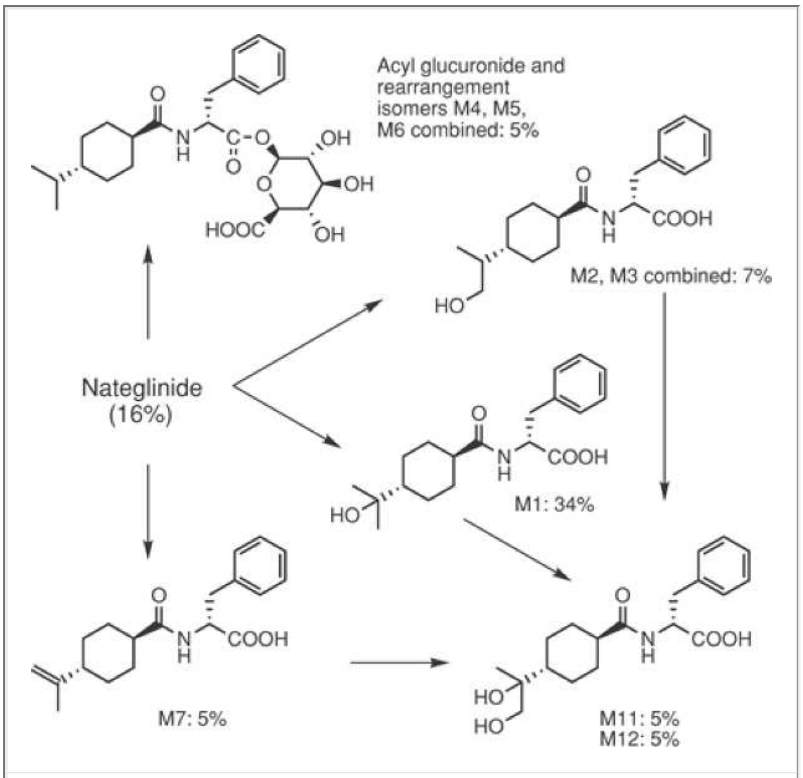

Fig. 32.7. Urinary metabolites of nateglinide.

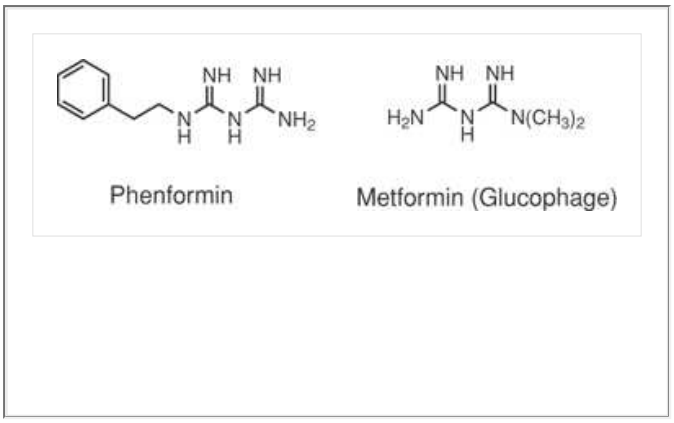

Mechanism of Action

Metformin and the other biguanides are described as insulin sensitizers. Their complete mechanism of action has not been fully elucidated. The biguanides act in the liver by decreasing excessive glucose production, most likely via reduced gluconeogenesis resulting from an increased sensitivity to insulin. They also improve glucose utilization by restoring tissue sensitivity to insulin (63). They appear to have their main action in the liver mitochondria via activation of adenosine 5′-monophosphate–activated protein kinase (AMPK) (64). Additional favorable effects resulting from metformin therapy, such as an improved lipid profile, have been reported. Metformin can lower free fatty acid concentrations by 10 to 30%. This antilipolytic effect may help to explain the reduction in gluconeogenesis through reduced levels of available substrate (65). When given as a monotherapy, metformin treatment does not lead to hypoglycemia, so it is better described as an antihyperglycemic agent rather than a hypoglycemic agent. The therapeutic effect of metformin requires the presence of insulin, and metformin does not stimulate the release of insulin or other factors, such as glucagon. In fact, the secretion of adiponectin, an insulin-sensitizing hormone, appears to be suppressed by metformin (66).

Pharmacokinetics and Metabolism

Metformin is quickly absorbed from the small intestine. Bioavailability is from 50 to 60%, and the drug is not protein bound. Peak plasma concentrations occur at approximately 2 hours. The drug is widely distributed in the body and accumulates in

the wall of the small intestine. This depot of drug serves to maintain plasma concentrations. Metformin is excreted in the urine, via tubular excretion, as unmetabolized drug with a half-life of approximately 2 to 5 hours; therefore, renal impairment as well as hepatic disease are contraindications for the drug (63,65). One key drug–drug interaction of note is the competitive inhibition of renal excretion of metformin by cimetidine, which can lead to increased metformin blood levels (67).

Therapeutic Applications

Metformin is widely used as a monotherapy or in combination with a sulfonylurea in type 2 diabetes. For overweight and obese patients, it is the agent of choice. It is effective in patients of normal weight as well. Other benefits of metformin therapy are the potential for weight reduction and a 15 to 20% lowering of plasma triglycerides. Additional benefits of metformin therapy, particularly for patients with metabolic syndrome, are increased fibrinolysis and decreased plasminogen activator inhibitor-1 (PAI-1), an antithrombolytic protein (63). One study with overweight patients given metformin versus conventional treatment reported a statistically significant, 39% reduced risk of myocardial infarction (68).

Contraindications for metformin include renal insufficiency, liver disease, alcohol abuse, cardiac insufficiency, metabolic acidosis or any hypoxia-related condition. An additional consideration is that chronic metformin therapy can decrease oral absorption and subsequent serum concentrations of cyanocobalamin (vitamin B_{12}); nevertheless, this effect, which is seen in approximately one in four patients, does not appear to result in anemia.

Thiazolidinediones ("Glitazones")

The thiazolidinediones (Fig. 32.8), also known as "glitazones," sometimes are referred to as insulin enhancers. They are exemplified by ciglitazone, the first of the glitazones. Ciglitazone's antihyperglycemic effects were discovered serendipitously. The first drug in this class to be marketed was the drug troglitazone, which was introduced in the United States in 1997. Although clinical studies did indicate hepatic and cardiac toxicity, the toxicities were not considered to be severe, and it was felt that the drug could be used if liver function was closely monitored. In a 96-week study of patients with type 2 diabetes, little or no cardiac toxicity was noted (69). Unfortunately, rare cases of liver failure, liver transplants, and deaths were reported during postmarketing use, and the drug was voluntarily withdrawn in 2000 (70). More recently, two new glitazones have been approved and marketed. These include rosiglitazone and pioglitazone, both of which were introduced in 1999. Both drugs have been approved for monotherapy and combination therapy with metformin, sulfonylureas, or insulin. The

glitazones lower blood glucose concentrations by improving sensitivity to insulin in target tissue, which includes adipose tissue, skeletal muscle, and liver. These agents are dependent on insulin for their activity.

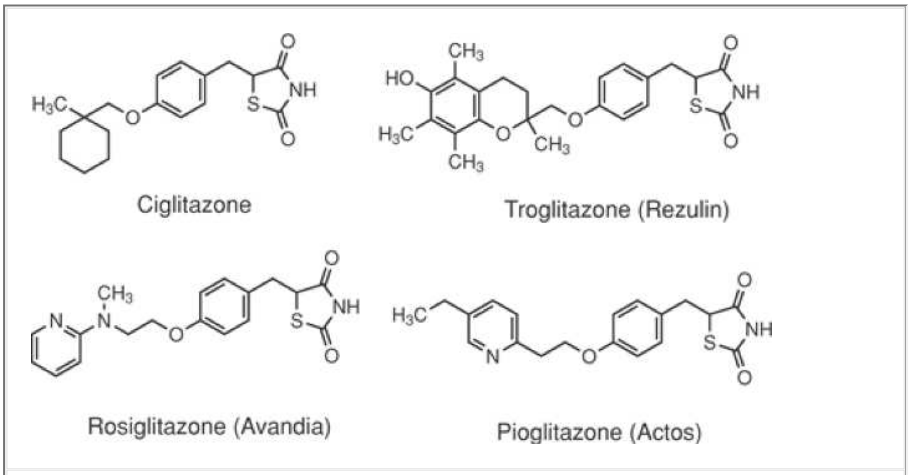

Fig. 32.8. Thiazolidinedione hypoglycemic agents ("glitazones").

Mechanism of Action

Like biguanides, thiazolidinediones are insulin sensitizers; however, they have a different mechanism of action from that of the biguanides. The thiazolidinediones stimulate peroxisome proliferator-activated receptor (PPAR)-γ stimulation. The PPARγ expression is highest in adipose tissue. In association with the retinoid X receptor, PPARγ binds to nuclear response elements, leading to the transcription of insulin-sensitive genes and, subsequently, a wide variety of actions including increases in: glucose uptake (adipose, muscle, liver), lipogenesis (adipose, liver), fatty acid uptake and preadipocyte differentiation (adipose), and glycolysis and glucose oxidation (muscle); in addition to decreases in gluconeogenesis, and glycogenolysis (liver).

Pharmacokinetics and Metabolism

The thiazolidinediones differ by the nature of the groups attached to the 2,4-thiazolidinedione nucleus (Fig. 32.8). These agents are extensively metabolized, with all metabolic changes occurring on or adjacent to the second aryl group. Considerable interest in the metabolism of troglitazone exists, because hepatic toxicity may be associated with a metabolite of troglitazone. Metabolic studies in rats, mice, dogs, monkeys, and humans report the presence of the four metabolites shown in Figure 32.9, with sulfate conjugation (M-1) being the primary metabolite in humans (71,72). The more interesting metabolite is the quinone product M-3, which is thought to arise through the action of CYP2C8 and CYP3A4. Quinone-type metabolites are considered to be reactive intermediates that may induce hepatic toxicity.

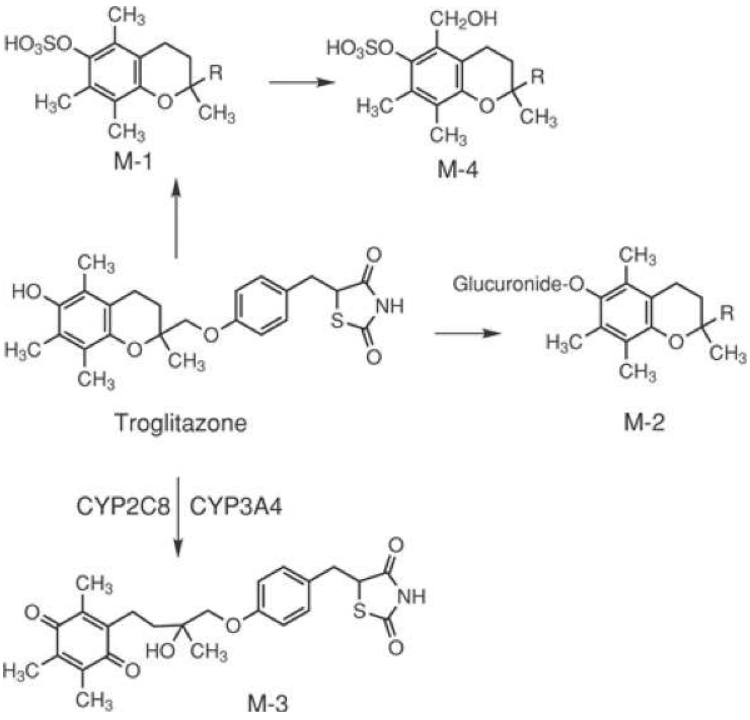

Fig. 32.9. Metabolic pathway of troglitazone.

The metabolism of pioglitazone has been studied in rats and dogs and has led to the discovery of up to eight metabolic products. These products result from oxidation at either carbon adjacent to the pyridine ring and are found as various conjugates in the urine and bile (Fig. 32.10) (73,74). Metabolites M-1, M-2, and M-3 appear to contribute to the biological activity of pioglitazone.

The metabolism of rosiglitazone has been reported in humans, and in excess of 14 metabolites have been identified (75). The primary metabolites consist of sulfate and glucuronic acid conjugates of hydroxylation and N-demethylation products (Fig. 32.11). It is unlikely that these metabolites contribute to the biological activity of rosiglitazone.

Therapeutic Applications

The thiazolidinediones are beneficial in type 2 diabetes through a unique set of pharmacological effects. In a 6-month study of type 2 diabetes, a 600-mg daily dose of troglitazone lowered fasting serum glucose by 60 mg/dL, HbA_{1c} by 1.1%, insulin by 2.4 μU/mL, and triglycerides by 72 mg/dL versus placebo (76). The drugs appear to enhance insulin action, especially in liver, muscle, and fat tissue, where insulin-dependent glucose transport is essential.

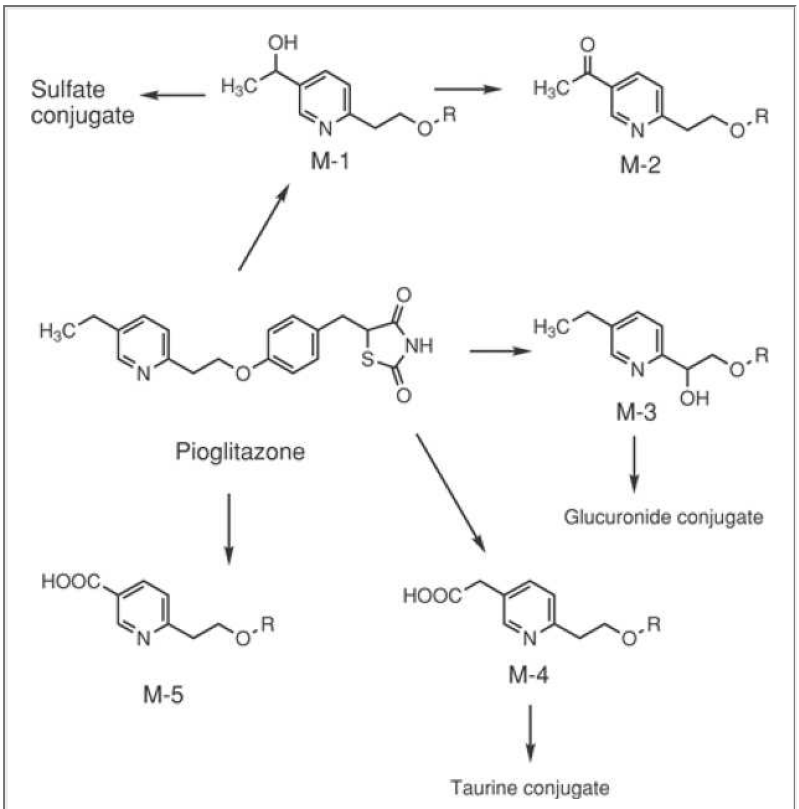

Fig. 32.10. Metabolic pathway of pioglitazone.

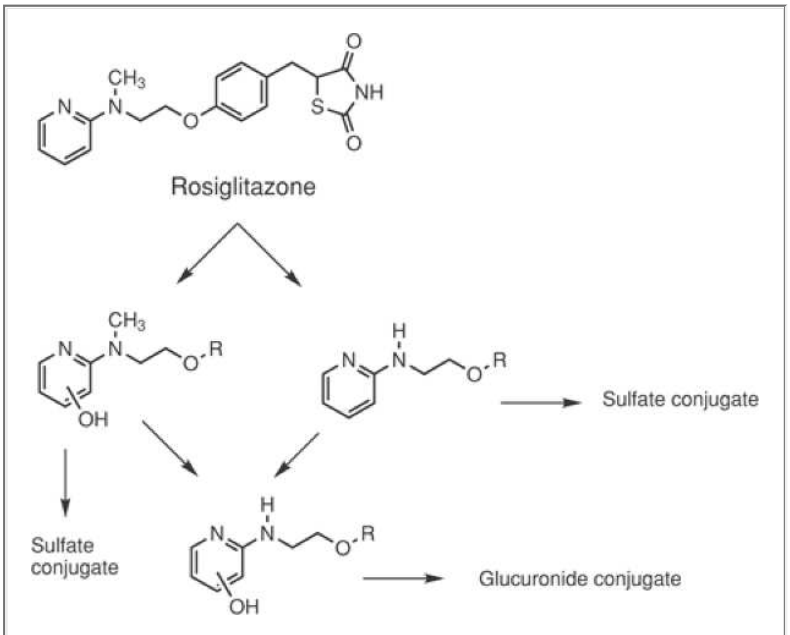

Fig. 32.11. Metabolic pathway of rosiglitazone.

Dual PPARα and PPARγ Coactivators

Because of the adipocyte differentiation effect of PPARγ activators (e.g., thiazolidinediones), weight gain can occur as an

undesirable effect. In theory, a drug that activated both PPARα and PPARγ may be less prone to this side effect because of promotion of fatty acid oxidation. Activation of PPARα also is reported to reduce plasma triglyceride levels and to increase high-density lipoprotein levels; these are very desirable actions for the populations prone to type 2 diabetes. Two such agents that act on both of these targets are muraglitazar and tesaglitazar (Fig. 32.12). Others are in the clinic as well. Clinical trials demonstrated the expected benefits for muraglitazar, and it is intended as a monotherapy or in combination with metformin. Some concerns from the trials, however, are an increase, compared to placebo, in serious cardiovascular events, including death, myocardial infarction, transient ischemic attack, and congestive heart failure (77).

α-Glucosidase Inhibitors

Mechanism of Action

To be absorbed from the GI tract into the bloodstream, the complex carbohydrates that we ingest (i.e., starch) as part of our diet must first be hydrolyzed to monosaccharides (Fig. 32.13). The rationale for the α-glucosidase inhibitor class of drugs is that by preventing the hydrolysis of carbohydrates, their rate of absorption could be reduced. Starch normally is digested by salivary and pancreatic α-amylases to yield disaccharides (maltose), trisaccharides (maltotriose), and oligosaccharides (dextrin). The oligosaccharidases responsible for final hydrolysis of these materials are all located in the brush border of the small intestine and consist of two classes. The β-galactosidases hydrolyze β-disaccharides, such as lactose, whereas the α-glucosidases act on α-disaccharides, such as maltose, isomaltose, and sucrose (78).

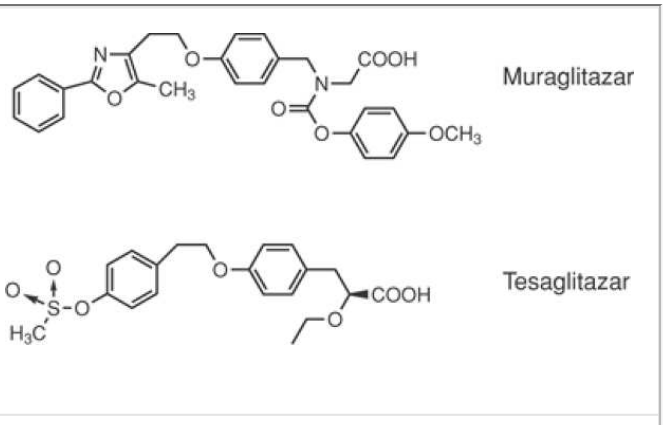

Fig. 32.12. Dual PPARα and PPARγ activators.

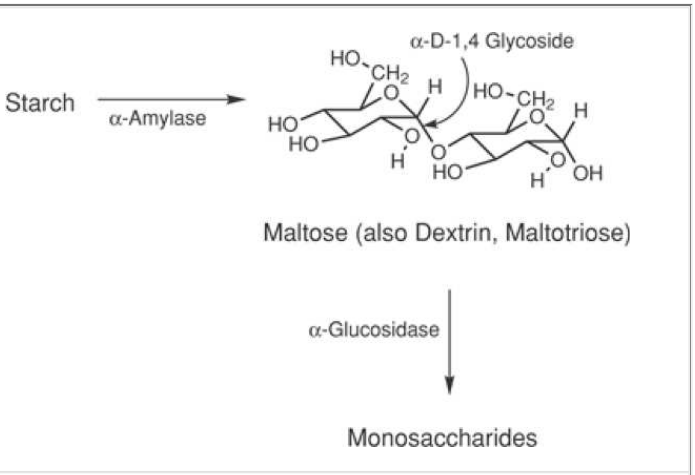

Fig. 32.13. Metabolism of complex carbohydrates.

Structure Activity Relationships

An extensive search for α-glucosidase inhibitors from microbial cultures led to the isolation of acarbose from an actinomycete (Fig. 32.14) (79). Extensive structure–activity investigations revealed that active α-glucosidase inhibitors have a common pharmacophore, comprising a substituted cyclohexane ring and a 4,6-dideoxy-4-amino-D-glucose unit

known as carvosine. It appears that the

secondary amino group of this core structure prevents an essential carboxyl group of the α-glucosidase from protonating the glycosidic oxygen bonds of the substrate (80).

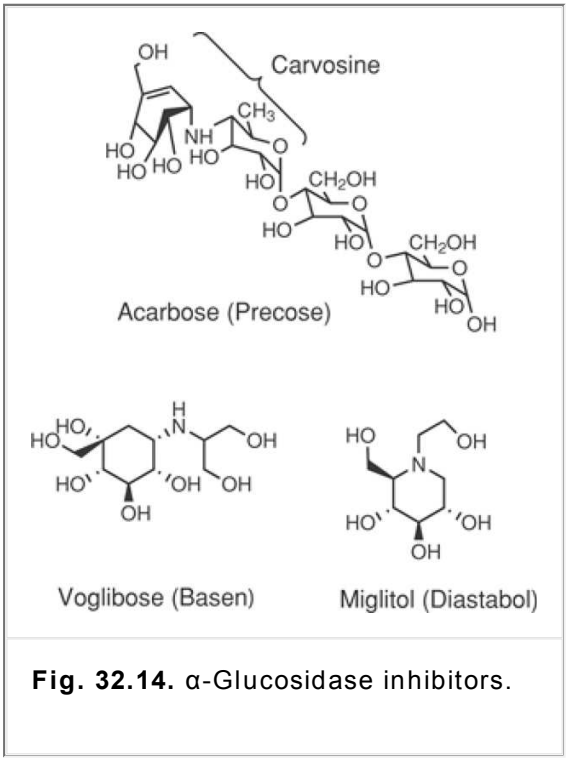

Fig. 32.14. α-Glucosidase inhibitors.

More recently, screening programs of small molecules have yielded several other α-glucosidase inhibitors resembling simple amino sugars, such as miglitol and voglibose (Fig. 32.14).

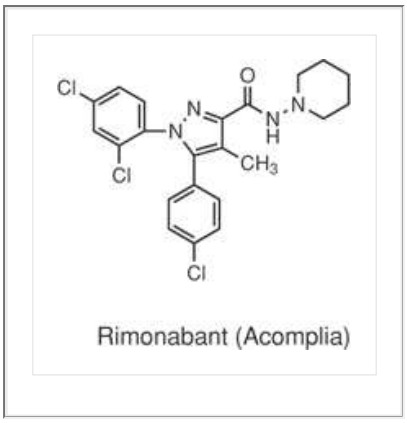
Therapeutic Applications

Clinical studies on α-glucosidase inhibitors reveal that disaccharide hydrolysis is not blocked but, rather, is delayed. Because acarbose impacts end-stage hydrolysis of both starch and sucrose, however, it affects all primary dietary sources of glucose. Patients with type 2 diabetes have an insulin response that is slow as well as inadequate; therefore, slowing the rate of absorption of glucose following a meal should be helpful in preventing the large postprandial increases in serum glucose, which are associated with degenerative complications of diabetes. Treatment with acarbose in insulin-requiring patients with type 2 diabetes was associated with significantly decreased levels of HbA_{1c} (0.4%) and total daily insulin dose (8.3%) (81). Additionally, significant decreases in fasting glucose and in area under glucose–time curves following a meal. Overall, 45% of patients in the study showed a good clinical response to acarbose therapy. Acarbose is only minimally absorbed (0.5–1.7%) into the bloodstream; therefore, it is not associated with any significant systemic toxicity at normal doses. In the small intestine, amylases and bacteria degrade acarbose. Some of the by-products are systemically absorbed and eliminated in the urine. Because doses in excess of 100 mg three times daily are associated with increased serum transaminase levels indicative of liver damage, doses in excess of 100 mg are not recommended. Acarbose also is not recommended in patients with significant renal dysfunction or who suffer from inflammatory bowel disease, colonic ulceration, or partial intestinal obstruction. The drug does cause annoying flatulence and bloating in approximately 60% of the patients who use it, and it is suggested that this may be overcome by starting with a low dose of the drug and then titrating the dose upward. Acarbose (50–100 mg) is taken with the first bite of each meal.

The small molecule α-glucosidase inhibitor voglibose was marketed in Japan in 1994. It also slows the release of monosaccharides from polymeric materials and, thereby, lowers postprandial glucose levels. Additionally, the drug maintains low levels of glucose, triglycerides, and insulin in genetically obese rats, indicating possible effectiveness in conditions other than diabetes, such as obesity.

Miglitol, introduced in 1998, seems to produce therapeutic results similar to those of acarbose. It causes significant lowering of HbA_{1c} and of postprandial and fasting serum glucose. Unlike acarbose, however, miglitol is rapidly and completely absorbed into the bloodstream following oral administration. It is distributed primarily to the extracellular space, and it is rapidly cleared through the kidney without evidence of hepatic metabolism. It is not transferred into the central nervous system (82,83).

Rimonabant



Rimonabant (Acomplia)

Obesity is a major factor leading to type 2 diabetes. As such, effective treatment of obesity may prevent or slow the onset of diabetes. Researchers at Sanofi-Aventis hypothesized that if cannabinoids stimulate appetite in a receptor-specific fashion (e.g., "the munchies"), then blocking central cannabinoid receptors might lead to decreased appetite. Rimonabant was discovered as part of a screening effort directed at the CB1 endocannabinoid receptor. It was found to be a selective and potent antagonist of the receptor. Both preclinical studies with animals and human trials with obese patients indicated that administration of rimonabant led to the decreased consumption of fats and sugar, resulting in weight loss. Additionally, a Phase III trial (the RIO-Diabetes trial) in patients with type 2 diabetes using oral antidiabetic medications demonstrated significant improvement in HbA_{1c}, high-density lipoprotein cholesterol, triglycerides, and systolic blood pressure, along with a reduction in waist circumference (84).

Approaches in Discovery and Development Phases

Considering the medical and economic importance of type 2 diabetes and the need for improvement over existing treatments, new agents for existing targets and the development of new therapeutic targets are being actively pursued in the laboratory and the clinic. Many promising targets are only in the early stages of preclinical development (e.g., small molecule insulin mimetics or glucagon antagonists, glucokinase activators, and β-cell potassium channel openers). Listed below are some selected new classes of therapeutics, some of which are in clinical trials or earlier in research.

Retinoid X Receptor Modulators

The retinoid X receptor (RXR) forms a functional heterodimer with PPARγ as well as other nuclear hormone receptors. The RXR modulators can activate the RXR-PPARγ complex, improving glucose tolerance in animal models; however, selectivity for this particular heterodimer is required to avoid undesirable side effects. Analogues acting by this mechanism are in earlier stages of development.

Protein Tyrosine Phosphatase 1B Inhibitors

It has been observed that mice lacking the protein tyrosine phosphatase 1B (PTP1B) gene generally are normal but have greater insulin sensitivity and gain less weight when given a high-fat diet. The enzyme dephosphorylates both the insulin receptor and the insulin receptor substrate-1, leading to decreased insulin sensitivity. Hence, PTP1B has been an active target for type 2 diabetes drug research. Creating a bioavailable inhibitor has proved to be challenging, however, and research is still ongoing. As an alternative approach, ISIS 113715, which is in Phase II clinical trials, is an antisense oligonucleotide designed to block transcription of PTP1B. The low doses from this trial reduced HbA_{1c} and plasma glucose without causing hypoglycemia.

Case Study

Victoria F. Roche

S. William Zito

BA is an African American male and a former professional football player who at 68 years of age is obese, with a body weight 40% greater than his ideal weight. Along with his obesity, BA has hypertension, hyperlipidemia, and type 2 diabetes. His hypertension is under control with enalapril (10 mg q.d.), and his hyperlipidemia is controlled with atorvastatin (20 mg q.d.). His blood glucose, however, was uncontrollable by diet and glipizide (20 mg q.d.) or by various regimens of insulin (currently regular insulin and NPH insulin administered subcutaneously in the morning and at bedtime, respectively). Last week, BA had laboratory tests, and his results showed that he had developed mild diabetic nephropathy (creatinine clearance, 75 mL/min; urine albumin, 590 g/24 hours). His blood tests showed continued uncontrollable fasting plasma glucose (202 mg/dL; HbA_{1c}, 11%), and now his physician wants to add an oral antidiabetic drug to his insulin therapy. Evaluate structures 1 thought 4 for use in this case.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. The physician seeks your advice in selecting an oral antidiabetic agent (other than glipizide) to add to BA's insulin treatment. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 33

Adrenocorticoids

Duane D. Miller

Robert W. Brueggemeier

James T. Dalton

Introduction

The adrenal glands are flattened, cap-like structures located above the kidneys. The inner core (medulla) of the gland secretes catecholamines, whereas the shell (cortex) of the gland synthesizes steroid hormones known as the adrenocorticoids. The adrenocorticoid steroids include the glucocorticoids, which regulate carbohydrate, lipid, and protein metabolism, and the mineralocorticoids, which influence salt balance and water retention. A third class of steroids produced by the adrenal glands is called the adrenal androgens, which have weak androgenic activity in men and women and can serve as precursors to the sex hormones, estrogens and androgens.

The adrenocorticoids (this chapter) and sex hormones (see Chapters 45 and 46) have much in common. All are steroids; consequently, the rules that define their structures, chemistry, and nomenclature are the same. The rings of these biochemically dynamic and physiologically active compounds have a similar stereochemical relationship. Changes in the geometry of the ring junctures generally result in inactive compounds regardless of the biological category of the steroid. Similar chemical groups are used to render some of these agents water soluble or active when taken orally or to modify their absorption.

In addition, the adrenocorticoids and the sex hormones, which include the estrogens, progestins, and androgens, are biosynthesized mainly from cholesterol (see Chapter 30), which in turn is synthesized from acetyl–coenzyme A. Cholesterol and steroid hormone catabolism take place primarily in the liver. Although the products found in the urine and feces depend on the hormone undergoing catabolism, many of the metabolic reactions are similar for these compounds. For example, reduction of double bonds at positions 4 and 5 or 5 and 6, epimerization of 3α-hydroxyl groups, reduction of 3-keto groups to the 3α-hydroxyl function, and oxidative removal of side chains are transformations common to these agents.

Despite the similarities in chemical structures and stereochemistry, each class of steroids demonstrates unique and distinctively different biological activities. Minor structural modifications to the steroid nucleus, such as changes in or insertion of functional groups at different positions, cause marked changes in physiologic activity. The first part of this chapter focuses on the similarities among the steroids and reviews steroid nomenclature, stereochemistry, and general mechanism of action. The second portion of the chapter focuses on the adrenocorticoids and discusses the biosynthesis, metabolism, medicinal chemistry, pharmacology, and pharmacokinetics of endogenous steroid hormones, synthetic agonists, and synthetic antagonists.

Steroid Nomenclature and Structure

Steroids consist of four fused rings (A, B, C, and D) (Fig. 33.1). Chemically, these hydrocarbons are cyclopentanoperhydrophenanthrenes; they contain a five-membered cyclopentane (D) ring plus the three rings of phenanthrene. A perhydrophenanthrene (rings A, B, and C) is the completely saturated derivative of phenanthrene. The polycyclic hydrocarbon known as 5α-cholestane will be used to illustrate the numbering system for a steroid (Fig. 33.1). The term “cholestane” refers to a steroid with 27 carbons that includes a side chain of eight carbons at position 17. Numbering begins

in ring A at C1 and proceeds around rings A and B to C10, then into ring C beginning with C11, and snakes around rings C and D to C17. The angular methyl groups are numbered 18 (attached to C13) and 19 (attached to C10). The 17 side chain begins with C20, and the numbering finishes in sequential order. Using the planar representation for drawing the steroid structure (Fig. 33.2), the basic steroid structure becomes a plane with two surfaces: A top or β surface is pointing out toward the reader, and the bottom or α surface is pointing away from the reader. Hydrogens or functional groups on the β side of the molecule are denoted by solid lines; those on the α side are designated by dotted lines. The 5α notation is used to denote the configuration of the hydrogen atom at C5, which is opposite from the C19 angular methyl group, making the A/B ring juncture *trans*.

The C19 angular methyl group is assigned the β side of the molecule. Similarly, the configuration of the 8β and 9α hydrogens, and the 14α hydrogen and C18 angular methyl group, denote *trans* fusion for rings B/C and C/D. The side chains at position 17 are always β unless indicated by dotted lines or in the nomenclature of the steroid (e.g., 17β or 17α).

Clinical Significance

Few groups of drugs can rival the adrenocorticoids, which are used for the widest variety of conditions. From asthma to rheumatologic diseases to dermatological disorders, the adrenocorticoids are commonly prescribed for their beneficial action, but unfortunately, they also exhibit toxicity. Only by understanding their complicated mechanisms of action can pharmacists help in maximizing the therapeutic benefits while minimizing the numerous adverse effects of these agents.

Pharmacists must be familiar with the numerous steroid products and dosage forms that are available as well as with the structure–activity relationships that determine their effects at different receptors. By understanding these factors, the likelihood that patients will derive significant benefits without untoward toxicities is significantly increased.

Finally, an appreciation concerning the role of endogenous mineralocorticoids in the pathophysiology of other diseases, such as heart failure and hypertension, is growing. An understanding of how the structure of endogenous and exogenous mineralocorticoids affects their physiologic properties provides insight regarding how drugs that antagonize this system may provide therapeutic benefits for these and other conditions.

Clinical Assistant Professor, University of Houston College of Pharmacy

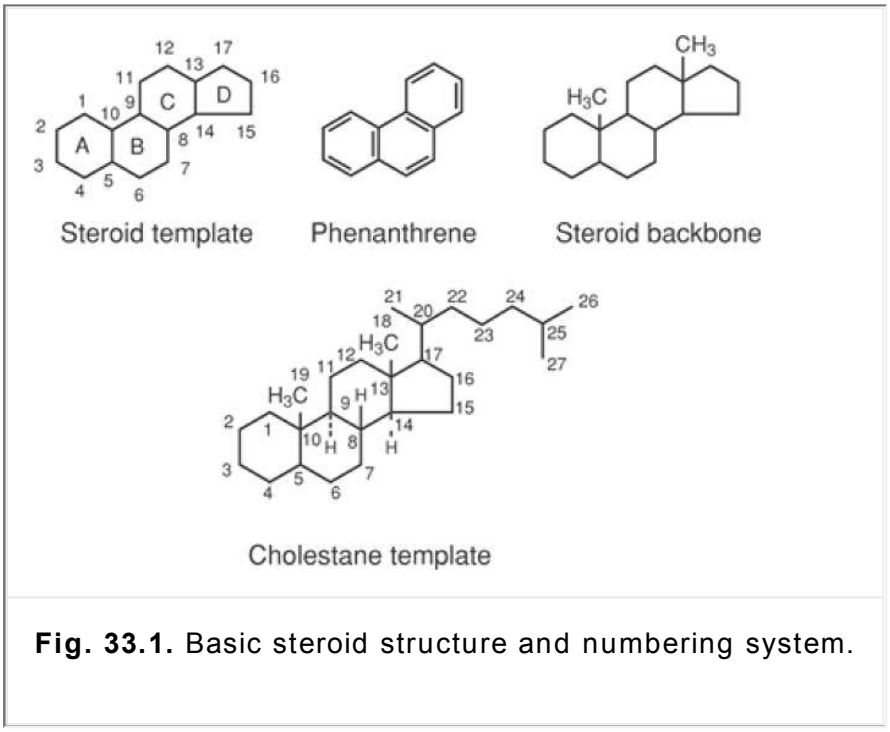

Fig. 33.1. Basic steroid structure and numbering system.

Just as cyclohexane can be drawn in a chair conformation, the three-dimensional representation for 5α-cholestane is shown by the following conformational formula. Although cyclohexane may undergo a flip in conformation, steroids are rigid structures, because they generally have at least one *trans* fused ring system and these rings must be diequatorial to each other.

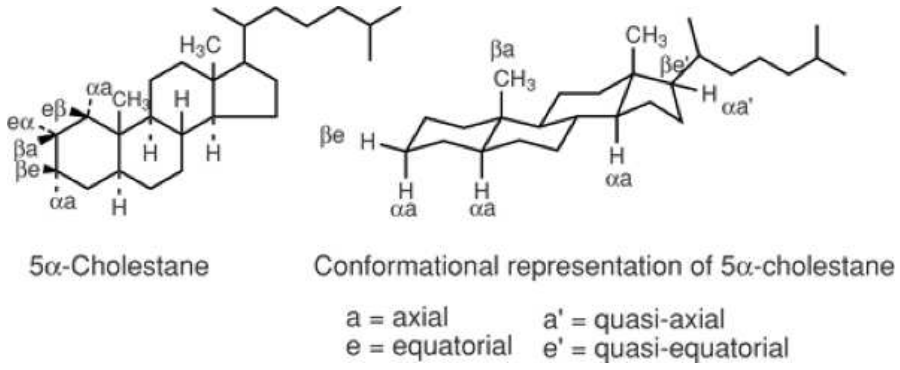

Fig. 33.2. Planar and conformational structures of 5α-cholestane.

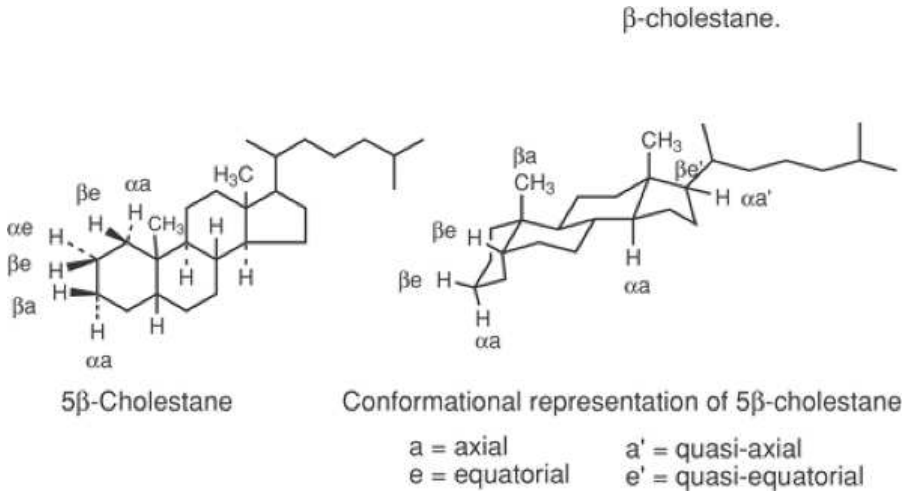

Fig. 33.3. Planar and conformational structures of 5β-cholestane.

If one is aware that the angular methyl groups at positions 18 and 19 are β and have an axial orientation (i.e., perpendicular to the plane of the rings), the conformational orientation of the remaining bonds of a steroid can be easily assigned. For example, in 5α-cholestane, the C19 methyl group attached at position 10 is always β-axial; the two bonds at position 3 must be β-equatorial and α-axial, as indicated. The orientation of the remaining bonds on a steroid may be determined if one recalls that groups on a cyclohexane ring that are positioned on adjacent carbon atoms (vicinal, $-C_1H-C_2H-$) of the ring (i.e., 1,2 to each other) are *trans* if their relationship is 1,2-diaxial or 1,2-diequatorial and are *cis* if their relationship is 1,2-equatorial-axial.

Steroid chemists often refer to the series of carbon–carbon bonds shown with heavy lines as the backbone of the steroid (Fig. 33.1). The *cis* or *trans* relationship of the four rings may be expressed in terms of the backbone. The compound 5α-cholestane (Fig. 33.2) is said to have a *trans-anti-trans-anti-trans* backbone. In this structure, all the fused rings have *trans* (diequatorial) stereochemistry; in other words, the A/B fused ring, the B/C fused ring, and the C/D fused ring are *trans*. The term *anti* is used in backbone notation to define the orientation of rings that are connected to each other and have a *trans*-type relationship. For example, the bond equatorial to ring B, at position 9, which forms part of ring C, is *anti* to the bond equatorial to ring B, at position 10, which forms part of ring A. 5β-Cholestane (Fig. 33.3) has a *cis-anti-trans-anti-trans* backbone in which the A/B rings are fused *cis*. The term *syn* is used in a similar fashion as *anti* to define a *cis*-type relationship. No

natural steroids exist with a *syn*-type geometry, although such compounds can be chemically synthesized. Thus, the conventional drawing of the steroid nucleus is the natural configuration and does not show the hydrogens at 8β, 9α, or 14β positions. If the carbon at position 5 is saturated, the hydrogen is always drawn as either 5α or 5β. Also, the conventional drawing of a steroid molecule has the C18 and C19 methyl groups shown only as solid lines (no CH_3 drawn).

The stereochemistry of the rings markedly affects the biological activity of a given class of steroids. Nearly all biologically active steroids have the cholestane-type backbone. In most of the important steroids discussed in this chapter, a double bond is present between positions 4 and 5 or 5 and 6; consequently, there is no *cis* or *trans* relationship between rings A and B. The symbol Δ often is used to designate a carbon–carbon double bond (C==C) in a steroid. If the C==C is between positions 4 and 5, the compound is referred to as a Δ^4-steroid. If the C==C is between positions 5 and 10, the compound is designated a $\Delta^{5(10)}$-steroid.

Cholesterol (cholest-5-en-3α-ol) is a Δ^5-steroid or, more specifically, a Δ^5-sterol, because it is an unsaturated alcohol. Biologically active compounds include members of the 5α-pregnane, 5α-androstane, and 5α-estrane steroid classes (Fig. 33.4). Pregnanes are steroids with 21 carbon atoms, androstanes 19 carbon atoms, and estranes 18 carbon atoms, with the C19 angular methyl group at C10 replaced by hydrogen. Numbering is the same as in 5α-cholestane.

The adrenocorticoids (adrenal cortex hormones) are pregnanes and are exemplified by cortisone, which is a 17α,21-dihydroxypregn-4-ene-3,11,20-trione. The acetate ester is named 17α,21-dihydroxypregn-4-ene-3,11,20-trione 21-acetate (cortisone acetate) (Fig. 33.4). Progesterone (pregn-4-ene-3,20-dione), a female sex hormone synthesized by the corpus luteum, also is a pregnane analogue. The male sex hormones (androgens) are based on the structure of 5α-androstane. Testosterone, an important and naturally occurring androgen, is named 17β-hydroxyandrost-4-en-3-one. Dehydroepiandrosterone (DHEA) is the major adrenal androgen and is named 3β-hydroxyandrost-5-en-17-one (Fig. 33.4). The estrogens, which are female sex hormones synthesized by the graafian follicle of the ovaries, are estrane analogues containing an aromatic A ring. Although the A ring does not contain isolated C==C groups, these analogues are named as if the bonds were in the positions shown in 17β-estradiol. Hence, 17β-estradiol, a typical member of this class of

drugs, is named estra-1,3,5,(10)-triene-3,17β-diol. Other examples of steroid nomenclature are found throughout this chapter.

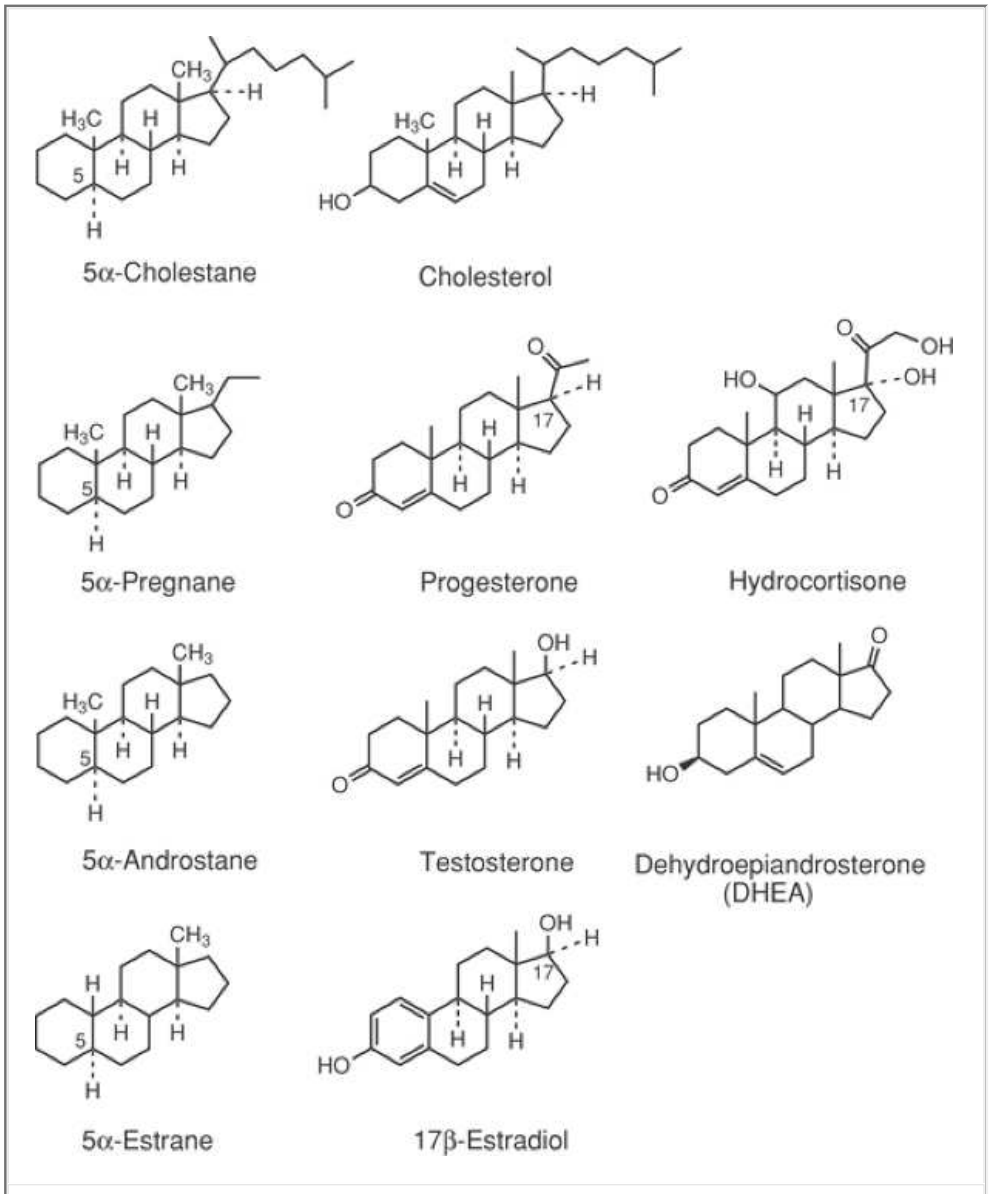

Fig. 33.4. Steroid classes and corresponding natural hormones.

Aliphatic side chains at position 17 are always assumed to be β when cholestane or pregnane nomenclature is employed. Hence, the notation 17β need not be used when naming these compounds. If a pregnane has a 17α chain, however, this should be indicated in the nomenclature. Finally, the final "e" in the name for the parent steroid hydrocarbon is always dropped when it precedes a vowel, regardless of whether a number appears between the two parts of the word (e.g., note the nomenclature for cholesterol and testosterone versus that for cortisone). For a more extensive discussion of steroid nomenclature, consult the literature (1).

Mechanism of Steroid Hormone Action

In addition to their structural similarities, adrenocorticoids, estrogens, progestins, and androgens share a common mode of action. They are present in the body only in extremely low concentrations (e.g., 0.1–1.0 nM), they exert potent physiologic effects on sensitive tissues, and they bind with high affinity to intracellular receptors. Extensive research activities directed at elucidation of the general mechanism of steroid hormone action have been performed for several decades, and many reviews have appeared (2,3,4,5,6,7).

The steroid hormones act on target cells to regulate gene expression and protein biosynthesis via the formation of steroid–receptor complexes, as outlined in Figure 33.5. The lipophilic steroid hormones are carried in the bloodstream, with the majority of the hormones reversibly bound to serum carrier proteins. The free steroids

can diffuse through the cell membrane and enter cells. Those cells sensitive to the particular steroid hormone (referred to as target cells) contain steroid receptors capable of high-affinity binding with the steroid. These receptors are soluble intracellular proteins that can both bind steroid ligands with high affinity and act as transcriptional factors via interaction with specific DNA sites. Early studies suggested that the unoccupied steroid receptors were located solely in the cytosol of target cells (8). Recent investigations on estrogen, progestin, and androgen action, however, indicate that active, unoccupied receptors also are present in the nucleus of the cell (2,7,9). Before the binding of the

steroid, the steroid receptor is complexed with heat shock proteins. In the current model, the steroid enters the cell and binds to the steroid receptor in the cytoplasm or nucleus. This binding initiates a conformational change and dissociation of the heat shock protein, allowing steroid receptor dimerization and translocation to the nucleus. The receptor dimer interacts with particular regions of the cellular DNA, referred to as hormone-responsive elements (HRE), and with various coactivators and nuclear transcriptional factors. Binding of the nuclear steroid–receptor complex to DNA initiates transcription of the DNA sequence to produce mRNA. Finally, the elevated levels of mRNA lead to an increase in protein synthesis in the endoplasmic reticulum. These proteins include enzymes, receptors, and secreted factors that subsequently result in the steroid hormonal response regulating cell function, growth, and differentiation and playing central roles in normal physiological processes as well as in many important diseases.

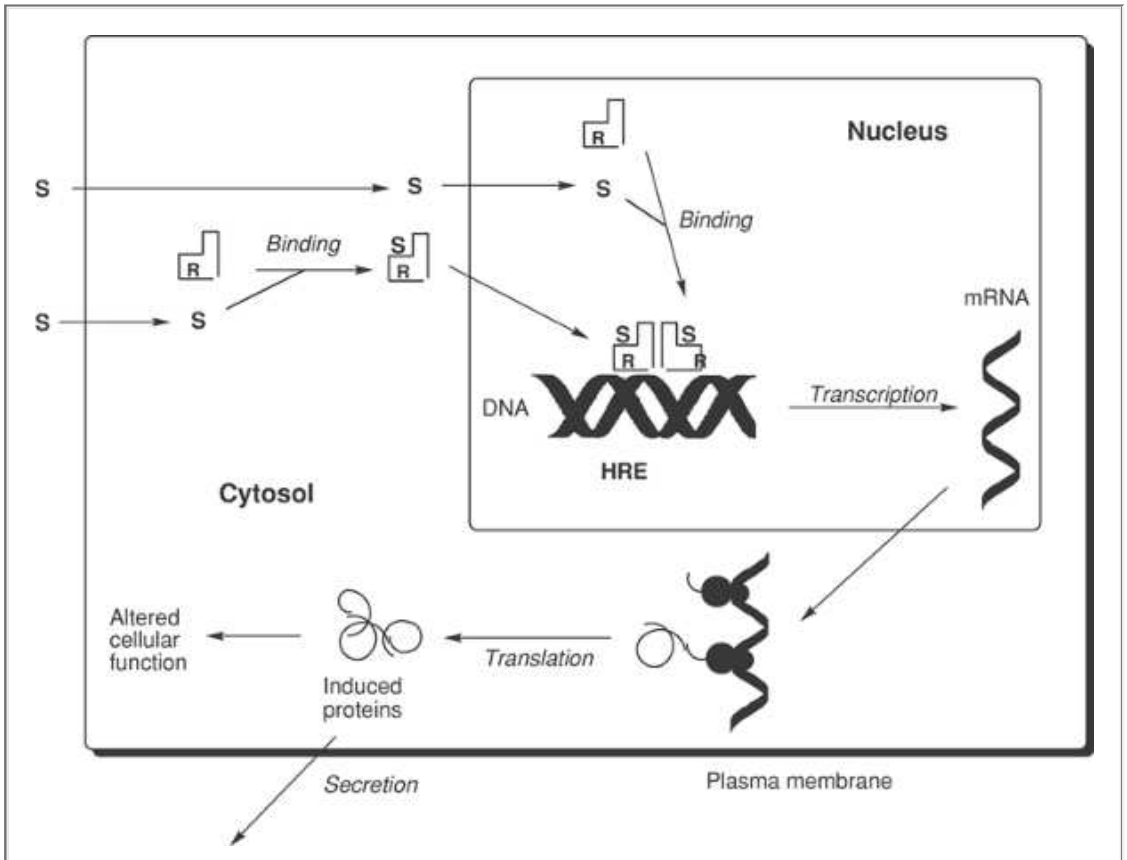

Fig. 33.5. Mechanism of steroid hormone action.

The primary amino acid sequences of the various steroid hormone receptors have been deduced from cloned cDNA (3,5). The steroid receptor proteins are part of a larger family of nuclear receptor proteins that also include receptors for vitamin D, thyroid hormones, and retinoids. The overall structures of the receptors have strong similarities (Fig. 33.6). A high degree of homology (sequence similarities) in the steroid receptors is found in the DNA binding region that interacts with the HRE. The DNA binding region has critically placed cysteine amino acids that chelate zinc ions, forming finger-like projections, called zinc fingers, that bind to the DNA. Structure–function studies of cloned receptor proteins also identify regions of the molecules that are important for interactions with nuclear transcriptional factors, coactivator or corepressor proteins, activation of

gene transcription, and protein-to-protein interactions. Recent evidence suggests that the protein–protein interactions with AP-1 and/or NFκB (other known transcriptional proteins) work to titrate out the effects of the steroid receptors on DNA. This may be critical for cross-talk between signaling pathways within the cell and may play an important role in feedback systems. Additional evidence suggests that steroid receptors may activate transcription in the absence of hormone, an effect that appears to depend on the phosphorylation of the receptor via cross-talk with membrane-bound adrenergic and/or growth factor receptors (10). The interactions necessary for formation of the steroid–receptor complexes and subsequent activation of gene transcription are complicated, involve multistage processes, and leave many unanswered questions.

The basic mechanism of steroid hormone action on target cells is similar for the various classes of agents. Differences in the actions of adrenocorticoids, estrogens, progestins, and androgens arise from the specificity of

the particular receptor proteins, the particular genetic processes initiated, and the specific cellular proteins produced.

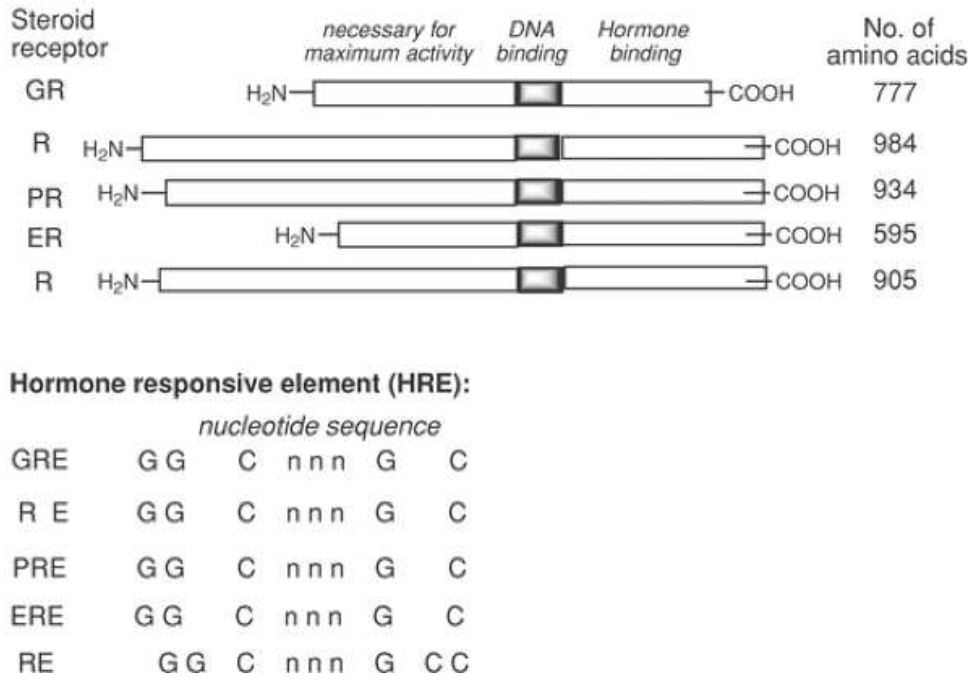

Fig. 33.6. Structural features of steroid hormone receptors and hormone-responsive elements (HREs). Schematic comparison of the amino acid sequences of steroid receptors (GR, glucocorticoid; MR, mineralocorticoid; PR, progesterone; ER, estrogen; AR, androgen) with high homology in the DNA binding region. The HRE sequences also are compared (GRE, glucocorticoid; MRE, mineralocorticoid; PRE, progesterone; ERE, estrogen; ARE, androgen).

History and Disease States

The importance of the adrenal glands was recognized long ago. Addison's disease, Cushing's disease, and Conn's syndrome are pathological conditions related to the adrenal cortex and the hormones produced by the gland.

Addison's disease was named after Thomas Addison. In 1855, Addison described a syndrome in which the physiologic significance of the adrenal cortex was emphasized (11). This disease is characterized by extreme

weakness, anorexia, anemia, nausea and vomiting, low blood pressure, hyperpigmentation of the skin, and mental depression resulting from decreased secretion of steroid hormones by the adrenal cortex. Addison's disease is a rare affliction that affects roughly 1 in 100,000 people and is seen equally in both sexes and in all age groups.

Conditions of this type, generally referred to as hypoadrenalism, may result from several causes, including destruction of the cortex by tuberculosis or atrophy or decreased secretion of adrenocorticotropin (adenocorticotropic hormone [ACTH]) because of diseases of the anterior pituitary (adenohypophysis). Cushing's disease, or hyperadrenalism, on the other hand, may result from adrenal cortex tumors or increased production of ACTH caused by pituitary carcinoma. Cushing's syndrome also is rare, occurring in only two to five people for every 1 million people each year. Approximately 10 percent of newly diagnosed cases are observed in children and teenagers.

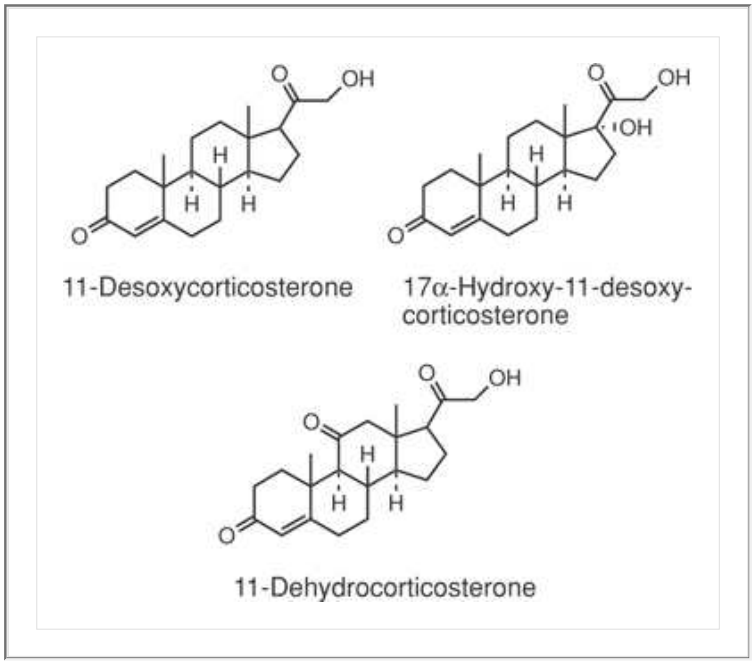
Conn's syndrome is apparently caused by an inability of the adrenal cortex to carry out 17α-hydroxylation during the biosynthesis of the hormones from cholesterol. Consequently, the disease is characterized by a high secretory level of aldosterone, which lacks a 17α-hydroxyl functional group. In addition, hypernatremia, polyuria, alkalosis, and hypertension are observed (12).

The importance of the adrenocorticoids is most dramatically observed in adrenalectomized animals. There is an increase of urea in the blood, muscle weakness (asthenia), decreased liver glycogen, decreased resistance to insulin, lowered resistance to trauma (e.g., cold and mechanical or chemical shock), and electrolyte disturbances. Potassium ions are retained, and excretion of Na^+, Cl^-, and water is increased. Adrenalectomy in small animals causes death in a few days.

After Addison's observations in 1855, physiologists, pharmacologists, and chemists from many countries contributed to our understanding of adrenocorticoids. It was not until 1927, however, that Rogoff and Stewart found that extracts of adrenal glands, administered by intravenous (IV) injection, kept adrenalectomized dogs alive.

P.883

Since that discovery, similar experiments have been repeated many times. Originally, the biological activity of the extract was thought to result from a single compound. Later, 47 compounds were isolated from such extracts, and some were highly active. Among the biologically active corticoids isolated, hydrocortisone, corticosterone, aldosterone, cortisone, 11-desoxycorticosterone (17α-hydroxyprogesterone), 11-dehydrocorticosterone (11-desoxycortisol), and 17α-hydroxy-11-desoxycorticosterone were found to be most potent (13). The biosynthesis of these steroids is described below.



Biosynthesis

Pregnenolone Formation

In the adrenal glands, cholesterol is converted by enzymatic cleavage of its side chain to pregnenolone (3β-hydroxypregn-5-en-20-one), which serves as the biosynthetic precursor of the adrenocorticoids (Fig. 33.7).This biotransformation is performed by a mitochondrial cytochrome P450 enzyme complex. This enzyme complex found in the mitochondrial membrane consists of three proteins: cytochrome P450 11A1 (CYP11A1; also known as $P450_{SCC}$), adrenodoxin, and adrenodoxin reductase (14). Defects in CYP11A1 lead to a lack of glucocorticoids, feminization, and hypertension. Three oxidation steps are involved in the conversion, and three moles of NADPH and molecular oxygen are consumed for each mole of cholesterol converted to pregnenolone. The first oxidation results in the formation of cholest-5-ene-3β,22R-diol (step a), followed by the second oxidation yielding cholest-5-ene-3β,20R,22R-triol (step b). The third oxidation step catalyzes the cleavage of the C20-C22 bond to release pregnenolone and isocaproic aldehyde (step c).

Pregnenolone serves as the common precursor in the formation of the adrenocorticoids and other steroid hormones. This C21 steroid is converted via enzymatic oxidations and isomerization of the double bond to a number of physiologically active C21 steroids, including the female sex hormone progesterone and the adrenocorticoids hydrocortisone (cortisol), corticosterone, and aldosterone. Oxidative cleavage of the two-carbon side chain of pregnenolone and subsequent enzymatic oxidations and isomerization lead to C19 steroids, including the androgens testosterone and dihydrotestosterone. The final group of steroids, the C18 female sex hormones, are derived from oxidative aromatization of the A ring of androgens to produce estrogens. More detailed information regarding these biosynthetic pathways are described in this and the following chapters under the particular class of steroid hormones.

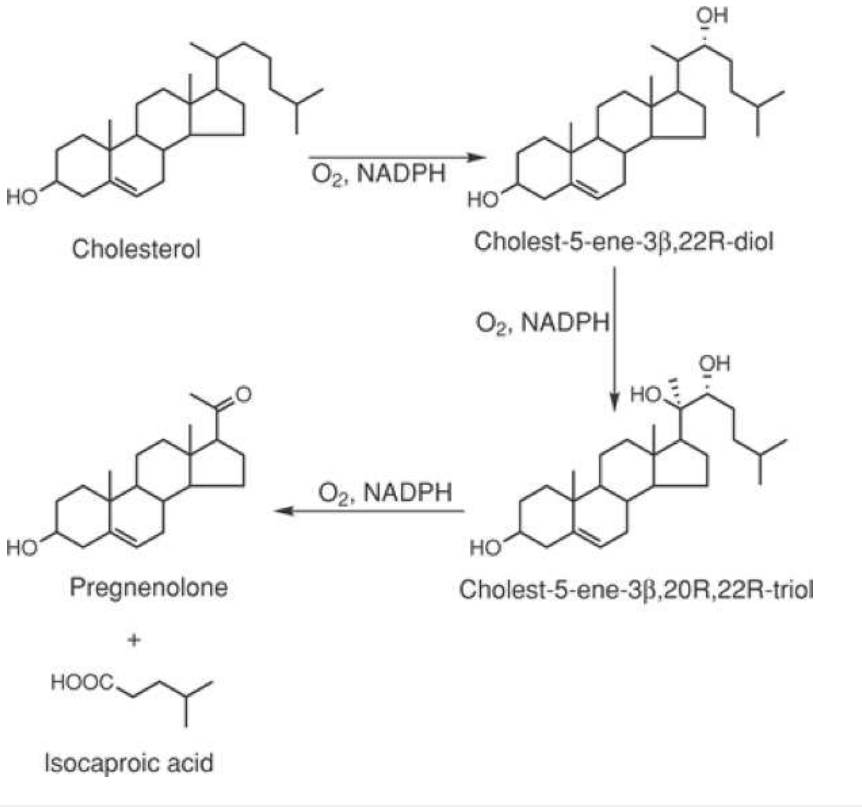


Fig. 33.7. Biosynthesis of pregnenolone from cholesterol.

Pregnenolone to Glucocorticoids and Mineralocorticoids

The biosynthesis of the glucocorticoids and mineralocorticoids are regulated by independent mechanisms. The glucocorticoids, such as cortisol, are biosynthesized and released under the influence of peptide hormones secreted by the hypothalamus and anterior pituitary (adenohypophysis) to activate the adrenal cortex (the

hypothalamic-pituitary-adrenal [HPA] axis). Removal of the pituitary results in atrophy of the adrenal cortex and a marked decrease in the rate of glucocorticoid formation and secretion. On the other hand, the secretion of the mineralocorticoids, corticosterone and aldosterone, are under the influence of the octapeptide, angiotensin II. Angiotensin II is the active metabolite resulting from the renin-catalyzed proteolytic hydrolysis of plasma angiotensinogen to angiotensin I in the blood. In hypophysectomized animals, the rate of secretion of aldosterone is only slightly decreased or remains

unchanged. Consequently, the electrolyte balance remains nearly normal.

The peptide hormone in the anterior pituitary that influences glucocorticoid biosynthesis is ACTH (corticotropin), whereas the peptide hormone in the hypothalamus is corticotropin-releasing factor (CRF). The production of both ACTH and CRF is regulated by the central nervous system and by a negative corticoid feedback mechanism. The CRF is released by the hypothalamus and is transported to the anterior pituitary, where it stimulates the release of ACTH into the bloodstream. Then, ACTH is transported to the adrenal glands, where it stimulates the biosynthesis and secretion of the glucocorticoids. The circulating levels of glucocorticoids act on the hypothalamus and anterior pituitary to regulate the release of both CRF and ACTH. As the levels of glucocorticoids rise, smaller amounts of CRF and ACTH are secreted, and a negative feedback is observed (HPA suppression). Stimuli, such as pain, noise, and emotional reactions, increase the secretion of CRF, ACTH, and consequently, the glucocorticoids. Once the stimulus is alleviated or removed, the negative feedback mechanism inhibits further production and helps to return the body to a normal hormonal balance (15,16).

Adrenocorticotropic hormone acts at the adrenal gland by binding to a receptor protein on the surface of the adrenal cortex cell to stimulate the biosynthesis and secretion of glucocorticoids. The only steroid stored in the adrenal gland is cholesterol, found in the form of cholesterol esters stored in lipid droplets. Adrenocorticotropic hormone stimulates the conversion of cholesterol esters to glucorticoids by initiating a series of biochemical events through its surface receptor. The ACTH receptor protein is coupled to a G protein and to adenylate cyclase. Binding of ACTH to its receptor leads to activation of adenylate cyclase via the G protein. The result is an increase in intracellular cyclic adenosine monophosphate (cAMP) levels. One of the processes influenced by elevated cAMP levels is the activation of cholesterol esterase, which cleaves cholesterol esters and liberates free cholesterol.

Free cholesterol is then converted within mitochondria to pregnenolone via the side-chain cleavage reaction described earlier (Fig. 33.7). Pregnenolone is converted to adrenocorticoids by a series of enzymatic oxidations and isomerization of the double bond (Fig. 33.8). The next several enzymatic steps in the biosynthesis of glucocorticoids occur in the endoplasmic reticulum of the adrenal cortex cell. Hydroxylation of pregnenolone at position 17 by the enzyme 17α-hydroxylase (CYP17) produces 17α-hydroxypregnenolone (step b). The 17α-hydroxyl group is important for adrenocorticoid hormone action. In one step, 17α-hydroxypregnenolone is oxidized to a 3-keto intermediate by the action of the enzyme 5-ene-3β-hydroxysteroid dehydrogenase (3β-HSD) and isomerized to 17α-hydroxyprogesterone by the enzyme 3-oxosteroid-4,5-isomerase (steps c and d). Another hydroxylation occurs by the action of 21-hydroxylase (CYP21) to give rise to 11-deoxycortisol, which contains the physiologically important ketol (-$COCH_2OH$) side chain at the 17β position (step e). A lack of CYP21 prevents cortisol biosynthesis, diverting excess 17α-hydroxypregnenolone and 17α-hydroxyprogesterone into overproduction of C19 androgens. The final step in the biosynthesis of hydrocortisone is catalyzed by the enzyme 11β-hydroxylase, a mitochondrial cytochrome P450 enzyme complex (CYP11B2). This last enzymatic step (step f) results in the formation of hydrocortisone (cortisol), the most potent endogenous glucocorticoid secreted by the adrenal cortex. Approximately 15 to 20 mg of hydrocortisone are biosynthesized daily. Several reviews (14,15,17,18,19) provide more detailed discussions about the enzymology and regulation of adrenal steroidogenesis.

The pathway for the formation of the potent mineralocorticoid molecule, aldosterone, is similar to that for hydrocortisone and uses several of the same enzymes (Fig. 33.8). The preferred pathway involves the conversion of pregnenolone to progesterone by 5-ene-3β-hydroxysteroid dehydrogenase and 3-oxosteroid-4, 5-isomerase (steps c and d). Hydroxylation at position 21 of progesterone by 21-hydroxylase results in 21-hydroxyprogesterone (11-deoxycorticosterone) (step e). Again, these first conversions occur in the endoplasmic reticulum of the cell, whereas the next enzymatic steps occur in the mitochondria. 11β-Hydroxylase (CYP11B2) catalyzes the conversion of 21-hydroxyprogesterone to corticosterone (step f), which exhibits mineralocorticoid activity. The final two oxidations involve hydroxylations at the C18 methyl group and are catalyzed by 18-hydroxylase (step g). These reactions produce first 18-hydroxycorticosterone (not shown) and then aldosterone, the most powerful endogenous mineralocorticoid secretion of the adrenal cortex. The aldehyde at C18 of aldosterone exists in equilibrium with its hemiacetal form.

Metabolism

Hydrocortisone (hormonally active) and cortisone (the inactive metabolite of hydrocortisone) are biochemically interconvertible by the enzyme 11β-hydroxysteroid dehydrogenase (Fig. 33.9). Two isozymes of 11β-hydroxysteroid dehydrogenase are present, type 1 11β-hydroxysteroid dehydrogenase (11β-HSD1), referred to as the "liver" isozyme, and type 2 11β-hydroxysteroid dehydrogenase (11β-HSD2), referred to as the "kidney" isozyme (20,21,22). The 11β-HSD1 isozyme is a bidirectional enzyme, readily interconverts hydrocortisone and cortisone, and is found in many tissues in the body. This isozyme plays an important role in the regulation of hepatic gluconeogenesis in the liver and in fat production in adipose tissues. By contrast, the 11β-HSD2 isozyme is only unidirectional, catalyzing the 11β-dehydrogenation of hydrocortisone to give cortisone. The 11β-HSD2 is present in placenta and in kidney, specifically the distal convoluted tubules and cortical collecting ducts in the kidney. The 11β-HSD2 isozyme plays an important role in the rapid metabolism

of hydrocortisone, thus preventing hydrocortisone from binding to the mineralocorticoid receptors present in the same kidney tissues. A deficiency of 11β-HSD2 is associated with the inherited genetic disease, apparent mineralocorticoid excess, which is characterized by hypertension, excessive salt retention, and hypokalemia caused by the elevated hydrocortisone levels in the kidney.

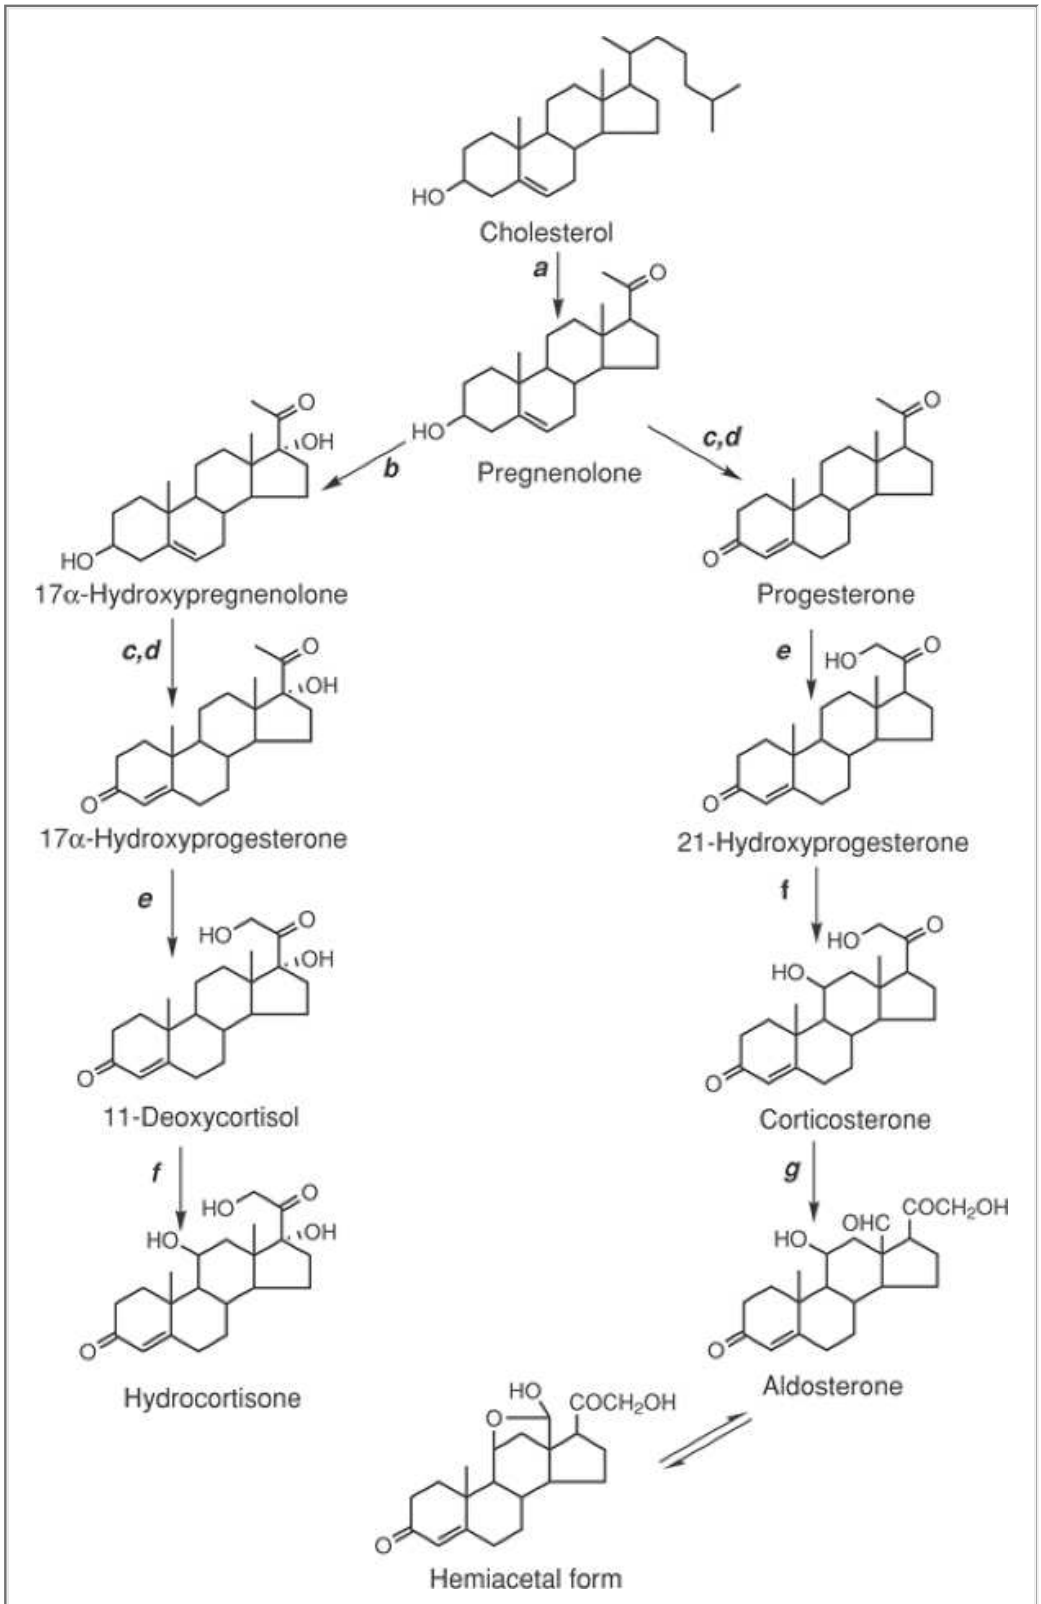

Fig. 33.8. Biosynthesis of the adrenocorticoids from cholesterol.

Hydrocortisone is metabolized by the liver following administration by any route, with a half-life of approximately l.0 to 1.5 hours (23). Hydrocortisone is mainly excreted in the urine as inactive O-glucuronide conjugates and minor O-sulfate conjugates of urocortisol, 5β-dihydrocortisol, and urocortisone (Fig. 33.9). The

tetrahydro metabolite urocortisol is the major metabolite formed and has the 5β-pregnane geometry and 3α-hydroxyl function. The 5β configuration is similar to the ring geometry for the nonhormonal bile acids. Several compounds of this type have been isolated (24,25). All of the biologically active adrenocorticoids contain a ketone at the 3-position and a double bond in the 4,5-position. The formation of 5β-metabolites from hydrocortisone is characterized by reduction of the 4,5-double bond to a 5β geometry for rings A and B (a *cis* configuration) by 5β-reductase or reduction of the 3-ketone by 3α-hydroxysteroid dehydrogenase (3α-hydroxyl configuration) or 3β-hydroxysteroid dehydrogenase (3β-hydroxyl configuration). These

P.886

reactions represent the major pathways of metabolism for the glucocorticoids and their endogenous counterparts. Urocortisol and urocortisone are named after cortisol (hydrocortisone) and cortisone. Reversible oxidation of the 11β-hydroxyl group of many glucocorticoids (e.g., hydrocortisone, prednisolone, and methylprednisolone, but not dexamethasone and other 9α-fluorinated glucocorticoids) by 11β-hydroxysteroid dehydrogenase inactivates these drugs and limits their mineralocorticoid activity in the kidneys. Other routes of metabolism include 6β-hydroxylation (CYP3A4) and reduction of the 20-ketone (e.g., prednisolone) to form 20-hydroxyl analogues as well as oxidation of the 17-ketol side chain to 17β-carboxylic acids and loss of the 17-ketol side chain, resulting in 11β-hydroxy-17-keto-C19 steroids with the geometry of either 5α-androstane or 5β-androstane (15,17,18,19). In addition, some ring A aromatic adrenocorticoid metabolites that resemble the estrogens have been isolated (26). Biliary and fecal excretion contribute little to the elimination of the adrenocorticoids. The rate of formation of 6β-hydroxyhydrocortisone is a biomarker for determining the level of HPA suppression and adrenal insufficiency.

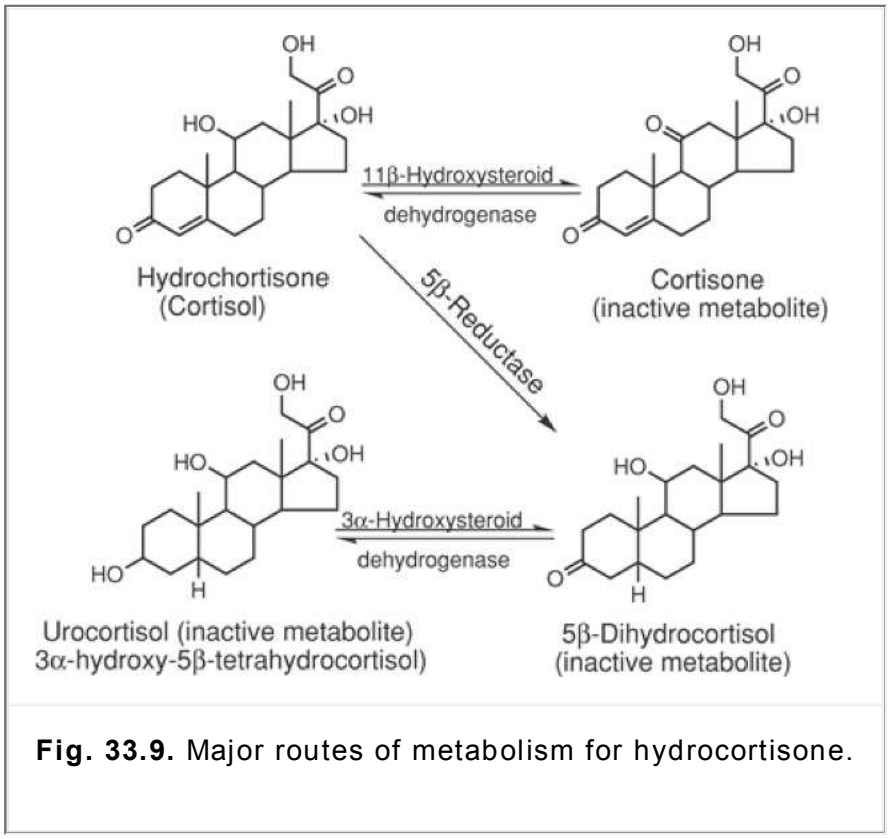

Fig. 33.9. Major routes of metabolism for hydrocortisone.

Development of Adrenocorticoid Drugs

Systemic Corticosteroids

Overview

The route of administration depends on the disease being treated and the physicochemical, pharmacologic, and pharmacokinetic properties of the drug (Table 33.1). The clinically available adrenocorticoids may be administered by IV injection, oral tablets or solutions, topical formulations, intra-articular administration, and oral or nasal inhalation (Table 33.2). Only a handful of

P.887

P.888

corticosteroids are used clinically by the oral route, including hydrocortisone, prednisone, prednisolone, methylprednisolone, and dexamethasone (Fig. 33.10). These corticosteroids often are described as short-acting, intermediate-acting, or long-acting according to their biological half-life and duration of action (Table 33.2). They are well-absorbed, undergo little first-pass metabolism in the liver, and demonstrate oral bioavailabilities of 70 to 80%, except for triamcinolone (Table 33.3). The larger volume of distribution for methylprednisolone compared to prednisolone is thought to result from a combination of increased lipophilicity, decrease in metabolism, and better tissue penetration. Glucocorticoids vary in the extent to which they are bound to the plasma proteins, albumin, and corticosteroid-binding globulin (transcortin) (Table 33.3) (27).

Table 33.1. Pharmacological and Pharmacokinetic Properties for Some Adrenocorti

Adrenocorticoid	Oral Gluco-corticoid Dosea (mg)	Potency Relative to Hydrocortisone: Gluco-corticoid Activityb	Potency Relative to Hydrocortisone: Mineralo-corticoid Activityc	Protein Binding (%)d	Half-life (hours): Plasma	Half-life (hours): Biologic (tissue)	D o (

Table 33.3. Pharmacokinetics of Commonly Used Oral Adrenocorticoids

Adrenocorticoid	Bioavailability (%)	Half-Life (hours)	Protein Binding (%)	Volume Distribution (L/kg)	Log P (experimental)	Clearar (ml/mi kg)
Dexamethasone	78	3.0	90–95	0.2	1.83	260
Hydrocortisone	96	1.7	90	0.5	1.61	400
Methylprednisolone	90	2.3	90–95	1.5	1.76	430

Prednisone	80	3.6	~90	1.0	1.46	250
Prednisolone	82	2.8	90–95	0.7–1.5	1.62	60
Triamcinolone	23	2.6	~90	1.3	1.16	61

Hydrocortisone is extensively bound to the plasma proteins, primarily to transcortin (corticosteroid-binding globulin), with only 5 to 10% of plasma hydrocortisone unbound. Prednisolone and methylprednisolone, but not the 9α-fluoro analogues betamethasone, dexamethasone, or triamcinolone, have a high affinity for transcortin and, thus, compete with hydrocortisone for this binding protein. The 9α-halo analogues bind primarily to albumin.

P.889

Only the unbound fraction of hydrocortisone and the synthetic corticosteroids are biologically active. Generally, the amount of transcortin in the plasma determines the distribution of glucocorticoids between free and bound forms, and free glucocorticoid concentrations determine the drug's half-life. Glucocorticoids cross the placenta and may be distributed into milk.

The degree of systemic side effects is dose-dependent, related to the half-life of the drug, frequency of administration, time of day when administered, and route of administration. In other words, the higher the plasma corticosteroid concentration and longer the half-life, the greater the systemic side effects will be (Table 33.3).

Regardless of the route of administration, all the synthetic adrenocorticoids are excreted from the body in a manner similar to the endogenous adrenocorticoids (i.e., they are metabolized in the liver and excreted into the urine primarily as glucuronide conjugates but also as sulfate conjugates) (28). In fact, hepatic oxidative metabolism rapidly converts many of the systemic and topical corticosteroids to inactive metabolites and, thus, serves to protect patients from the HPA-suppressive effects of these drugs on endogenous steroid production. The corticosteroids are metabolized in many tissues, including the liver, muscles, and red blood cells (15,18,29); however, the liver metabolizes them most rapidly. The fact that many of the endogenous corticosteroids are rapidly metabolized by the liver precludes their administration by the oral route. Catabolic products can be isolated from the urine and bile and can be formed in tissue preparations in vitro (30,31).

Specific Drugs

11-Desoxycorticosterone was the first naturally occurring corticoid to be synthesized. It was prepared, before its isolation from the adrenal cortex, by Steiger and Reichstein (32). As a result of his synthesis of 11-desoxycorticosterone and other early work with corticoids, Reichstein later shared the Nobel Prize with Kendall, another chemist who was instrumental in carrying out early steroid syntheses, and with Hench, a rheumatologist who in 1929 discovered that cortisone is effective in the treatment of rheumatoid arthritis. Kendall's basic research ultimately led to the synthesis of cortisone from naturally occurring bile acids (33).

Cortisone, hydrocortisone, and their derivatives

After the synthesis of 11-desoxycorticosterone in 1937, all the corticoids were synthesized and their structures confirmed. The first synthesis of cortisone from methyl 3α-hydroxy-11-ketobisnorcholanate was reported by Sarett (34) in 1946. Earlier work of Kendall and coworkers involving its preparation from the methyl ester of desoxycholic acid was used in his research (35). Later, several chemists, including Sarett (36), Kendall, and Tishler, found ways to improve the yields and to decrease the labor involved in the multistep conversion of bile acids to cortisone acetate. In 1949, Merck sold limited quantities of this glucocorticoid to physicians at $200 per gram for treating rheumatoid arthritis. Subsequent improvements in the methods of synthesis reduced the price to $10 per gram by 1951. In 1955, Upjohn used an efficient process involving the synthesis of cortisone acetate from progesterone, with the latter steroid being prepared from diosgenin. This further reduced the price to $3.50 per gram. In 2005, the cost was $8 per gram. Other pharmaceutical companies also began to sell cortisone synthesized from bile acids by a well-developed but lengthy procedure (33).

Cortisone is administered orally or by intramuscular (IM) injection as its 21-acetate (cortisone acetate).

Cortisone acetate or hydrocortisone usually is the corticosteroid of choice for replacement therapy in patients with adrenocortical insufficiency, because these drugs have both glucocorticoid and mineralocorticoid properties. Following oral administration, cortisone acetate and hydrocortisone acetate are completely and rapidly deacetylated by first-pass metabolism (37). Much of the oral cortisone, however, is inactivated by oxidative metabolism (Fig. 33.9) before it can be converted to hydrocortisone in the liver. The pharmacokinetics for hydrocortisone acetate is indistinguishable from that of orally administered hydrocortisone. Oral hydrocortisone is completely absorbed, with a bioavailability of greater than 95% and a half-life of 1 to 2 hours (23). The metabolism of hydrocortisone (Fig. 33.9) has been previously described. Cortisone acetate is slowly absorbed from IM injection sites over a period of 24 to 48 hours and is reserved for patients who are unable to take the drug orally. The acetate ester derivative demonstrates increased stability and has a longer duration of action when administered by IM injection. Thus, smaller doses can be used. Similarly, hydrocortisone may be dispensed as its 21-acetate (hydrocortisone acetate), which is superior to cortisone acetate when injected intra-articularly. Systemic absorption of hydrocortisone acetate from intra-articular injection sites usually is complete within 24 to 48 hours. When administered intrarectally, hydrocortisone is poorly absorbed (38,39).

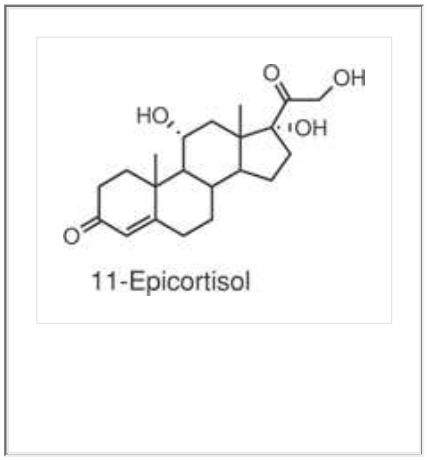
Other ester derivatives that are available include hydrocortisone cypionate [21-(3-cyclopentylpropionate) ester], hydrocortisone butyrate (17α-butyrate ester), hydrocortisone buteprate (17α-butyrate, 21-propionate esters), hydrocortisone valerate (17α-valerate ester), hydrocortisone sodium succinate (21-sodium succinate ester), and hydrocortisone sodium phosphate (the 21-sodium phosphate ester) (Fig. 33.10). The water-insoluble hydrocortisone cypionate is used orally in doses expressed in terms of hydrocortisone for slower absorption from the gastrointestinal (GI) tract. The extremely water-soluble 21-sodium succinate and 21-sodium phosphate esters are used for IV or IM injection in the management of emergency conditions that can be treated with anti-inflammatory steroids. The phosphate ester is completely

and rapidly metabolized by phosphatases, with a half-life of less than 5 minutes (38). Peak hydrocortisone levels are reached in approximately 10 minutes. The sodium succinate ester is slowly and incompletely hydrolyzed, and peak hydrocortisone levels are attained in 30 to 45 minutes (38). Hydrocortisone butyrate, hydrocortisone buteprate, and hydrocortisone valerate are used topically.

After the introduction of cortisone (1948) and, later, hydrocortisone (1951) for the treatment of rheumatoid arthritis, many investigators began to search for superior agents having fewer side effects. When these drugs are used in doses necessary to suppress symptoms of rheumatoid arthritis, they also affect other metabolic processes. Side effects, such as excessive sodium retention and potassium excretion, negative nitrogen balance, increased gastric acidity, edema, and psychosis, are exaggerated manifestations of the normal metabolic functions of the hormones.

It was hoped that a compound with high glucocorticoid and low mineralocorticoid activity could be synthesized. Because it was recognized early that a carbonyl group at C3, a double bond between carbons 4 and 5, an oxygen (C==O or β-OH) at carbon 11, and a β-ketol side chain at position 17 are necessary for superior glucocorticoid activity, investigators began to synthesize analogues containing these functions. Additional groups were inserted into other positions of the basic steroid structure, with the expectation that these new substituents might modify the glucocorticoid and mineralocorticoid activities of the parent drugs.

The first potent analogues discovered, however, did not result from a concentrated effort to find a better drug but, rather, from basic chemical research concerned with the preparation of hydrocortisone from 11-epicortisol (11α-hydrocortisone).



Fludrocortisone

A 9α-bromo analogue was prepared that had one-third the glucocorticoid activity of cortisone acetate (40). Other halogens were introduced into the 9α-position, and it was soon observed that glucocorticoid activity is inversely proportional to the size of the halogen at carbon 9. The 9α-fluoro analogue (fludrocortisone) is approximately 11 times as potent as cortisone acetate (Fig. 33.10). Fludrocortisone is orally administered as its 21-acetate derivative. When tested clinically in patients with rheumatoid arthritis, it was found to be effective at approximately one-tenth the dose of cortisone acetate. Although glucocorticoid activity is increased 11 times by insertion of the 9α-fluoro substituent, mineralocorticoid activity is increased 300 to 800 times (27). Because of its intense sodium-retaining activity, fludrocortisone is contraindicated in all conditions except those that require a high degree of mineralocorticoid activity, because it leads to edema. Fludrocortisone acetate is used orally for mineralocorticoid replacement therapy in patients with adrenocortical insufficiency, such as Addison's disease. This drug, introduced in 1954, helped to provide the impetus for the synthesis and biological evaluation of newer halogenated analogues.

Prednisone, prednisolone, and its derivatives

One year after the introduction of fludrocortisone, the Δ-corticoids were brought forth into clinical medicine. Investigators at Schering observed that the 1-dehydro derivatives of cortisone and hydrocortisone—namely, prednisone and prednisolone—are more potent antirheumatic and antiallergenic agents than the parent compounds and produced fewer undesirable side effects. These compounds are known as Δ^1-corticoids, because they contain an additional double bond between positions 1 and 2 (Fig. 33.10).

The Δ^1-corticoids, which can be prepared by microbial dehydrogenation of cortisone or hydrocortisone with *Corynebacterium simplex* (41) and by several synthetic methods (33), represent the first chemical innovation leading to the creation of a modified compound that could be prescribed for rheumatoid arthritis. One high-yield route involves oxidation of 5α- or 5β-pregnane precursors that have appropriate oxygen substitutions with selenium dioxide (42).

Both prednisone and prednisolone were found to have adrenocortical activity (measured by eosinopenic response, liver glycogen decomposition, and thymus involution in adrenalectomized mice). In these tests, prednisone and prednisolone were found to be three- or fourfold more potent than cortisone and hydrocortisone. Antiphlogistic strengths in human subjects were similarly augmented, but their electrolyte activities were not proportionately increased.

The increased potency reflects the effect in the change in geometry of ring A caused by the introduction of C1==C2 function on glucocorticoid receptor (GR) affinity and altered pharmacokinetics (primarily metabolism). Although the remaining portions of the steroid are essentially unchanged (except for less easily visualized molecular perturbations), the conformation of ring A changes from a chair, as in 5α-pregnan-3-one, to a half-chair (pregn-4-en-3-one) and to a flattened boat (pregna-1,4-dien-3-one) on introduction of unsaturation (Fig. 33.11). The order of GR affinity is dexamethasone (10×) > triamcinolone (5×) > methylprednisolone (4×) > prednisolone (2×) > hydrocortisone (1×) (43).

When orally administered, prednisone and prednisolone are almost completely absorbed, with a bioavailability of greater than 80% (Table 33.3) (44,45). As with

the relationship between cortisone and hydrocortisone, prednisone and prednisolone are interconvertible by 11β-hydroxysteroid dehydrogenase in the liver. For practical purposes, prednisone and prednisolone are equally potent and may be used interchangeably. When prednisone or prednisolone is used in the treatment of rheumatoid arthritis, smaller doses are required than with hydrocortisone. The usual dose is 5 mg two to four times a day. Prednisolone is metabolized into a number of hydrophilic and less active metabolites, as shown in Figure 33.12, except there is no reduction of ring A as with hydrocortisone. The major metabolites (6β- and 16β-hydroxy) are primarily excreted as glucuronide conjugates in the urine. Prednisolone acetate is available in suspension and ointment forms for use externally. As with hydrocortisone, several other 21-esters of prednisolone are available. Prednisolone tert-butylacetate (3,3-dimethylbutyrate) is used in suspension form and by injection for the same reasons the 21-ester derivatives of hydrocortisone are employed. The butylacetate ester, which is suitable only for use by injection, has a long duration of action because of low water solubility and a slow rate of hydrolysis. The drug is administered in doses of 4 to 20 mg.

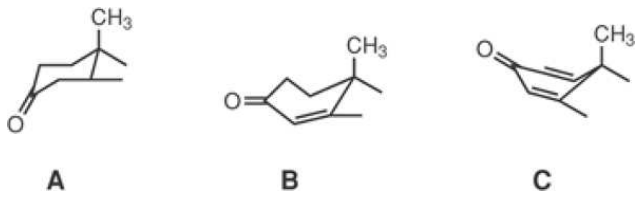


Fig. 33.11. Ring A conformations for 5α-pregnan-3-one (A), for pregn-4-en-3-one (B), and for pregna-1,4-dion-3-one (C).

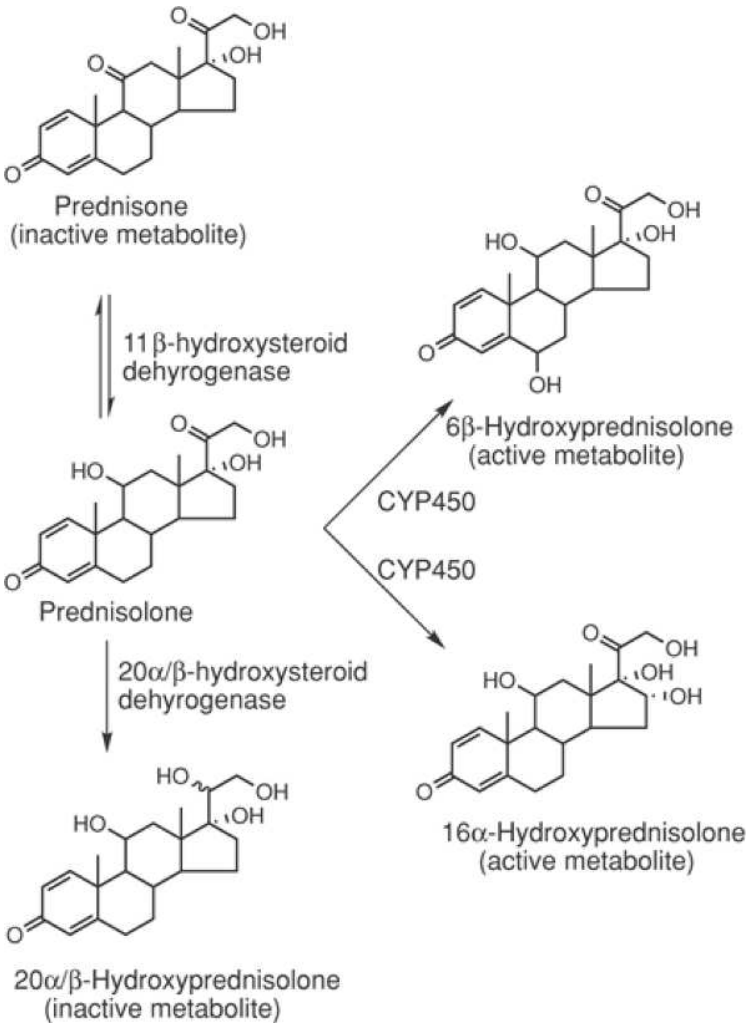

Fig. 33.12. Major routes of metabolism for prednisolone.

Prednisolone sodium phosphate is the water-soluble sodium salt of the 21-phosphate ester, with a half-life of less than 5 minutes because of rapid hydrolysis by phosphatases (44,46). Peak plasma levels for prednisolone are attained in approximately 10 minutes following its administration by injection (usual dose of 20 mg IV or IM). Topically, one or two drops of a 0.5% solution may be used four to six times daily for its anti-inflammatory action in the eye.

When doses of equivalent antirheumatic potency are given to patients not treated with steroids, the Δ^1-corticoids promote the same pattern of initial improvement as hydrocortisone. Statistical results of the improvement status during the first few months of therapy have been similar with prednisolone, prednisone, and hydrocortisone. The results of longer-term therapy have been significantly better with the modified compounds. Studies indicate that the Δ^1-corticoids may be used continuously in patients with rheumatoid arthritis without undue GI hazard. Although the Δ^1-corticoids are considered not to have significant mineralocorticoid activity, hypokalemia as well as sodium and fluid retention may occur, depending on the dosage and duration of use.

Methylprednisolone

Between 1953 and 1962, many derivatives of the Δ^1-corticoids and the halogen-containing analogues (especially fluorinated compounds) were synthesized, and some became useful clinical agents. Studies with methylcorticoids revealed 2α-methyl derivatives to be inactive, whereas the 2α-methyl-9α-fluoro analogues had potent mineralocorticoid activity. Methyprednisolone (6α-methyl-11β,17,21-trihydroxypregna-1,4-diene-

3,20-dione) was synthesized in 1956 and introduced into clinical medicine (Fig. 33.10). Methylprednisolone is extensively metabolized, with approximately 10% recovered unchanged in urine (47). The metabolic pathways include reduction of C20 ketone, oxidation of 17β-ketol group to C21-COOH and C20-COOH, and 6β-hydroxylation (CYP3A4). These compounds potentiated glucocorticoid activity with negligible salt retention for short-term therapy (Table 33.2) (48).

In human subjects, the metabolic effects did not differ appreciably from those of prednisolone. Its activities with respect to nitrogen excretion, ACTH suppression, and reduction of circulating eosinophils were similar to those of prednisolone. The sodium retention and potassium loss were slightly less than with prednisolone (49).

Methylprednisolone is administered IV as its water-soluble sodium salt of the 21-succinate ester. The succinate ester is slowly and incompletely hydrolyzed. Peak

plasma levels for methylprednisolone is attained in approximately 30 to 60 minutes following its IV administration, and approximately 15% of its IV dose is recovered unchanged in urine (45,46). CYP3A4 inhibitors such as the antifungals, ketoconazole, and itraconazole can potentiate the effects of prednisolone.

Triamcinolone

A natural extension of corticoid research involved examination of compounds containing both a 9α-fluoro group and a double bond between positions 1 and 2. Triamcinolone (9-fluoro-11β, 16α, 17, 21-tetrahydroxypregna-1,4-diene-3,20-dione), introduced in 1958, combines the structural features of a Δ^1-corticoid and a 9α-fluoro corticoid (Fig. 33.10). As mentioned previously, the 9α-fluoro group increases the anti-inflammatory potency, but it also markedly increases the mineralocorticoid potency. This is undesirable if the drug is to be used internally for the treatment of rheumatoid arthritis. By inserting a 16α-hydroxy group into the molecule, one can decrease the mineralocorticoid activity.

The original interest in 16α-hydroxycorticosteroids stemmed from their isolation from the urine of a boy with an adrenal tumor. The desire of chemists to synthesize these corticoids, and the hope that such analogues might have potent biological activity furthered their development (50,51,52). Therefore, inserting a 16α-hydroxy group into 9α-fluoroprednisolone resulted in triamcinolone with glucocorticoid activity equivalent to prednisolone but decreased mineralocorticoid activity. In fact, 16α-hydroxy analogues of natural corticoids retain glucocorticoid activity and have a considerably reduced mineralocorticoid activity. The lower-than-expected oral anti-inflammatory potency for triamcinolone (Table 33.2) has been attributed to its low oral bioavailability (Table 33.3), in part because of increased hydrophilicity from the 16α-hydroxy group and first-pass metabolism, primarily to its 6β-hydroxy metabolite. These glucocorticoids actually may cause sodium excretion rather than sodium retention. Triamcinolone diacetate (17,21-diacetate) and its hexacetonide [16α, 17α-methylenedioxy-21-(3,3-dimethylbutyrate)] esters are administered IM or intra-articularly for a prolonged release of triamcinolone. Triamcinolone diacetate has a duration of action depending on its route of administration from 1 to 8 weeks, and triamcinolone hexacetonide has a duration of action of 3 to 4 weeks (53,54).

On a weight-for-weight basis, the antirheumatic potency of triamcinolone is greater than that of prednisolone (~20%) and approximately the same as that of methylprednisolone. Initial improvement following administration of triamcinolone is similar to that noted with other compounds. Reports in the literature, however, indicate that the percentage of patients maintained satisfactorily for long periods has been distinctly smaller than that with prednisolone.

Even though triamcinolone has an apparently decreased tendency to cause salt and water retention and edema and may induce sodium and water diuresis, it causes other unwanted side effects, including anorexia, weight loss, muscle weakness, leg cramps, nausea, dizziness, and a general toxic feeling (55). Intramuscular triamcinolone is reportedly effective and safe in the treatment of dermatoses, and in combination with folic acid antagonists, it is effective in the treatment of psoriasis (56,57).

Dexamethasone

Research with 16-methyl substituted corticoids was initiated in part because investigators hoped to stabilize the 17β-ketol side chain to metabolism in vivo and improve bioavailability (Fig. 33.10). These studies led to the development of dexamethasone (9-fluoro-16α-methyl-11β,17,21-trihydroxypregna-1,4-diene-3,20-dione), which was introduced for clinical trial. A 16α-methyl group does decrease the reactivity of the 20-keto group to carbonyl reagents and increases the stability of the drug in human plasma in vitro (58,59). Unlike 16α-hydroxylation, a methyl group increases the anti-inflammatory activity by increasing lipophilicity and, consequently, receptor affinity. Like the 16α-hydroxyl group, the methyl group appears to reduce markedly the

salt-retaining properties of the corticosteroids (Table 33.2) (60,61,62). The activity of dexamethasone, as measured by glycogen deposition, is 20 times greater than that of hydrocortisone. It has five times the anti-inflammatory activity of prednisolone. Clinical data indicate that this compound has seven times the antirheumatic potency of prednisolone. It is roughly 30 times more potent than hydrocortisone. Its pharmacokinetics are presented in Table 33.3. Routes of metabolism for dexamethasone are similar to those for prednisolone, with its primary 6β-hydroxy metabolite being recovered in urine (63). Dexamethasone sodium phosphate is the water-soluble sodium salt of the 21-phosphate ester, with an IV half-life of less than 10 minutes because of rapid hydrolysis by plasma phosphatases (64). Peak plasma levels for dexamethasone usually are attained in approximately 10 to 20 minutes following its IV administered dose. A similar reaction occurs when the phosphate ester is applied topically or by inhalation.

In practical management, 0.75 mg of dexamethasone promotes a therapeutic response equivalent to that from 4 mg of triamcinolone or methylprednisolone, 5 mg of prednisolone, and 20 mg of hydrocortisone. Clinical investigations with small groups of patients indicate that this compound could control patients who did not respond well to prednisolone. Over long periods, the improved status of some patients deteriorated.

In summarizing the biological properties of this drug, it seems clear that with doses of corresponding antirheumatic strength, this steroid has approximately the same tendency as prednisolone to produce facial mooning, acne, and nervous excitation. Peripheral edema is uncommon (7%) and mild. The more common and most objectionable side effects are excessive appetite and weight gain, abdominal bloating, and distention. The frequency and severity of

these symptoms vary with the dose (1 mg maximum for females, and 1.5 mg maximum for males). The longer biological half-life for dexamethasone significantly increases the potential for glucocorticoid-induced adrenal insufficiency (see Adverse Effects).

The striking increase in potency does not confer a general therapeutic index on dexamethasone that is higher than that of prednisolone. Again, this drug probably is best employed as a special-purpose corticoid. It may be useful when other steroids are no longer effective or when increased appetite and weight gain are desirable (64,65,66,67,68,69). Its efficacy may be increased when it is used in combination with cyproheptadine as an antiallergenic, antipyretic, and anti-inflammatory agent (60).

Betamethasone

Shortly after the introduction of dexamethasone, betamethasone, which differs from dexamethasone only in configuration of the 16-methyl group (Fig. 33.10), was made available for the treatment of rheumatic diseases and dermatologic disorders. This analogue, which contains a 16β-methyl group, has received sufficient clinical trial examination to indicate that it is as effective as dexamethasone or, perhaps, even slightly more active. Although this drug has been reported to be less toxic than other steroids, some clinical investigators suggest that it is best used for short-term therapy. Toxic side effects, such as increased appetite, weight gain, and facial mooning, occur with prolonged use. Generally, a 0.5-mg tablet of betamethasone is equivalent to a 5.0-mg tablet of prednisolone, and except for isolated instances, this drug is apparently on a par with dexamethasone (70).

Selective glucocorticoid receptor modulators

The long-term use of glucocorticoids is associated with severe adverse effects (see Adverse Effects), including osteoporosis, hyperglycemia, muscle wasting, hypertension, and impaired wound healing. Improved glucocorticoids that demonstrate potent anti-inflammatory activity without these serious side effects would provide a significant therapeutic advance and are the focus of intense research efforts by the pharmaceutical industry. The molecular mechanism of the GR makes it a particularly suitable target for this effort. The majority of unwanted side effects of the glucocorticoids arise from the interaction of the GR with DNA (i.e., GR-mediated transcription), whereas the anti-inflammatory effects are mediated via protein–protein interactions between the GR and pro-inflammatory transcription factors (i.e., AP-1 and NFκB) that results in repression of the inflammatory response. A variety of selective GR modulators with the ability to repress inflammation but with lesser ability to elicit GR-mediated transcription have been reported (71,72,73). Early investigations indicate that a variety of different nonsteroidal pharmacophores (e.g., spirocyclic dihydropyridines, triphenylmethanes, and benzoindazoles) bind with high affinity and selectivity to the GR. Importantly, some of these analogues demonstrate preferential ability to repress pro-inflammatory genes and a lesser ability to induce GR-mediated transcription. Although these nonsteroidal ligands have yet to be evaluated in clinical studies, these drugs may someday prove to be the first members of an improved class of anti-inflammatory drugs.

Discontinued oral glucocorticoids

Paramethasone acetate (6α-fluoro-16α-methyl-11β-17,21-trihydroxypregna-1,4-diene-3,20-dione 21-acetate), synthesized in 1960, retains the 16α-methyl group, but the 9α-fluoro substituent has been moved to the 6α position. It was thought that this manipulation would reduce the electrolyte loss associated with dexamethasone. Reports in the literature indicate that paramethasone causes a slight loss of sodium and chloride with little or no loss of potassium (with doses as large as 15 mg). An analysis of continuous therapy over 9 months, however, showed that the therapeutic efficacy of paramethasone did not differ greatly from that of fluprednisolone (74).

Fluprednisolone (6α-fluoro-11β,17,21-trihydroxy-pregna-1,4-diene-3,20-dione) is the 16-desmethyl analogue of paramethasone. Its activity is similar to that of paramethasone, and it has approximately 2.5 times the antirheumatic potency of prednisolone. With doses of 2 to 7 mg, evidence of salt and water retention has not been noted. The therapeutic index, however, probably is the same or only a little greater than that for prednisolone. Because no new adverse reactions have been noted during the administration of this drug on a short-term basis, it seems that a 6α-fluoro group does not deleteriously affect the activity of prednisolone (49,75).

Topical Glucocorticoids

Topically applied glucocorticoids are also capable of being systemically absorbed, although to a much smaller extent. The extent of absorption of topical adrenocorticoids is determined by several factors, including the type of cream or ointment, the condition of the skin to which it is being applied, and the use of occlusive dressings. Previous studies with halobetasol propionate showed that approximately 6% of the drug was systemically absorbed after topical application. Although this is a small fraction of the dose, the very high potency of halobetasol propionate contributed to its ability to cause mild adrenal suppression in some patients. The relative potency of the topical glucocorticoids is commonly determined using topical vasoconstriction assays and is dependent on the intrinsic activity of the drug, its concentration in the formulation, and the vehicle in which it is applied (Table 33.4).

Once absorbed through the skin, topical corticosteroids are handled through metabolic pathways similar to the systemically administered corticosteroids. They are metabolized, primarily in the liver, and are then excreted into the urine or in the bile (76). The fact that circulating

levels of the topical glucocorticoids often are well below the level of detection does not reduce the risk for potential adverse effects from systemic exposure of topical corticosteroids. The structures for the glucocorticoids applied topically are shown in Figure 33.13 and their relative potencies in Table 33.4. Topical dermatological products with a low potency ranking have a modest anti-inflammatory effect and are safest for chronic application. Those products with a medium potency ranking are used in moderate inflammatory dermatoses of limited duration. High potency preparations are used in more severe inflammatory dermatoses, but only for a short duration of treatment. Very high potency products are used primarily as an alternative to systemic corticosteroid therapy when local areas are involved and for only a short duration of therapy and on small surface areas.

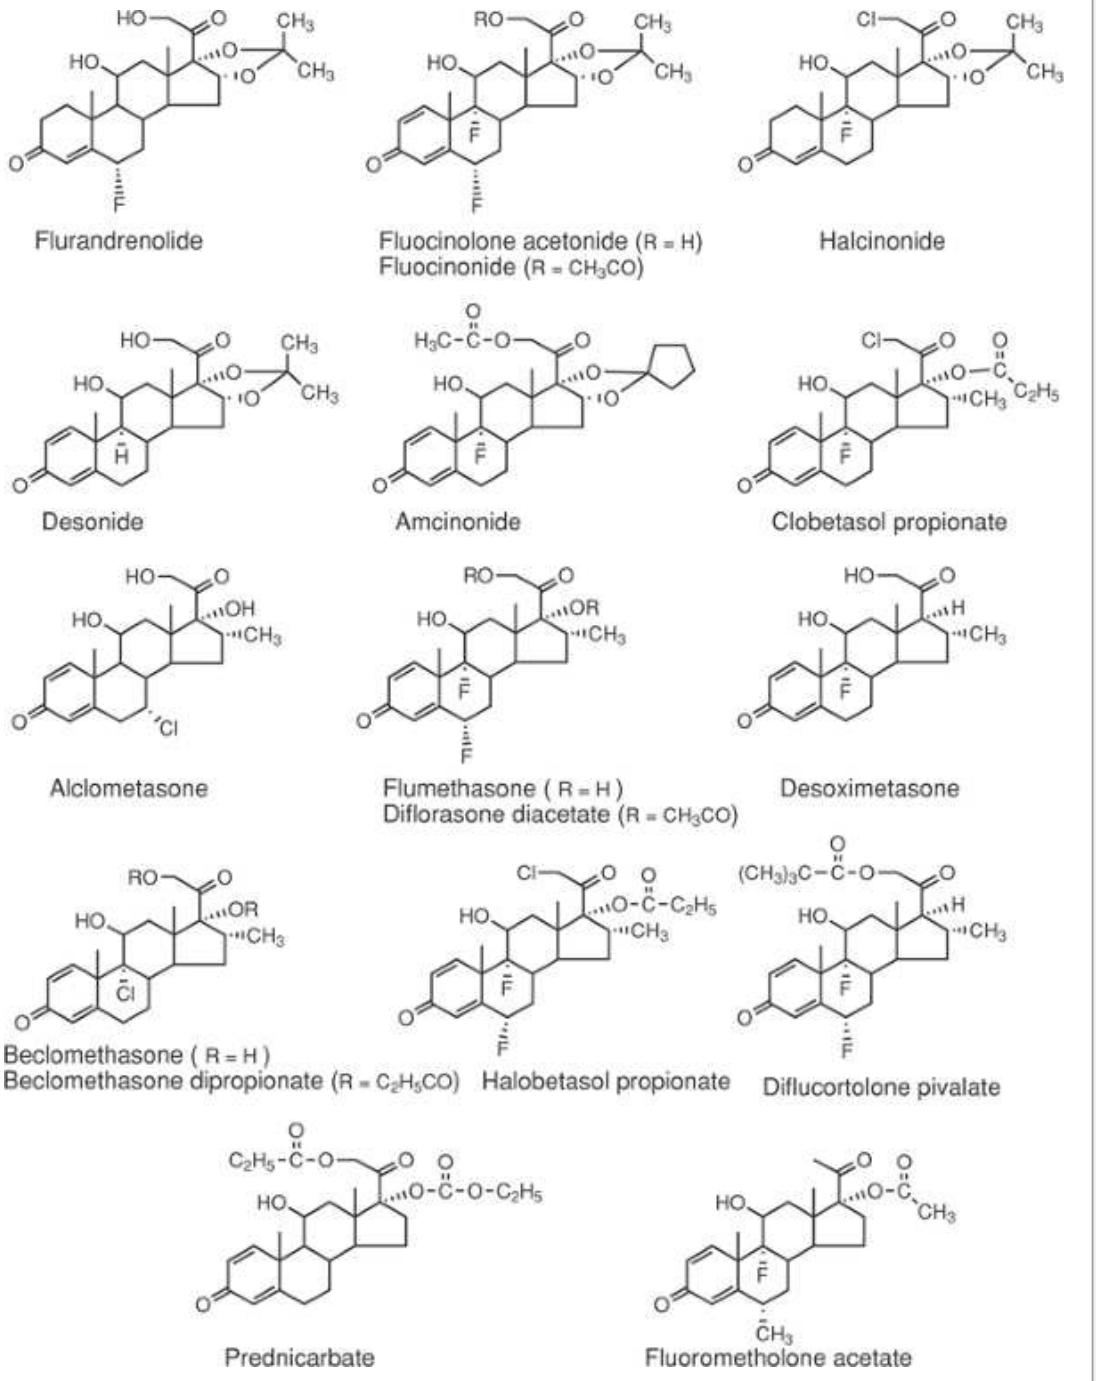

Fig. 33.13. Topical corticosteroids.

Triamcinolone to be used topically is generally dispensed as its more potent and lipophilic acetonide, a 16α,17α-methylenedioxy cyclic ketal or isopropylidene derivative (Fig. 33.14) (see Inhaled and Intranasal Glucocorticoids). It is effective in the treatment of psoriasis and other corticoid-sensitive dermatologic conditions. Topically, triamcinolone acetonide is a more potent derivative of triamcinolone and is approximately eight times more active than prednisolone. The side effects of the drug, however, have occurred with sufficient frequency

to discourage its routine use for rheumatoid patients requiring steroid therapy. The drug may be employed advantageously as a special-purpose steroid for instances in which salt and water retention (from other

corticoids, hypertension, or cardiac compensation) or excessive appetite and weight gain are problems in management.

Table 33.4. Potency Ranking for Topical Corticosteroids

I. **Very high potency**
- Augmented Betamethasone dipropionate
- Clobetasol propionate
- Diflorasone diacetate
- Halobetasol propionate

II. **High potency**
- Amcinonide
- Augmented betamethasone dipropionate
- Betamethasone dipropionate
- Betamethasone valerate
- Desoximetasone
- Diflorasone diacetate
- Fluocinolone acetonide
- Fluocinonide
- Halcinonide
- Triamcinolone acetonide

III. **Medium potency**
- Betamethasone benzoate
- Betamethasone dipropionate
- Betamethasone valerate
- Clocortolone pivalate
- Desoximetasone
- Fluocinolone acetonide
- Flurandrenolide
- Fluticasone propionate
- Hydrocortisone butyrate
- Hydrocortisone valerate
- Mometasone furoate
- Triamcinolone acetonide

IV. **Low potency**
- Alclometasone dipropionate
- Desonide
- Dexamethasone
- Dexamethasone sodium phosphate
- Fluocinolone acetonide
- Hydrocortisone
- Hydrocortisone acetate
- Prednicarbate

The relative potency is based on the drug concentration, type of vehicle used, and the vasoconstrictor assay as a measure of topical anti-inflammatory activity.

Newer synthetic glucocorticoids have incorporated chlorine atoms onto the steroid molecule as fluorine substitutes. Beclomethasone, a 9α-chloro analogue of betamethasone, is a potent glucocorticoid with approximately half the potency of its fluoro analogue. It is used topically as its dipropionate derivative in inhalation aerosol therapy for asthma and rhinitis (see Inhaled and Intranasal Glucocorticoids) but not for treatment of steroid-responsive dermatoses (77). The topical anti-inflammatory potency for beclomethasone

dipropionate (BDP) is approximately 5,000 times greater than hydrocortisone, 500 times greater than betamethasone or dexamethasone, and approximately five times greater than fluocinolone acetonide or triamcinolone acetonide, as measured by vasoconstrictor assay. Another potent topical glucocorticoid that contains a 7α-chloro group is alclometasone (78).

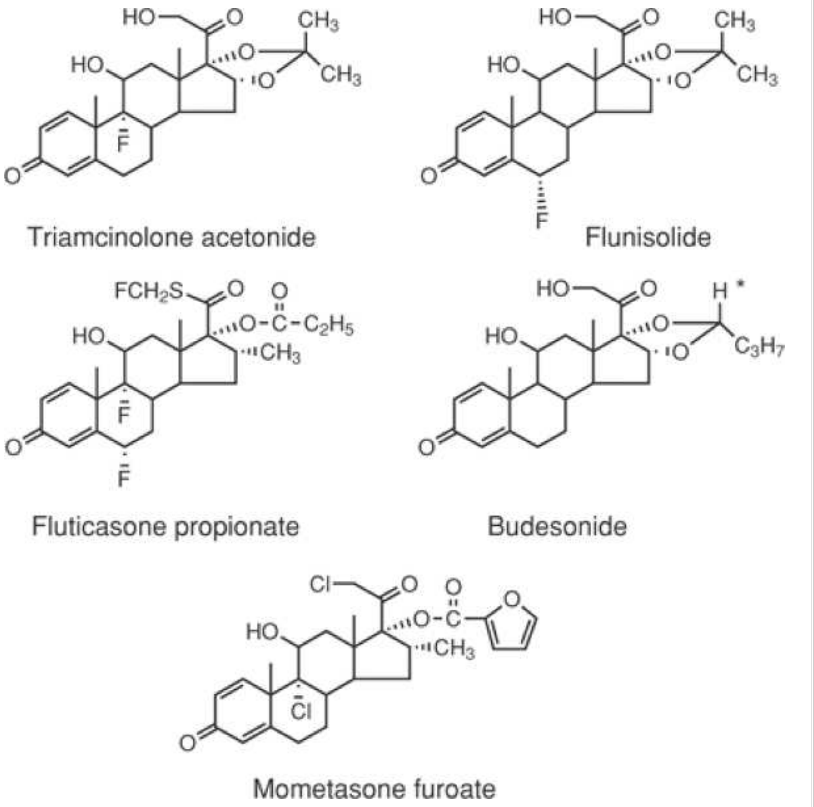

Fig. 33.14. Inhaled and intranasal corticosteroids.

Additional mono- and difluorinated analogues for topical application include fluorometholone (6α-methyl-9α-fluoro; ophthalmic use), flurandrenolide (6α-fluoro-16α,17α-acetonide), fluocinolone acetonide (a 6α, 9α-difluoro-16α,17α-acetonide), and fluocinonide (21-acetate ester of fluocinolone acetonide) (Fig. 33.13). These compounds are classified as high to medium potency anti-inflammatory agents depending on the concentration and vehicle used (Table 33.4). The acetonide (ketal) derivatives at the 16,17-position enhance lipophilicity to provide potent topical anti-inflammatory agents (Table 33.4).

Psoriasis is one of the few inflammatory dermatoses that has not responded to routine topical steroid therapy, but these more potent steroids appear to work if a special occlusive dressing is used. In this technique, a thin layer of cream or ointment containing flurandrenolide is applied to the individual patch of psoriasis. The area is then covered with plastic food wrap or a similar pliable plastic film.

Clinical investigations generally show (0.05%) flurandrenolide to be more effective than 1% hydrocortisone acetate and to have approximately the same activity as 0.1% triamcinolone acetonide. Some investigators believe that its greater activity results from an increased biological

half-life. In other words, these analogues are not metabolized as readily. Fluocinolone acetonide has about the same anti-inflammatory activity as fluorometholone.

Clobetasol propionate, halcinonide, halobetasol propionate, and mometasone furoate are examples of 21-chlorocorticoids, in which the 21-chloro group replaces the 21-hydroxyl group (79,80,81,82) (Figs. 33.13 and 33.14). Clobetasol propionate, the 21-chloro analogue of betamethasone 17-propionate, is approximately eight times more active as topical anti-inflammatory agent than betamethasone 17α-valerate, the standard of comparison for topical vasoconstrictor/anti-inflammatory activity. Mometasone furoate, a 9α,21-dichloro

derivative (see Inhaled and Intranasal Glucocorticoids), also is approximately eight times more active than betamethasone 17α-valerate as a topical anti-inflammatory agent. Thus, substitution of a chlorine (or a fluorine) atom for the 21-hydroxyl group on the glucocorticoids greatly enhances topical anti-inflammatory activity (80). Clobetasol propionate and halobetasol propionate are classified as very high potency topical corticosteroid preparations (Table 33.4). The HPA suppression has occurred following the topical application of 2 g of the 0.05% clobetasol propionate ointment or cream (1 mg of clobetasol propionate total) daily. Because of its high potency and potential for causing adverse systemic effects during topical therapy, the usual dosage for very high potency topical steroids should not be exceeded. Fluticasone propionate is similar to the 21-chloro steroids, except that it has a 17α-fluoromethylcarbothioate group instead of the 17-ketol group derivative (see Inhaled and Intranasal Glucocorticoids) (Fig. 33.14). Although mometasone furoate and fluticasone propionate are very lipophilic and have the highest binding affinity for the GR (see Inhaled and Intranasal Glucocorticoids) when compared to triamcinolone acetonide and dexamethasone, their topical potency is listed as medium, in part because of their insolubility and poor dissolution into inflamed tissue.

Several nonfluorinated analogues of triamcinolone acetonide with the potency-enhancing cyclic ketal moiety are marketed, suggesting that halogens are not always necessary for topical activity. These nonfluorinated cyclic ketals include desonide and amcinonide (Fig. 33.13). Amcinonide's potency is greatly enhanced by the more lipophilic cyclopentanone ketal and 21-acetate. A recent addition to the nonhalogenated prednisolone derivatives is prednicarbate, a 17,21-diester (17α-ethylcarbonate-21-propionate) derivative of prednisolone (Fig. 33.13), which is used for the local treatment of corticoid-sensitive skin diseases (83). Any prednicarbate that is absorbed systemically is readily metabolized by hydrolysis of the 21-ester to its primary and pharmacologically active metabolite, prednisolone-17-ethylcarbonate. This metabolite has a half-life of approximately 1 to 2 hours and is further metabolized by the liver to prednisolone. In vitro binding studies with the GR suggest that the ethyl carbonate metabolite has a receptor binding affinity comparable to that of dexamethasone. The low systemic bioavailability for prednicarbate after dermal application has been attributed to its metabolism to less active prednisolone, which may be a factor for the low systemic side effects of prednicarbate.

Inhaled and Intranasal Glucocorticoids

Overview

It generally is accepted that the anti-inflammatory effect of glucocorticosteroids cannot be separated from their adverse effects at the receptor level. Therefore, pulmonary and nasal pharmacokinetics become important determinants for the potential of an inhaled or nasally applied corticosteroid to cause systemic effects, because the lung and nasal tissue provide an enormous surface area from which drug absorption can occur into the systemic circulation (84,85). The main areas of concern with regard to drug-induced systemic effects include HPA-axis suppression, change in bone mineral density and growth retardation in children, cataracts, and glaucoma. The degree of systemic side effects is dose-dependent, related to the half-life of the drug, the frequency of administration, the time of day when administered, and the route of administration; in other words, the higher the plasma corticosteroid concentration and longer the half-life, the greater the systemic side effects will be (86). Thus, the search is to develop inhaled/intranasal corticosteroids with the following desirable pharmacokinetic qualities: They would exhibit fast systemic clearance following GI absorption (high degree of first-pass intestinal/hepatic metabolism), short half-life, lack of active metabolites, and high affinity for the corticosteroid receptor. These qualities determine the proportion of the drug that reaches the target cells as well as the fraction of the dose that reaches the systemic circulation to produce side effects.

Modification of the pharmacokinetics through structural alterations has provided several new steroids with a better GR affinity and therapeutic index and a lower bioavailability than the older drugs (Fig. 33.14). The new inhaled/intranasal glucocorticosteroids like mometasone furoate, budesonide and fluticasone propionate are more lipophilic than those used in oral and systemic therapy and have greater affinity for the GR than does dexamethasone as a consequence of their greater lipophilicity (43). Several of the topical corticosteroids, such as mometasone furoate, BDP, triamcinolone acetonide, and flunisolide, were reintroduced as inhalation and intranasal dosage forms for treatment of respiratory diseases (e.g., asthma or rhinitis). Inhaled budesonide and flunisolide are readily absorbed from the airway mucosa into the blood and are rapidly biotransformed in the liver into inactive metabolites. Mometasone furoate and fluticasone propionate are very potent anti-inflammatory steroids with an oral bioavailability of less than 1%. Obviously, the risk of systemic side effects for these newer corticosteroids is greatly reduced when compared with

the older glucocorticosteroids (e.g., dexamethasone). Beclomethasone dipropionate was discovered to be a

pro-drug, and this discovery led to the reexamination of other 17α-monoesters as the active form of the corticosteroid esters. The absorption of budesonide, fluticasone propionate, and BDP into the airway tissue was 25 to 130 times greater than that for dexamethasone and hydrocortisone (86). The GR affinity and the pharmacokinetic properties for the inhaled and intranasal corticosteroids are listed in Table 33.5.

Table 33.5. Pharmacokinetics of Inhaled and Intranasal Corticosteroids

[e]Calculated log P for mometasone furoate = 4.7.

[f]Estimated for inhaled beclomethasone aerosol.

[g]Data from oral inhalation administration.

It is generally recognized that when administered by oral inhalation, 10 to 30% of a dose of the corticosteroid is deposited in the respiratory tract depending on type of inhaler (metered dose inhaler or dry powder inhaler [DPI]) and spacer used (87,88). The remainder of the dose is deposited primarily in the mouth and throat to be swallowed into the GI tract, where the drug may be absorbed, metabolized, and eliminated unchanged in the feces. Thus, systemic bioavailability of the inhaled/intranasal steroids is determined by the fraction of the dose absorbed from the lungs/nasal mucosa and the GI tract into systemic circulation and the degree of first-pass metabolism. Although these corticosteroids are very lipid soluble, they display variable degrees of absorption from respiratory and GI tissues, in part because of dissolution problems. When systemically absorbed, they are capable of suppressing the HPA and adrenal function with high and chronic dosing regimens (88,89). Although as much as 40% of the dose for the high-potency adrenocorticoids flunisolide, mometasone furoate, or fluticasone propionate is absorbed into airway and nasal tissues during oral inhalation, the remainder of the drug is swallowed to undergo extensive first-pass metabolism in the liver to essentially inactive metabolites, with no apparent suppression effects on adrenal function with long-term therapy.

Lipophilicity can positively or negatively alter the pharmacokinetic and pharmacodynamic actions of the inhaled/intranasal steroids (90). The lipophilic substituents attached to the corticosteroid nucleus may improve receptor affinity (Table 33.5), or they can affect pharmacokinetic properties, such as absorption, protein and tissue binding, distribution, and excretion. The inhaled/intranasal corticosteroids are inhaled as microcrystals and need sufficient water solubility to be dissolved in the nasal or lung epithelial tissue for local anti-inflammatory activity to occur. Lipophilicity, however, can delay their rate of dissolution into these tissues, which may be advantageous by prolonging their retention within these tissues, affecting their onset and duration of action, or a disadvantage by facilitating their transport away from these tissues via mucociliary clearance before full dissolution can occur. The systemic steroids prednisolone and hydrocortisone are less effective as inhaled/intranasal steroids because of their higher water solubility and lower lipophilicity. For inhaled/intranasal steroids, there is a sharp drop in water solubility when the lipophilicity is log P ≥ 4.5 (P =

30,000), which is the case for fluticasone propionate, mometasone furoate, and BDP. High lipophilicity correlates well with low oral bioavailability (Table 33.5).

The use of dexamethasone sodium phosphate inhalation aerosol is not recommended because of the potential for extensive systemic absorption and the long metabolic half-life for dexamethasone after absorption, resulting in an increased risk of adverse effects with usual inhalation doses (27). Following the oral inhalation of dexamethasone sodium phosphate, a cumulative dose of 1,200 µg/day will result in the systemic absorption of 400 to 600 µg of dexamethasone, which is sufficient to cause HPA suppression. Dexamethasone sodium phosphate nasal aerosol delivers 100 µg per metered spray. The total daily adult nasal dose is 1,200 µg.

Specific Drugs

Triamcinolone acetonide

Triamcinolone acetonide frequently is used by inhalation for the treatment of lung diseases (e.g., asthma). After inhalation, triamcinolone acetonide can become systemically available when the inhaled formulation is swallowed and absorbed unchanged from the GI tract, causing undesirable systemic effects (91,92,93). Triamcinolone acetonide that is swallowed is metabolized to 6β-hydroxytriamcinolone acetonide, 21-carboxytriamcinolone acetonide, and 21-carboxy-6β-hydroxytriamcinolone acetonide, all of which are more hydrophilic than their parent drug. Only approximately 1% of the dose was recovered from the urine as triamcinolone acetonide (94). Triamcinolone is not a major metabolite of triamcinolone acetonide in humans, suggesting that acetonide is resistant to hydrolytic cleavage. Triamcinolone acetonide is approximately eight times more potent than prednisolone.

Triamcinolone acetonide inhalation aerosol for pulmonary delivery is a microcrystalline suspension in a chlorofluorocarbon propellant that delivers 200 µg per metered spray, which is equivalent to 100 µg delivered at the mouthpiece. The total daily adult nasal dose for triamcinolone acetonide is 1.6 mg. Triamcinolone acetonide nasal aerosol is a microcrystalline suspension in a chlorofluorocarbon propellant that delivers 55 µg per metered spray. The total daily dose for triamcinolone acetonide is 440 µg.

Beclomethasone 17,21-dipropionate

Beclomethasone dipropionate is used primarily as an inhalation aerosol therapy for asthma and rhinitis (77). A breakthrough in the discovery of new inhalation corticosteroids with reduced risks from systemic absorption was that the 17α-monopropionate ester of beclomethasone (17-BMP) was more active than BDP and 21-monopropionate (21-BMP) esters (95). Thus, BDP is a pro-drug that is rapidly metabolized by esterases in the lung and other tissues to its more active metabolite, 17-BMP, which has 30 times greater affinity for the GR than BDP and approximately 14 times dexamethasone (Table 33.5) (43).

Whether orally administered or swallowed from inhalation, BDP undergoes rapid first-pass metabolism of the unhindered 21-ester via enzymatic hydrolysis in the liver or GI tract primarily to 17-BMP but more slowly to 21-BMP and to beclomethasone and other unidentified metabolites and polar conjugates (96,97). The terminal half-life for 17-BMP is 6.5 hours. The portion of the inhaled dose of BDP that enters the lung is rapidly metabolized to 17-BMP in the respiratory tract before reaching systemic circulation, where it can be further metabolized by the liver. Following oral administration, BDP and its metabolites are excreted mainly in feces via biliary elimination, and 12 to 15% of a 4-mg dose of BDP is excreted in urine as free and conjugated metabolites. The usual therapeutic dose (<1,200 µg/day) for BDP oral inhalation does not produce systemic glucocorticoid effects, probably because the drug is rapidly metabolized to less active metabolites. At doses greater than 1,200 µg/day, HPA suppression has been observed (27).

The BDP monohydrate nasal suspension is available as an aqueous microcrystalline suspension of BDP, which delivers 42 µg per metered spray. The BDP nasal aerosol or inhalation aerosol consists of microcrystalline suspension of BDP in chlorofluorocarbon propellant, both of which delivers 42, 50, or 84 µg per metered spray. The total daily adult dose for BDP is 600 µg from the nasal spray or nasal inhaler and 336 to 1,000 µg for the aerosol inhaler. Doses exceeding 2,000 µg/day need to be monitored for HPA suppression.

Flunisolide

When administered intranasally or by inhalation, flunisolide (Fig. 33.14) is rapidly absorbed

from nasal or lung tissue (Table 33.5) (94). This corticosteroid is efficiently metabolized by the liver to inactive metabolites with no apparent effects on adrenal function with long-term therapy. Flunisolide that is swallowed

undergoes extensive first-pass metabolism in the liver, and that which is absorbed directly from the nasopharyngeal mucosa or lung bypasses this initial metabolism (98). It is not known if the drug undergoes metabolism in the GI tract. Flunisolide is rapidly hydroxylated by CYP3A4 at the 6β position, followed by elimination of the 6α-fluoro group to its more polar 6β-hydroxy metabolite, which attains plasma concentrations that usually are greater than those for flunisolide (94,98).

Following IV administration of flunisolide, the 6β-hydroxy metabolite has 1/100 the potency of flunisolide and a plasma half-life of 3.9 to 4.6 hours. Flunisolide and its 6β-hydroxy metabolite are conjugated in the liver to inactive glucuronides and sulfates. After intranasal administrations of 100 μg, the plasma levels for flunisolide were undetectable within 4 hours. The duration of its systemic effects is short because of its short half-life.

Flunisolide nasal solution is available in an aqueous solubilized form, which delivers 25 μg per spray. The total daily adult dose for flunisolide from the nasal spray is 200 to 400 μg. Flunisolide inhalation aerosol for pulmonary delivery is a microcrystalline suspension in a chlorofluorocarbon propellant that delivers 250 μg per metered spray. The total daily adult inhalation dose for flunisolide is 1,000 μg. Doses exceeding 2,000 μg/day need to be monitored for HPA suppression.

Budesonide

Budesonide is a highly potent, nonhalogenated glucocorticoid intended for the local treatment of lung disease and rhinitis. It was designed to have a high ratio between local and systemic effects. Budesonide is composed of a 1:1 mixture of epimers of the 16,17-butylacetal, creating a chiral center (Fig. 33.14) (99). The 22R-epimer binds to the GR with higher affinity than does the 22S-epimer (Table 33.5) (43). The butyl acetal chain provided the highest potency for the homologous acetal chains. Its rate of topical uptake into epithelial tissue is more than 100 times faster than that for hydrocortisone and dexamethasone. Approximately 85% of the IV administered dose of budesonide undergoes extensive first-pass hepatic metabolism by CYP3A4 to its primary metabolites, 6β-hydroxybudesonide and 16α-hydroxyprednisolone, which have approximately 1/100 the potency of budesonide (100,101). This is an important inactivation step in limiting budesonide's systemic effect on adrenal suppression. Budesonide was metabolized three- to sixfold more rapidly than triamcinolone acetonide. The pharmacokinetics of budesonide after inhalation, oral, and IV administration displayed a mean plasma half-life of 2.8 hours and a systemic bioavailability of approximately 10% after oral administration (Table 33.5) (101). Pulmonary bioavailability is less than 40% after inhalation (70–75% after correction for the amounts of budesonide deposited in the inhalation device and oral cavity). No oxidative metabolism was observed in the lung. When given by inhalation, 32% of the dose is excreted in the urine as metabolites, 15% in the feces, and 41% of the dose remained in the mouthpiece of the inhaler. Following intranasal administration, very little of intranasal budesonide is absorbed from the nasal mucosa. Much of the intranasal dose (~60%) was swallowed, however, and remained in the GI tract to be excreted unchanged in the feces, whereas that fraction of the intranasal dose that was absorbed was extensively metabolized.

Inhaled budesonide, in spite of its lower lipophilicity, exhibits greater retention within the airways than other inhaled corticosteroids do (100,101). This unusual behavior for inhaled budesonide has been attributed to the subsequent formation of intracellular fatty acid esters of the 21-hydroxy group of budesonide in the airway and lung tissue (102,103). Following inhalation, approximately 70 to 80% of budesonide was reversibly esterified by free fatty acids in the airway tissue. These inactive esters behave like an intracellular depot drug by slowly regenerating free budesonide. Thus, this reversible esterification prolongs the local anti-inflammatory action of budesonide in the airways and may contribute to the high efficacy and safety of budesonide in the treatment of mild asthma when inhaled once daily.

The systemic availability of budesonide in children was estimated to be 6.1% of the nominal dose, and the terminal half-life was 2.3 hours (104,105). Approximately 6% of the nominal dose reached the systemic circulation of young children after inhalation of nebulized budesonide. This is approximately half the systemic availability found in healthy adults using the same nebulizer.

Budesonide nasal aerosol is supplied as a micronized suspension using a chlorofluorocarbon propellant, which delivers 32 μg from the nasal adapter supplied per metered spray. The total daily adult dose for budesonide is 256 μg. Budesonide powder for pulmonary inhalation uses micronized dry powder in a turboinhaler (DPI) that delivers 200 μg per metered sprayed. The total daily adult dose for budesonide from the DPI is 200 to 800 μg. Full benefit is attained in approximately 1 to 2 weeks.

Mometasone furoate

The development of mometasone furoate resulted from reexamination of the effect of 17α-ester functionalities

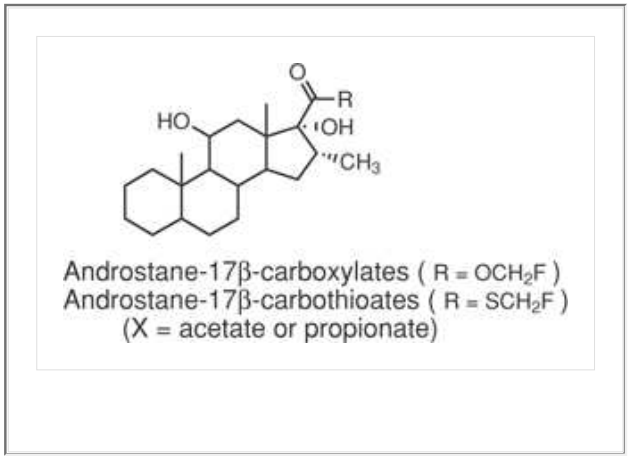
on topical anti-inflammatory potency relative to the potent 17-benzoate ester of betamethasone. The structure–activity relationship study involved substitution of the 17-benzoate ester with heteroaromatic furoic, thienoic, and pyrrolic esters (81,106). Of the numerous 17α-heteroaryl esters studied,

the 2-furoate ester displayed the greatest increase in potency. Therefore, combining the 17α-(2-furoate) ester with the potency-enhancing effect of the 21-chloro group, the resultant glucocorticoid (mometasone furoate) (Fig. 33.14) was 5 to 10 times more potent than the betamethasone benzoate ester, with a more rapid onset of action. Mometasone furoate was originally marketed as a topically applied corticosteroid, but because of its low systemic bioavailability, it was found to be more useful in the treatment of allergic disorders and lung diseases (107). It has the greatest binding affinity for the GR (Table 33.5), followed by fluticasone propionate, budesonide, triamcinolone acetonide, and dexamethasone (43). Mometasone furoate has strong local anti-inflammatory activity equivalent to that of fluticasone propionate. It has a quick onset of action relative to the other inhaled/intranasal steroids with the least systemic availability and, consequently, the fewest systemic side effects.

Following IV suspension or inhalation administration, mometasone furoate was detected in the plasma for up to 8 hours, with a half-life of 4 to 6 hours (Table 33.5) and an oral bioavailability of less than 1%. It is extensively metabolized with less than 10% of the administered dose recovered in the urine unchanged (108). Among the polar metabolites (~80%) and their conjugates (42%) that were recovered were 6β-hydroxymometasone furoate and its 21-hydroxy metabolite. In contrast, following intranasal administration, its plasma concentrations were below the limit of quantification, and the systemic bioavailability by this route was estimated to be less than 1%. The majority of the intranasal dose for mometasone furoate is deposited in the nasal mucosa and swallowed without absorption in the GI tract until eliminated in the feces (approximately 50–90% of the intranasal dose is recovered in the feces). That portion of the intranasal dose that was absorbed was extensively metabolized. These results indicate that inhaled mometasone furoate has negligible systemic bioavailability and is extensively metabolized, with reduced risk for causing systemic adrenal suppression effects.

Mometasone furoate nasal suspension is supplied as an aqueous suspension with an atomizing pump that dispenses 50 μg per metered spray. The total daily dose for mometasone furoate is 200 μg.

Androstane 17β-carboxylates and 17β-carbothioates



The androstane 17β-hydroxyl-17β-carboxylates and 17β-carbothioates were designed to be metabolically susceptible to hydrolysis and to have a low systemic bioavailability to minimize systemic glucocorticoid-induced adrenal suppression. The androstane 17α-hydroxyl-17β-carboxylates lacked the 17-ketol group found in most of the systemic corticosteroids. When these 17β-carboxylates were esterified to their 17α/β-diesters, however, they proved to be extremely potent anti-inflammatory corticosteroids, whereas the parent carboxylic acids were inactive (109). Thus, enzymatic hydrolysis of the 17-carboxylate ester function by intestinal or liver esterases would lead to formation of inactive metabolites. The greatest anti-inflammatory activity was observed with 17α-acetoxy and 17α-propionoxy groups and simple alkyl carboxylate esters, although the fluoromethyl esters showed the highest activity. Superseding the androstane 17β-carboxylates were the corresponding 17β-carbothioates (thioesters) derived from flumethasone. The 17β-fluoromethylcarbothioate when combined with the 17α-propionoxy group yielded fluticasone (Fig. 33.14) (110). The androstane 17β-carbothioates proved not only to be very potent anti-inflammatory agents but also to exhibit weak HPA suppression in the rat. Both the androstane 17β-carboxylates and the androstane 17β-carbothioates are very lipophilic and exhibit minimal

oral bioavailability and very low systemic activity after inhalation because of intestinal and hepatic enzymatic hydrolysis to inactive metabolites, which have 1/2,000 the activity of the parent molecule (111).

Fluticasone Propionate

Fluticasone propionate, a trifluorinated glucocorticoid based on the androstane 17β-carbothioate nucleus (Fig. 33.14), was designed to be metabolically susceptible to hydrolysis and to have a low systemic bioavailability to minimize the systemic effects on plasma hydrocortisone levels. Its susceptibility to metabolic hydrolysis is doubly enhanced by the combination of a thioester and the high electronegativity of the fluorine group. Fluticasone propionate is approximately 0.5 times as lipophilic than BDP, eight times more lipophilic than budesonide, and 13 times more lipophilic than triamcinolone acetonide (Table 33.5) (90). It also displays high in vitro selectivity for the GR and a relative receptor affinity 1.5 times that of 17-BMP and mometasone furoate, three times that of budesonide, 18 times that of dexamethasone, and 20 times that of flunisolide and triamcinolone acetonide (43). The rate of association for fluticasone dipropionate with the receptor is faster, and the rate of dissociation is slower, than the other corticosteroids. The half-life of the fluticasone propionate active steroid–receptor complex is greater than 10 hours, compared with approximately 5 hours for budesonide, 7.5 hours for 17-BMP, and 4 hours for triamcinolone acetonide (43).

Following topical application to the nasal mucosa or after inhalation, fluticasone propionate produces potent anti-inflammatory effects, with an onset of action of approximately 2 to 3 days. The topical anti-inflammatory

potency for fluticasone propionate is approximately equal to that for mometasone furoate, 13-fold greater than that for triamcinolone acetonide, ninefold greater than that for fluocinolone acetonide, threefold greater than that for betamethasone 17-valerate, and twofold greater than that for BDP (111). Because of its low systemic bioavailability when administered intranasally or by inhalation and nondetectability in plasma, most pharmacokinetic data for fluticasone propionate are based on IV or oral administration (Table 33.5). Its rate of topical uptake into epithelial tissue is more than 100-fold faster than that for hydrocortisone and dexamethasone but is similar to BDP and budesonide.

As a consequence of its high lipophilicity (Table 33.5), fluticasone propionate is very insoluble and, therefore, is poorly absorbed from the respiratory (10–13%) and GI tract following nasal inhalation of the drug (112,113,114). The majority of the intranasal dose for fluticasone propionate is deposited in the nasal mucosa and swallowed into the GI tract until eliminated in the feces (~80–90% of the intranasal dose is recovered metabolized and unchanged in the feces). After administration of an IV suspension, fluticasone propionate displayed a systemic bioavailability of less than 2% and underwent extensive hydrolysis and CYP3A4 first-pass metabolism in the liver, with an elimination half-life of approximately 3 hours. Its primary hydrolysis product is 17β-carboxylate metabolite, which has 1/2,000 the affinity for the GR, can be recovered from the urine along with other unidentified hydroxy metabolites and their conjugates. Following oral administration of 1 to 40 mg, fluticasone propionate is poorly absorbed from the GI tract because of hydrolysis and its insolubility, with an oral bioavailability of less than 1%. Less than 5% of the oral dose is excreted unchanged in the urine. Fluticasone propionate was not detected in plasma for up to 6 hours after IV or oral administration (113). Approximately 80 to 90% of the oral dose is excreted unchanged in the feces, of which approximately 3 to 40% is the hydrolyzed 17β-carboxylate metabolite. Pulmonary bioavailability ranges between 16 and 30% depending on the inhalation device used, with an elimination half-life of approximately 14 hours, increasing its potential for drug accumulation with repeated dosing (114). The long elimination half-life for fluticasone propionate results, in part, from its very high lipophilicity and very poor water solubility and, consequently, slow dissolution into lung tissue. Some suppression of overnight hydrocortisone levels has been reported with inhaled fluticasone propionate at higher dosages (indicative of HPA-axis suppression) (115).

Fluticasone propionate nasal suspension and inhalation aerosol are both available as micronized suspensions in a chlorofluorocarbon propellant that delivers 50 μg per metered spray. The total daily adult dose for fluticasone propionate is 200 μg for the nasal suspension and 880 μg for the inhalation aerosol.

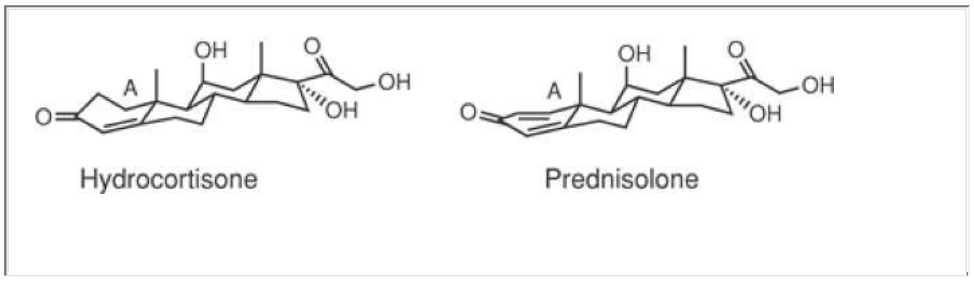


Fig. 33.15. Conformations of hydrocortisone and prednisolone.

Summary of Structure–Activity Relationships

The structure in Figure 33.15 depicts the ring conformation and the absolute configuration of hydrocortisone and prednisolone. The all-*trans* (B/C and C/D) backbone that is necessary for activity is very evident.

As previously pointed out, the adrenocorticoids generally are classified as either glucocorticoids, which affect intermediary metabolism and are associated with inhibition of the inflammatory process, or mineralocorticoids. In fact, most naturally occurring and semisynthetic analogues exhibit both of these actions. The 17β-ketol (-$COCH_2OH$) side chain and the Δ^4-3-ketone functions are found in clinically used adrenocorticoids, and these groups do contribute to the potency of the agents. Modifications of these groups may result in derivatives that retain biological activity. For example, replacement of the 21-OH group with fluorine increases glucocorticoid and sodium-retaining activities, whereas substitution with chlorine or bromine abolishes activity. Some compounds that do not contain the Δ^4-3-ketone system have appreciable activity. It has been suggested that this group makes only a minor contribution to the specificity of action by these drugs or to the steroid–receptor association constant (116).

Based on structure–activity studies, the C and D rings, involving positions 11, 12, 13, 16, 17, 18, 20, and 21, are more important for receptor binding than the A and B rings. Generally, insertion of bulky substituents on the β-side of the molecule abolishes glycogenic activity, whereas insertion on the α-side does not. It has been suggested that association of these steroids with receptors involves β-surfaces of rings C and D and the 17β-ketol side chain (116). It is possible, however, that association with the α-surface of rings A, C, and D, as well as with the ketol side chain, is essential for sodium-retaining activity. Many functional groups, such as 17α-OH, 17α-CH_3, 16α-CH_3, 16β-CH_3, 16α-CH_3O, and 16α-OH substituents, abolish or reverse this activity in 11-desoxycorticosterone and 11-oxygenated steroids. Discussions of exceptions of these generalities are found in the literature (116).

Although some steroids cause sodium retention, many have glucocorticoid and either sodium-retaining or sodium-excreting action. Difficulties in correlating the structures of adrenocorticoids with biological action are compounded because of differences in assay methods, species variation, and mode of drug administration. For

example, whereas liver glycogen and anti-inflammatory assays in the rat correlate well, some drugs show high anti-inflammatory action in the rat but little or no antirheumatic activity in humans. The 9α-F analogue, fludrocortisone acetate, is more active than the 9α-Cl analogue in terms of sodium retention in the dog; the reverse is true in the rat. Although 16α-methylation and 16β-methylation enhance glucocorticoid activity, anti-inflammatory action is increased disproportionately to glycogenic action in both series.

Table 33.6. Biological Potencies of Modified Adrenocorticoids in the Rat and Humans*

	Potency Relative to Hydrocortisone (Cortisol)				
	Rat			Humans	
Adrenocorticoid	Thymus Involution	Liver Glycogen Deposition	Eosinopenic Potency	Hyperglycemic Potency	Antirheumatic Potency
Corticosterone	—	0.8	0.06	0.06	<0.1
Prednisone	—	3	—	4	4

Prednisolone	2	3.9	4	4	4
Methylprednisolone	10	11	5	5	5
Triamcinolone	4	47	5	5	5
Paramethasone	—	150	12	12	11
Dexamethasone	56	265	28	28	29
Fludrocortisone acetate	6	9	8	8	10
Fluprednisolone	6	81	9	9	10
Triamcinolone acetonide	33	242	3	3	3
Flurandrenoione	4	—	1	—	2
Fluorometholone	25	115	10	10	—
Fluocinolone	19	112	5	6	9

*Data from Ringler I. Steroidal activity in experimental animals and man. In: Dorfman RI, ed. Methods of Hormone Research, vol 3. Part A. New York: Academic Press, 1964.

In humans, eosinopenic and hyperglycemic potencies are essentially the same. There is a close correlation in efficacy ratios derived from these tests and antirheu-matic potency (Table 33.6). Because the eosinopenic–hyperglycemic activity and antirheumatic potency show excellent agreement, it has been suggested that these assays afford advantages in the preliminary estimation of anti-inflammatory potency (27).

Structure–activity studies of glucocorticoids have been carried out mainly in animals and are not necessarily applicable to clinical efficacy in man. Relative activity and dose correlations for the clinically useful drugs are found in Table 33.2.

Several other compounds have been studied in animals and used to derive structure–activity relationships. For example, insertion of a double bond between positions 1 and 2 in hydrocortisone increases glucocorticoid activity. The Δ^1-corticoids have a much longer half-life in the blood than hydrocortisone. Ring A is much more slowly metabolized, but it is oxidatively metabolized at other positions, especially the 6β position and the 17β-ketol (Fig. 33.12). If, however, a double bond is inserted between positions 9 and 11 (no oxygen function at 11), a decrease in glucocorticoid activity is observed. Except for cortisone, which results in an analogue with decreased glucocorticoid activity when a double bond is inserted between position 6 and 7, such modification of other glucocorticoids generally produces no change in activity (16).

Insertion of α-CH_3 groups at positions 2 (in 11β-OH analogues), 6, and 16 increases glucocorticoid activity in animals. Again, insertion of a 2α-CH_3 group into the glucocorticoid almost completely prevents reduction of the

Δ^4-3-ketone system in vivo and in vitro. Substitutions at positions 4α, 7α, 9α, 11α, and 21 decrease activity.

Although some analogues, such as 16α,17α-isopropylidinedioxy-6α-methylpregna-1,4-diene-3,20-dione and the 1,2-dihydro derivative, are 11-desoxysteroids and biologically active, the 11β-OH group of hydrocortisone does seem to be involved in the drug–receptor interaction (116). Cortisone, which contains an 11-keto function, is reduced in vivo to hydrocortisone. The drug 2α-methylhydrocortisone exhibits high glucocorticoid activity, probably because of steric hindrance to reduction (i.e., C==O → C-β-OH) by the methyl group, thus rendering the analogue inactive (40,117,118). Insertion of α-OH groups into most other positions (1, 6, 7, 9, 14, and 16) or reduction of the 20-ketone, however, decreases glucocorticoid activity, in part because of increased hydrophilicity.

The 9α-F group increases glucocorticoid activity and nearly prevents metabolic oxidation of the 11β-OH group to a ketone. Redox metabolism of Δ^4-steroids is mainly restricted to the Δ^4-3-ketone, 6 and 16 positions, and 17β-ketol side chains, whereas for Δ^4-steroids it is only the 6 and 16 positions and 17β-ketol side chains. The 9α-F group may increase activity by an inductive effect, which increases the acidic dissociation constant of the 11β-OH group and, thereby, increases the ability of the drug to hydrogen bonding to GRs.

Fig. 33.16. Hydrogen bonding between 17α-hydroxyl and 12α-fluoro groups.

A 6α-F group also increases glucocorticoid activity, but it has less effect than the 9α-F function on sodium retention. Insertion of 2α-, 11α- (no OH group at 11), or 21-F groups decreases glucocorticoid activity. Of particular interest is a 12α-F group. When this function is inserted into corticosterone, which has no 17α-OH group, it potentiates activity to the same extent as a 9α-F group. Insertion of a 12α-F group into a 16α,17α-dihydroxy steroid, however, renders the compound inactive. A 9α-F group potentiates activity in such analogues.

It has been proposed that hydrogen bonding between the 12α-F and 17α-OH groups renders the analogue inactive (Fig. 33.16). Conversion to the 16α,17α-isopropylidinedioxy (acetonide) derivative, which cannot hydrogen bond, restores biological activity (119).

The mineralocorticoid activity of adrenocorticoids is another action of major significance. Many toxic side effects, making it necessary to withdraw steroid therapy in rheumatoid patients, are a result of this action. Highly active, naturally occurring mineralocorticoids have no OH function in positions 11 and 17. In fact, OH groups in any position reduce the sodium-retaining activity of the adrenocorticoid.

Generally, 9α-F, 9α-Cl, and 9α-Br substitution causes increased retention of urinary sodium with an order of activity in which F > Cl > Br, but species differences do exist. For these reasons, such compounds are not used internally in the treatment of diseases such as rheumatoid arthritis. Insertion of a 16α-OH group into the molecule affects the sodium retention activity so markedly that it not only negates the effect of the 9α-F atom but also causes sodium excretion.

A double bond between positions 1 and 2 (Δ^1-corticoids) also reduces the sodium retention activity of the parent drug. This functional group, however, contributes to the parent drug only approximately one-fifth the

sodium-excreting tendency of a 16α-OH group (120).

The 12α-F, 2α-CH_3, and 9α-Cl substitutions contribute equally to sodium retention. A 21-OH group, found in all these drugs, contributes to this action to the same degree. Because 21-OH groups also contribute to glucocorticoid activity, it is easy to understand why it is difficult to develop compounds with only one major action.

A 2α-CH_3 group is approximately threefold, and a 21-F substituent twofold, as effective as unsaturation between positions 1 and 2 in reducing sodium retention. Other substituents reported to inhibit sodium retention include 16α-CH_3, 16β-CH_3, 16α-CH_3O, and 6α-Cl functions. A 17α-OH group, which is present in naturally occurring and semisynthetic analogues, reduces sodium retention to about the same extent as does unsaturation between positions 1 and 2.

Conversion of the 17α-hydroxy to either a 17α-ester or an ether, as with 16α,17α-isopropylidinedioxy (acetonide), greatly enhances the anti-inflammatory potency and GR affinity (Table 33.5). As evidenced with BDP, however, esterifying the 21-hydroxy group reduces activity and receptor affinity. On the other hand, 21-halogens or 21-halomethylene groups greatly increase topical anti-inflammatory activity with no change or a decrease in mineralocorticoid activity. Perhaps a hydrogen bonding group at position 21 enhances or retains mineralocorticoid receptor affinity.

Adrenocorticoid Antagonists

Antagonists of adrenocorticoids include agents that compete for binding to steroid receptors (antiglucocorticoids or antimineralocorticoids) and inhibitors of adrenosteroid biosynthesis. The action of adrenal steroids can be blocked by antagonists that compete with the endogenous steroids for binding sites on their respective cytosolic receptor proteins. The antagonist–receptor complexes are unable to stimulate the production of new mRNA and protein in the target tissues and, thus, are unable to elicit the biological responses of the hormone agonist. Spironolactone (Fig. 33.17) and related analogues bind to the mineralocorticoid receptor in the kidney and result in the diuretic response of increased Na^+ excretion and K^+ retention. The 3-keto-4-ene A ring is essential for this antagonistic activity, and the opening of the lactone ring dramatically reduces activity. The 7α-substituent increases both intrinsic activity and oral activity (121,122). Progesterone also has shown antimineralocorticoid activity at 10^{-4} molar concentrations.

Receptor antagonists of glucocorticoids have been described that are derivatives of 19-nortestosterone (123). Mifepristone, also referred to as RU-486 (Fig. 33.17), was originally developed as an antiprogestin and also exhibits very effective antagonism of glucocorticoids.

Several inhibitors of adrenocorticoid biosynthesis have been described, with the majority of nonsteroidal agents inhibiting one or more of the cytochrome P450 enzyme complexes involved in adrenosteroid biosynthesis (Fig. 33.17). Metyrapone reduces cortisol biosynthesis by primarily inhibiting mitochondrial 11β-hydroxylase (124,125). It also inhibits, to a lesser degree, 18-hydroxylase and side-chain cleavage. This agent is used to test pituitary–adrenal function and the ability of the pituitary to secrete ACTH (125). Aminoglutethimide inhibits side-chain cleavage (125) and has been used as a medical adrenalectomy. Several azole antifungal drugs inhibit adrenocorticoid biosynthesis. Ketoconazole is one example of a potent inhibitor of fungal sterol biosynthesis at low concentrations;

however, at higher doses, ketoconazole inhibits CYP3A4 in adrenosteroid biosynthesis (126). Trilostane (4α,5α-epoxy-17β-hydroxy-3-oxoandrostan-2α-carbonitrile) is a steroidal inhibitor of 3β-hydroxysteroid dehydrogenase (127) and has been used in the treatment of Cushing's syndrome.

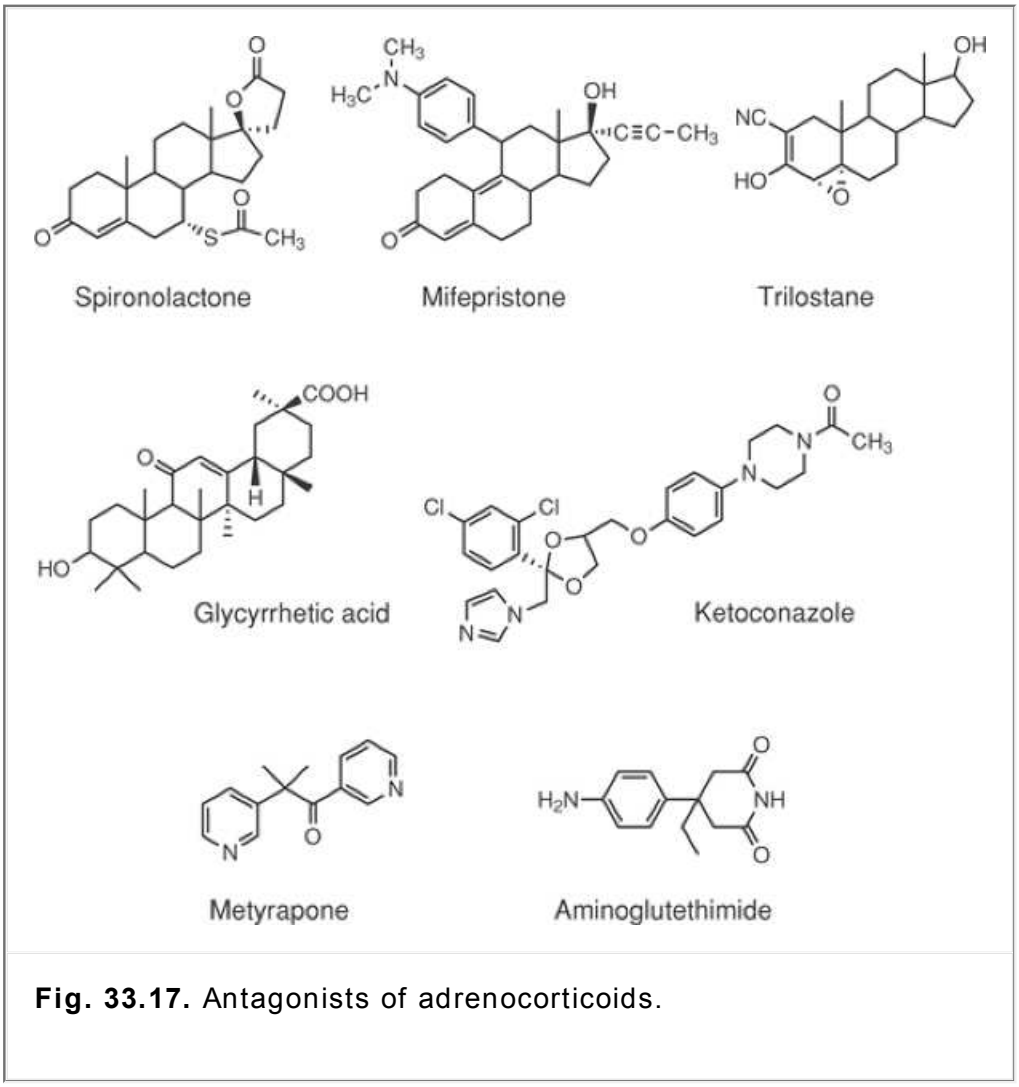

Fig. 33.17. Antagonists of adrenocorticoids.

Inhibition of the two 11β-hydroxysteroid dehydrogenase isozymes has been described. Excessive ingestion of licorice, an extract of the roots of *Glycyrrhiza glabra*, produces undesirable mineralocorticoid-like intoxication (hypertension, excessive salt retention, and hypokalemia). The active components of licorice, glycyrrhetic acid (Fig. 33.17) and carbenoxolone, inhibit both 11β-HSD isozymes (128), with the undesirable side effects resulting from inhibition of 11β-HSD2 in the kidney. Bile acids, such as chenodeoxycholic acid and lithocholic acid, have recently shown selective inhibition of 11β-HSD1 (129,130), and nonsteroidal arylsulfoamidothiazoles also recently have been reported as 11β-HSD1 inhibitors (131). Such enzyme inhibitors may be useful in the treatment on metabolic syndromes to reduce elevated glucose concentrations and as possible antidiabetic agents.

Mechanisms of Adrenocorticoid Action

Molecular Interaction

Glucocorticoid action is mediated through the glucocorticoid receptor, which is found primarily in the cytosol of the cell when not bound to glucocorticoids. The GR is stabilized in the cytosol by complexation with phosphorylated proteins, including a 90-kDa protein referred to as a heat shock protein 90 (132). The steroid molecule binds to the GR, resulting in a conformational change of the receptor to dissociate the other proteins and initiate translocation of the steroid–receptor complex into the nucleus. The steroid–nuclear GR complex interacts with particular HRE regions of the cellular DNA, referred to as glucocorticoid-responsive elements and initiates transcription of the DNA sequence to produce mRNA. Finally, the elevated levels of mRNA lead to increased protein synthesis in the endoplasmic reticulum. These proteins then mediate glucocorticoid effects on carbohydrate, lipid, and protein metabolism. An alternative isoform of the GR has been identified. This isoform of the receptor does not bind known glucocorticoids, and its function remains to be determined (133,134). Some

of the specific proteins induced by glucocorticoids have been identified and are discussed later. Mineralocorticoid effects are observed in several tissues, and specific mineralocorticoid receptors have been characterized that mediate mineralocorticoid functions (135).

Physiologic Effects

Glucocorticoids

Corticosteroids influence all tissues of the body and produce numerous and varying effects in cells (16).

These steroids regulate carbohydrate, lipid, and protein biosynthesis and metabolism (glucocorticoid effects), and they influence water and electrolyte balance (mineralocorticoid effects). Cortisol is the most potent glucocorticoid secreted by the adrenal gland, and aldosterone is the most potent endogenous mineralocorticoid. Both naturally occurring glucocorticoids and related, semisynthetic analogues can be evaluated in terms of their ability to sustain life, to stimulate an increase in blood glucose concentrations and a deposition of liver glycogen, to decrease circulating eosinophils (136), and to cause thymus involution in adrenalectomized animals (137,138). In addition, corticosteroids can affect immune system functions, inflammatory responses, and cell growth.

The primary physiologic function of glucocorticoids is to maintain blood glucose levels and, thus, ensure glucose-dependent processes critical to life, particularly brain functions. Cortisol and related steroids accomplish this by stimulating the formation of glucose, by diminishing glucose use by peripheral tissues, and by promoting glycogen synthesis in the liver to increase carbohydrate stores for later release of glucose. For glucose formation, glucocorticoids mobilize amino acids and promote amino acid metabolism and gluconeogenesis. These steroids, acting via the GR mechanism, induce the production of a variety of enzymes important for glucose formation. The synthesis of tyrosine aminotransferase increases within 30 minutes of glucocorticoid exposure (139,140,141). This enzyme promotes the transfer of amino groups from tyrosine to α-ketoglutarate to form glutamate and hydroxyphenylpyruvate. Another amino acid–metabolizing enzyme induced rapidly by glucocorticoids is tryptophan oxidase (142). This enzyme oxidizes tryptophan to formylkynurenine, which is subsequently converted to alanine. Alanine transaminase also is induced by glucocorticoids (143). Alanine and, to a lesser extent, glutamate are important for gluconeogenesis in the liver (144).

Several other enzymes important in gluconeogenesis and glycogen formation are elevated for several hours following glucocorticoid administration; these include glycogen synthetase, pyruvate kinase, phosphoenol pyruvate carboxykinase, and glucose-6-phosphate kinase (16,145,146). The delayed increases in these enzymes suggest that their biosyntheses are not regulated directly by glucocorticoids. In peripheral tissues, glucocorticoid-induced inhibition of phosphofructokinase is observed (146). This enzyme catalyzes the formation of D-fructose-1,6-diphosphate from D-fructose- 6-phosphate during glycolysis. Inhibition of this enzyme decreases glucose utilization by peripheral tissues and results in maintaining blood glucose levels. Reviews of the multiple effects of glucocorticoids on carbohydrate metabolism have been published (16,146).

Additional effects of glucocorticoids in the body are preventing or minimizing inflammatory reactions and suppressing immune responses. These steroids interfere with both early events in inflammation (e.g., release of mediators, edema, and cellular infiltration) and later stages (e.g., capillary infiltration and collagen formation). Only a few of the mechanisms involved in glucocorticoid suppression of inflammation are known. Cortisol will induce the production of lipocortin and related proteins by increasing gene expression through the GR mechanism (147,148). Lipocortin inhibits the activity of phospholipase A_2, which liberates arachidonic acid and leads to the biosynthesis of eicosanoids (e.g., prostaglandins and leukotrienes) (149). Lipocortin also mediates the decreased production and release of platelet-activating factor (150), and glucocorticoids can suppress the expression of interleukin (IL)-1, tumor necrosis factor, and inducible nitric oxide synthase (151,152,153). These eicosanoids and peptide factors are important as mediators in the inflammatory response. Some of these factors also play important roles in cellular infiltration and capillary permeability in the inflamed region. Suppression of the immune responses are mediated by inhibition of the synthesis and release of important mediators as well. In macrophages, glucocorticoids inhibit IL-1 synthesis and, thus, interfere with proliferation of B lymphocytes, which are important for antibody production (154). Additionally, IL-1 is important for activation of resting T lymphocytes, which are important for cell-mediated immunity. The activated T cells produce IL-2, the biosynthesis of which also is reduced by glucocorticoids (154).

Mineralocorticoids

The primary physiologic function of mineralocorticoids is to maintain electrolyte balances in the body by enhancing Na^+ reabsorption and increasing K^+ and H^+ secretion in the kidney. Similar effects on cation transport are observed in a variety of secretory tissues, including the salivary glands, sweat glands, and mucosal tissues of the GI tract and the bladder. Aldosterone is the most potent endogenous mineralocorticoid. Deoxycorticosterone is approximately 20-fold less potent than aldosterone. Cortisol exhibits weak mineralocorticoid activity in vivo because of rapid metabolism of cortisol by 11β-hydroxysteroid dehydrogenase. The mechanism of action of aldosterone involves binding of the steroid to the mineralocorticoid receptor and initiation of gene transcription, mRNA biosynthesis, and protein production. A protein referred to as aldosterone-induced protein is produced through this mechanism and is thought to aid in Na^+ retention. One possible mode of action of aldosterone-induced protein is to act as a permease to increase the permeability of the cell membrane to Na^+ (155). This results in an accelerated rate of Na^+ influx and elevated activity of Na^+, K^+-ATPase to pump Na^+ into extracellular space (156).

Pharmacological Effects And Clinical Applications

In addition to their natural hormonal actions, the adrenocorticoids have many clinical uses. Glucocorticoids and mineralocorticoids may be used for the treatment of adrenal insufficiency (hypoadrenalism), which results from failure of the adrenal glands to synthesize adequate amounts of the hormones. Adrenocorticoids also are used to maintain patients who have had partial or complete removal of their adrenal glands or adenohypophysis (adrenalectomy and hypophysectomy, respectively). Glucocorticoids can cross the placenta and can be distributed into milk.

Two major uses of glucocorticoids are in the treatment of rheumatoid diseases and allergic manifestations. Their use in the treatment of severe asthma is well documented, as is the utility of glucocorticoids in sepsis and acute respiratory distress syndrome (157,158). They are effective in the treatment of rheumatoid arthritis, acute rheumatic fever, bursitis, spontaneous hypoglycemia in children, gout, rheumatoid carditis, sprue, allergy (including contact dermatitis), and other conditions. The treatment of chronic rheumatic diseases and allergic conditions with glucocorticoids is symptomatic and continuous. Symptoms return after withdrawal of the drug.

In addition, these drugs are moderately effective in the treatment of ulcerative colitis, dermatomyositis, periarteritis nodosa, idiopathic pulmonary fibrosis, idiopathic thrombocytopenic purpura, regional ileitis, acquired hemolytic anemia, nephrosis, cirrhotic ascites, neurodermatitis, and temporal arteritis. The newer analogues with medium to high potency rankings (Table 33.4), such as diflorasone diacetate, desoximetasone, flurandrenolide, and fluocinonide (Fig. 33.12), are effective topically in the treatment of psoriasis. Glucocorticoids may be combined with antibiotics to treat pneumonia, peritonitis, typhoid fever, and meningococcemia.

When dosages with equivalent antirheumatic potency are given to patients not treated with steroids, the Δ^1-corticoids (prednisone and prednisolone) promote the same pattern of initial improvement as hydrocortisone. Statistical results of improvement during the first few months of therapy have been similar with prednisone, prednisolone, and hydrocortisone. The results of longer-term therapy have been significantly better with the modified compounds.

Satisfactory rheumatic control, lost after prolonged cortisone or hydrocortisone therapy, may be regained in an appreciable number of patients by changing to prednisone, prednisolone, or other modified drugs. Of patients whose conditions deteriorate below adequate levels during hydrocortisone administration, nearly half reach their previous level of improvement after Δ^1-corticoids (in doses slightly larger in terms of antirheumatic strength) are used. With further prolongation of steroid therapy, improvement again wanes in some patients, but in other patients, such management is successful for longer than 2 years. In some instances, the improvement is attributed to increased effectiveness of the drug because of correction of salt and water retention; in other instances, there is no adequate explanation.

When these drugs are administered in doses that have similar antirheumatic strengths, the general incidence of adverse reactions with prednisone and prednisolone is about the same as that with hydrocortisone. The compounds differ, however, in their tendencies to induce individual side effects. The incidence and degree of salt and water retention and blood pressure elevation are less with the Δ^1-corticoids. Conversely, these analogues are more likely to promote digestive complaints, peptic ulcer, vasomotor symptoms, and cutaneous ecchymosis.

Although these analogues have unwanted side effects, most clinical investigators prefer the Δ^1-corticoids to

cortisone and hydrocortisone for rheumatoid patients who require steroid therapy. The reasons are that these drugs have less tendency to cause salt and water retention and potassium loss and that they restore improvement in a significant percentage of patients whose therapeutic control has been lost during cortisone and hydrocortisone therapy.

It seems desirable to administer prednisone and prednisolone in conjunction with nonabsorbable antacids. This affords improvement of long-term therapy. It appears that the therapeutic indices of these two analogues, especially when used in conjunction with nonabsorbable antacids, are higher than those for the naturally occurring glucocorticoids.

Most important, glucocorticoids should not be withdrawn abruptly in cases of acute infections or severe stress, such as surgery or trauma. Myasthenia gravis, peptic ulcer, diabetes mellitus, hyperthyroidism, hypertension, psychological disturbances, pregnancy (first trimester), and infections may be aggravated by glucocorticoid administration. Hormone therapy is contraindicated in these conditions and should be used only with the utmost precaution.

Semisynthetic analogues exhibiting high mineralocorticoid activity are not employed in the treatment of rheumatic disorders because of toxic side effects resulting from a disturbance of electrolyte and water balance. Some newer synthetic steroids (Table 33.2) are relatively free of sodium-retaining activity. They may show other toxic manifestations, however, and eventually need to be withdrawn.

Glucocorticoids sometimes are used in the treatment of scleroderma, discoid lupus, acute nephritis, osteoarthritis, acute hepatitis, hepatic coma, Hodgkin's disease, multiple myeloma, lymphoid tumors, acute leukemia, metastatic carcinoma of the breast, and

chronic lymphatic leukemia. Glucocorticoids may be more or less effective in these diseases depending on the clinical condition.

Some modified compounds have been recommended for use when other analogues are no longer effective or when it is desirable to promote increased appetite and weight gain. Triamcinolone may be used advantageously when salt and water retention (from other glucocorticoids, hypertension, or cardiac compensation) or excessive appetite and weight gain are problems in management.

One factor must not be overlooked when applying potent anti-inflammatory agents with high mineralocorticoid activity to the skin. Consideration must be given to percutaneous absorption. Sodium retention and edema occur in patients with dermatitis who apply as much as 75 mg of fludrocortisone acetate (i.e., 30 mL of a 0.25% lotion) to the skin in 24 hours. The relative rate of percutaneous absorption, administered as a cream in rats, was triamcinolone acetate ≥ hydrocortisone > dexamethasone, but dexamethasone was deposited in skin longer than the other two drugs. Hydrocortisone disappeared most rapidly (159).

Topical Applications

Topical dermatological products with a low potency ranking have a modest anti-inflammatory effect and are safest for chronic application (Table 33.4). These products also are the safest products for use on the face with occlusion and in infants and young children. Those products with a medium potency ranking are used in moderate inflammatory dermatoses, such as chronic hand eczema and atopic eczema, and may be used on the face and intertriginous areas for a limited duration. High-potency preparations are used in more severe inflammatory dermatoses, such as severe eczema and psoriasis. They may be used for a limited duration and for longer periods in areas with thickened skin because of chronic conditions. High-potency preparations also may be used on the face and intertriginous areas, but only for a short treatment duration. Very-high-potency products are used primarily as an alternative to systemic corticosteroid therapy when local areas are involved. Examples of conditions for which very-high-potency products frequently are used include thick, chronic lesions caused by psoriasis, lichen simplex chronicus, and discoid lupus erythematosus. They may be used for only a short duration of therapy and on small surface areas. Occlusive dressings should not be used with these products. It has been suggested that patients using a lotion or ointment containing these drugs be instructed to apply them sparingly and to spread them lightly over the affected areas. The extent and frequency of applications should be carefully considered. A lotion vehicle is more effective when treating a dermatitis, but a greater degree of percutaneous absorption occurs than when ointments are used.

Intranasal and Inhaled Applications

The pulmonary and nasal bioavailability are important determinants for the potential of an inhaled or nasally

applied corticosteroid to cause systemic effects, because the lung and nasal tissue provide an enormous surface area from which drug absorption can occur into the systemic circulation. The main areas of concern with regard to systemic effects include HPA-axis suppression, change in bone mineral density and growth retardation in children, cataracts, and glaucoma. The degree of systemic side effects is dose-dependent, related to the half-life of the drug, frequency administration, time of day when administered, and route of administration; in other words, the higher the plasma corticosteroid concentration and longer the half-life, the greater the systemic side effects will be (Table 33.5) (27). The amount of an inhaled or nasal corticosteroid reaching the systemic circulation is the sum of the drug concentration available following absorption from the lungs/nasal mucosa and from the GI tract. The fraction deposited in the mouth will be swallowed, and the systemic availability will be determined by its absorption from the GI tract and the degree of first-pass metabolism.

Delivery devices can produce clinically significant differences in activity by altering the dose deposited in the lung (10–25%) and, for orally absorbed drugs, the amount deposited in the oropharynx and swallowed (75–90%). Clinical studies have shown the following relative potency differences: mometasone furoate > fluticasone propionate > budesonide = BDP > triamcinolone acetonide = flunisolide. Potency differences can be overcome by giving larger doses of the less potent drug, which increases risks from systemic effects. Adrenal suppression may be associated with high doses of inhaled corticosteroids (>1.5 mg/day, or >0.75 mg/day for fluticasone propionate), although there is a considerable degree of interindividual susceptibility.

All currently used inhaled corticosteroids are rapidly cleared from the body but show varying levels of oral bioavailability, with fluticasone propionate having the lowest (Table 33.5). Following inhalation, there also is considerable variability in the rate of absorption from the lung, and pulmonary residence times are greatest for fluticasone propionate and triamcinolone acetonide and shortest for budesonide and flunisolide. Adrenal suppression has not been observed when intranasal fluticasone propionate was administered in dosages of 200 to 4,000 µg daily for up to 12 months.

Adverse Effects

Although short-term administration of corticosteroids are unlikely to produce harmful effects, these drugs, when used for longer than brief periods, can produce a variety of devastating effects, including glucocorticoid-induced adrenocortical insufficiency, glucocorticoid-induced

osteoporosis, and generalized protein depletion (16,27). The duration of anti-inflammatory activity of glucocorticoids approximately equals the duration of HPA-axis suppression. The duration of HPA-axis suppression after a single oral dose of glucocorticoids in one study is shown in Table 33.7. When given for prolonged periods, glucocorticoids suppress the HPA axis, thereby decreasing secretion of endogenous corticosteroids and adrenal atrophy. Glucocorticoids inhibit ACTH production by the adenohypophysis, and in turn, this reduces endogenous glucocorticoid production. With time, atrophy of the adrenal glands takes place. The degree and duration of adrenocortical insufficiency produced by the synthetic glucocorticoids is highly variable among patients and depends on the dose, frequency and time of administration, and duration of glucocorticoid therapy. This effect may be minimized by use of alternate-day therapy.

Table 33.7. Effect of an Oral Single Dose on the Duration of HPA Suppression

Adrenocorticoid	Duration of Suppression (days)
Hydrocortisone (250 mg)	1.25–1.5
Cortisone (250 mg)	1.25–1.5
Methylprednisolone (40 mg)	1.25–1.5
Prednisone (50 mg)	1.25–1.5

Prednisolone (50 mg)	1.25–1.5
Triamcinolone (40 mg)	2.25
Dexamethasone (5 mg)	2.75
Betamethasone (6 mg)	3.25

Patients who develop drug-induced adrenocortical insufficiency may require higher corticosteroid dosage when they are subjected to stress (e.g., infection, surgery, or trauma). In addition, acute adrenal insufficiency (even death) may occur if the drugs are withdrawn abruptly or if patients are transferred from systemic glucocorticoid therapy to oral inhalation therapy. Therefore, the drugs should be withdrawn very gradually following long-term therapy with pharmacological dosages. Adrenal suppression may persist up to 12 months in patients who receive large dosages for prolonged periods. Until recovery occurs, patients may show signs and symptoms of adrenal insufficiency when they are subjected to stress, and replacement therapy may be required. Because mineralocorticoid secretion may be impaired, sodium chloride or a mineralocorticoid also should be administered.

Although side effects and toxicities vary with the drug and, sometimes, with the patient, facial mooning, flushing, sweating, acne, thinning of the scalp hair, abdominal distention, and weight gain are observed with most glucocorticoids. Protein depletion (with osteoporosis and spontaneous fractures), myopathy (with weakness of muscles of the thighs, pelvis, and lower back), and aseptic necrosis of the hip and humerus are other side effects. These drugs may cause psychological disturbances, headache, vertigo, and peptic ulcer, and they may suppress growth in children.

Patients with well-controlled diabetes must be closely monitored and their insulin dosage increased if glycosuria or hyperglycemia ensues either during or following glucocorticoid administration. Patients should also be watched for signs of adrenocorticoid insufficiency after discontinuation of glucocorticoid therapy. Individuals with a history of tuberculosis should receive prophylactic doses of antituberculosis drugs.

Osteoporosis is one of the most serious adverse effects of long-term glucocorticoid therapy. Moderate- to high-dose glucocorticoid therapy is associated with loss of bone and an increased risk of fracture that is most rapid during the initial 6 months of therapy. These adverse effects of glucocorticoids appear to be both dose- and duration-dependent, with oral prednisone dosages of 7.5 mg or more daily for 6 months or longer often resulting in clinically important bone loss and increased fracture risk. Bone loss has even been associated with oral inhalation of glucocorticoids and is of great concern in children. Most patients receiving long-term glucocorticoid therapy will develop some degree of bone loss, and more than 25% will develop osteoporotic fractures. Vertebral fractures have been reported in 11% of patients with asthma who are receiving systemic glucocorticoids for at least 1 year, and glucocorticoid-treated patients with rheumatoid arthritis are at increased risk of fractures of the hip, rib, spine, leg, ankle, and foot. Muscle wasting or weakness and atrophy of the protein matrix of the bone resulting in osteoporosis are manifestations of protein catabolism, which may occur during prolonged therapy with glucocorticoids. These adverse effects may be especially serious in debilitated patients, in geriatric populations, and in postmenopausal women who are especially prone to osteoporosis.

To minimize the risk of glucocorticoid-induced bone loss (osteoporosis) and those with low mineral bone density, the smallest possible effective dosage and duration should be used. Topical and inhaled preparations should be used whenever possible. The immunosuppressive effects of glucocorticoids increase the susceptibility to and mask the symptoms of infections and may result in activation of latent infection or exacerbation of intercurrent infections. The most common adverse effect of oral inhalation therapy with glucocorticoids is fungal infections of the mouth, pharynx, and occasionally, the larynx. The mineralocorticoid effects are less frequent with synthetic glucocorticoids (except fludrocortisone) than with hydrocortisone or cortisone but may occur, especially when synthetic glucocorticoids are given in high dosage for prolonged periods.

Case Study

Victoria F. Roche

S. William Zito

VS is a 42-year-old woman who presents at the ambulatory care clinic where you work with complaints of nausea, loss of appetite, and feeling tired all the time. She and her husband are vacationing in Maine, but she has not felt well enough to hike or accompany her husband on fishing excursions for the past 5 days. She has an apparent tan even though she has not been out of the house for several days. She denies fever, night sweats, visual disturbances, or changes in her menstrual cycle. She does admit to several months of nausea, anorexia, and a 15-lb weight loss. Examination and laboratory tests reveal a low blood pressure (97/73 mm Hg) with orthostatic hypotension, hyponatremia (127 mEq/L), low morning hydrocortisone (1.4 µg/dL), and elevated levels of ACTH (2,096 pg/mL), all of which confirm a diagnosis of Addison's disease. The physician feels that the symptoms are not severe enough to require parenteral cortisol and fluid replacement and, therefore, wants to begin oral adrenocorticoid therapy and asks your opinion of the following choices.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 34

Thyroid Function and Thyroid Drugs

Ali R. Banijamali

Introduction

The thyroid gland is a highly vascular, flat structure located at the upper portion of the trachea, just below the larynx. It is composed of two lateral lobes joined by an isthmus across the ventral surface of the trachea. The gland is the source of two fundamentally different types of hormones, thyroxine (T_4) and triiodothyronine (T_3). Both hormones are vital for normal growth and development and control essential functions, such as energy metabolism and protein synthesis.

The word thyroid, meaning shield-shaped, was introduced by Wharton in his description of the gland (1). Like many before him, he attributed a solely cosmetic function to it because of the more frequent presence of enlarged glands in women, giving the throat region a more beautiful roundness. Later, however, it was observed that some characteristic symptoms for diseases always were accompanied by an obvious change in the size of the thyroid. This change was correctly interpreted as evidence that this structure plays a major role in normal body function.

An important step in the understanding of thyroid function was taken by Baumann (2), who discovered that the thyroid gland was the only organ in mammals that had the capability to incorporate iodine into organic substances. That discovery was important in research concerning the phylogeny of the thyroid.

Major clues to the physiological roles of thyroid hormones were provided when normal and abnormal thyroid function were related to oxygen uptake (3) and when thyroid hormones were found to induce metamorphosis in tadpoles (4). The first discovery led to investigations regarding the role of thyroid hormone in metabolism and calorigenesis, and the second inspired research concerning specific receptors as points of initiation of thyroid hormone expression. A patient lacking thyroid hormones may be treated with synthetic hormones or natural preparations. Better agents to treat hyperthyroidism are still being sought. Presently available drugs, other compounds affecting thyroid function, and current approaches in the search for new drugs are presented in this chapter within the context of thyroid biochemistry and physiology.

Normal Biochemistry and Physiology

Thyroid Follicular Cells

All vertebrates have a thyroid gland consisting of functional units, the follicles. The morphological and functional characteristics of the follicles are essentially similar in all vertebrate groups.

The follicle is a spherical, cyst-like structure approximately 300 μm in diameter, and it consists of a luminal cavity surrounded by a one-cell-deep layer of cells called follicular or acinar cells. The center of the follicles is filled with a gelatinous colloid, the main component of which is a glycoprotein called thyroglobulin. The follicular cells contain an extensive network of rough endoplasmic reticulum, a well-developed Golgi apparatus, and lysosomes of various sizes (5). Thyroglobulin is synthesized in the rough endoplasmic reticulum of the follicular cells and transported by way of the Golgi complex to the apical membrane and then secreted into the follicle lumen.

The follicular cell contains two major assembly lines operating in opposite directions (6). One line moves in an apical direction and produces thyroglobulin that is delivered to the follicle lumen; the other line begins at the apical cell surface with endocytosis of thyroglobulin and ends by delivering hormones at the basolateral cell membrane. The follicular cell seems, therefore, to fulfill the functions of secretory and absorptive cells simultaneously. In addition to the functions associated with these two lines, the follicle has the specific ability to metabolize iodine, comprising the accumulation of iodide, iodination of tryosyl residues in thyroglobulin, and coupling of the iodinated tyrosyls to form thyroid hormones.

Parafollicular cells, also called light cells or C cells, are located individually or in clusters between follicular cells but do not border on the colloid. These cells produce

thyrocalcitonin, a peptide hormone involved in calcium homeostasis. The extrafollicular space of the gland is occupied by blood vessels, capillaries, lymphatic vessels, and connective tissue.

Clinical Significance

Differences in the activity profiles of available treatments for thyroid disorders make patient-specific drug selection extremely important. The development of synthetic thyroid hormones has significantly improved treatment of hypothyroidism by decreasing the variations in thyroxine (T_4) and triiodothyronine (T_3) blood levels that often resulted from inconsistent bovine and porcine sources. Once-daily or once-weekly dosing, which has been associated with improved patient compliance, is another clinically significant benefit of synthetic T_4, resulting from its extended half-life. Knowledge of levothyroxine's pharmacokinetic profile also has prompted patient counseling efforts promoting premeal administration because of marked reduction in absorption when combined with meals.

The understanding of structure–activity relationships also enabled the development of synthetic T_3 (liothyronine), the metabolically more active form of thyroid hormone with a much shorter duration of action. This is especially useful for patients with thyroid carcinoma who are to undergo radioiodine imaging and possible treatment. Because of a half-life of only 24 hours, liothyronine substitution enables timelier radioiodine imaging and treatment, and as a result, patients experience less symptomatic hypothyroidism.

The study of medicinal chemistry has improved the treatment of thyroid disorders by reducing variability in plasma concentrations of T_3 and T_4 and by increasing the reliability of available monitoring methods. Accurate monitoring and therapy adjustments have resulted in fewer complications and increased quality of life among the millions of patients with thyroid disorders.

Assistant Clinical Specialist, Northeastern University, Department of Pharmacy Practice, Bouvé College of Health Sciences

Hormones of the Thyroid Gland

Thyroid hormones are iodinated amino acids derived from L-tyrosine. They are synthesized in the thyroid gland and stored as amino acid residues of thyroglobulin. The first known biologically active iodine-containing compound of the thyroid gland was isolated from thyroid extracts by Kendall (7) and named L-thyroxine (T_4). Later, its structure was established by Harington (8) as the 3,5,3′,5′-tetraiodo-L-thyronine (T_4) (Fig. 34.1), and its synthesis was accomplished by Harington and Bargar (9). Twenty-five years later, with the availability of chromatographic techniques and radioactive iodine, researchers discovered another major thyroid hormone, which was identified as 3,5,3′-triiodo-L-thyronine (T_3) (Fig. 34.1). This far more potent hormone is largely synthesized from T_4 by deiodinase enzymes outside the thyroid. The body is therefore able to use a dose of T_4 to produce its own T_3.

The thyroid hormones, T_4 and T_3, play numerous, profound roles in regulating metabolism, growth, and development and in maintaining homeostasis. Their reactions and products influence carbohydrate metabolism, protein synthesis and breakdown, and cardiovascular, renal, and brain function. It generally is believed that these actions result from effects of thyroid hormones on protein synthesis.

The thyroid gland also contains two quantitatively important iodinated amino acids, diiodo-L-tyrosine (DIT) and monoiodo-L-tyrosine (MIT). In addition, there are small amounts of other iodothyronines, such as 3,3′-diiodo-L-thyronine (T_2) and 3,3′,5′-triiodo-L-thyronine (reverse T_3 [rT_3]). None of the latter compounds possesses any significant hormonal activity. Chemically, MIT is 3-iodo-L-tyrosine, and DIT is 3,5-diiodo-L-tyrosine. The coupling of the two outer rings of DIT or of one outer ring of DIT with that of MIT (each with the net loss of

alanine) leads to the formation of the two major thyroid hormones, T_4 and T_3, respectively.

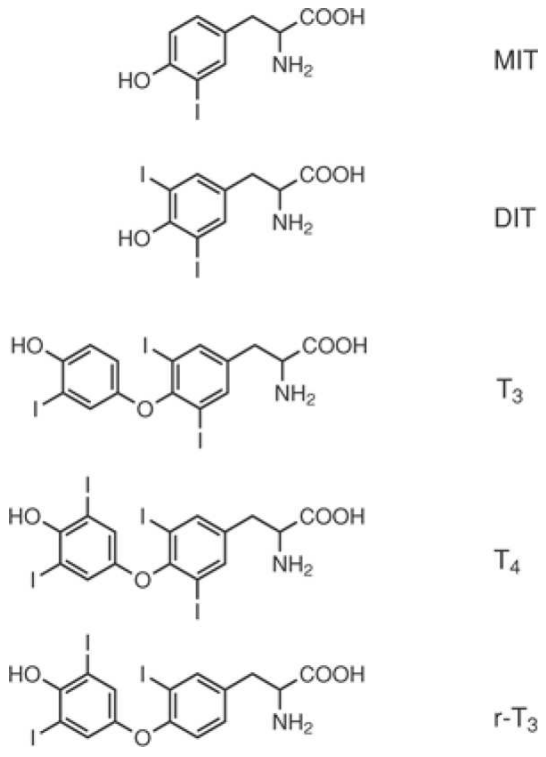

Fig. 34.1. Structure of the iodinated compounds of the thyroid gland.

Thyroglobulin is of special importance, because it serves as the matrix for the synthesis of T_4 and T_3 and as the storage form of the hormones and iodide. Thyroglobulin, a large glycoprotein with a molecular weight of 660,000 Da, accounts for about one-third of the weight of the thyroid gland. Thyroglobulin carries an average of 6 tyrosyl residues as monoiodo-L-tyrosine, 5 residues as diiodo-L-tyrosine, 0.3 residues as T_3, and 1 residue as T_4 (10). From these values, it can be estimated that a 20 g thyroid stores roughly 10 µmol (7.8 mg) of T_4 and 3 µmol (2.0 mg) of T_3 and that the normal human thyroid gland contains enough potential T_4 to maintain a euthyroid state for 2 months without new synthesis (11). The structures of the iodinated compounds of the thyroid gland are shown in Figure 34.1.

Biosynthesis of Thyroid Hormones

The synthesis of the thyroid hormones, T_3 and T_4, is regulated by thyrotropin (thyroid-stimulating hormone [TSH]), which stimulates the synthesis of thyroglobulin, thyroperoxidase (TPO), and hydrogen peroxide. The formation of the thyroid hormones depends on an exogenous supply of iodide. The thyroid gland is unique in that it is the only tissue of the body able to accumulate iodine in large quantities and incorporate it into hormones. Approximately 25% of the body's supply of iodide is located in the thyroid gland. The iodine atoms play a unique role in the conformational preferences for T_3 and T_4 because of their large steric bulkiness. The metabolism of iodine is so closely related to thyroid function that the two must be considered together. The formation of thyroid hormones involves the following complex sequence of events: 1) active uptake of iodide by the follicular cells, 2) oxidation of iodide and formation of iodotyrosyl residues of thyroglobulin, 3) formation of iodothyronines from iodotyrosines, 4) proteolysis of thyroglobulin and release of T_4 and T_3 into blood, and 5) conversion of T_4 to T_3. These processes are summarized in Figure 34.2 (12).

Active Uptake of Iodide by Follicular Cells

The first step in the synthesis of the thyroid hormones is the uptake of iodide from the blood by the thyroid gland. An adequate intake of iodide is essential for the synthesis of sufficient thyroid hormone. Dietary iodine is converted to iodide and almost completely absorbed from the gastrointestinal tract. Blood iodine is present in a steady state in which dietary iodide, iodide “leaked'' from the thyroid gland, and reclaimed hormonal iodide provide the input. Thyroid gland iodide uptake, renal elimination, and a small biliary excretion providing the output. The thyroid gland regulates both the fraction of circulating iodide that it takes up and the amount of iodide that it leaks back into the circulation. A simplified scheme of iodide metabolism is shown in Figure 34.3.

The mechanism enabling the thyroid gland to concentrate blood iodide against a gradient into the follicular cell is the iodide pump (NIS, sodium/iodide symporter), which is regulated by TSH. The NIS, a Na^+-dependent active transporter, is located at the basolateral plasma membrane. The NIS-mediated I^- uptake is coupled to the inward translocation of Na^+. NIS expression is regulated by TSH at the posttranscriptional level. Decreased stores of thyroid iodine enhance iodide uptake; conversely, dietary iodide can reverse this process. The iodide pump maintains about a ratio of thyroid iodide to serum iodide (T:S ratio) of 20:1 under basal conditions but of more than 100:1 in hyperactive gland. The iodide pump also is found in the placenta and mammary tissue to enable the fetal thyroid and the natal thyroid glands to develop properly.

Iodide uptake may be blocked by several inorganic ions, such as thiocyanate and perchlorate. Because iodide uptake involves concurrent uptake of potassium, it also can be blocked by cardiac glycosides that inhibit potassium accumulation.

Oxidation of Iodide and Formation of Iodotyrosines

To serve as an iodinating agent, iodide must be oxidized to a higher oxidation state, a step that is hydrogen peroxide dependent and is catalyzed by TPO, a membrane-bound heme-enzyme that utilizes hydrogen peroxide as the oxidant. In addition to catalyzing the oxidation of iodide, TPO is essential for the incorporation of iodide into tyrosine residues in thyroglobulin (aromatic iodin-ation) and coupling of the iodotyrosyl residues from DIT to form T_4 and T_3. The activity of TPO is increased by TSH from increased synthesis of TPO.

The second step in the synthesis of the thyroid hormones is a concerted reaction at the apical membrane in which the iodide in the follicle lumen is oxidized by TPO in the presence of hydrogen peroxide to an active iodine species that, in turn, iodinates selected tyrosyl residues of thyroglobulin. Consistent with the conditions necessary for aromatic halogenation, the iodination of the tyrosyl residues requires the iodinating species to be in a higher oxidation state compared with the iodide anion. The io-dinating species is thought to be hypoiodate (OI^2) (12). The two-electron oxidation of iodide to its hypoiodate reactive species is accomplished by TPO. Although the diiodotyrosyl residues constitute the major products, some MIT peptides also are produced. TSH stimulates the generation of hydrogen peroxide and, thus, the process of iodination.

Hydrogen peroxide is an essential and limiting factor in the oxidation of iodide, aromatic iodination of tyrosyl residues, and the coupling reaction. The hydrogen peroxide–generating system is localized at the apical membrane, and its generation involves the oxidation of NADPH by an NADPH/FAD oxidase called thyroid oxidase. The reaction product of TPO with hydrogen peroxide is described as TPO-P, a π-cation radical, which generates hypoiodate. The generation of hydrogen peroxide is concentration controlled by iodide, which permits efficient hormone synthesis when iodide is scarce

while avoiding excessive hormone synthesis when iodide is abundant. Deficient generation of hydrogen peroxide has been proposed as one explanation for goiter and decreased aromatic iodination in euthyroid patients. The in vitro addition of a hydrogen peroxide–generating system to thyroid homogenates or slices from these patients restored normal organification.

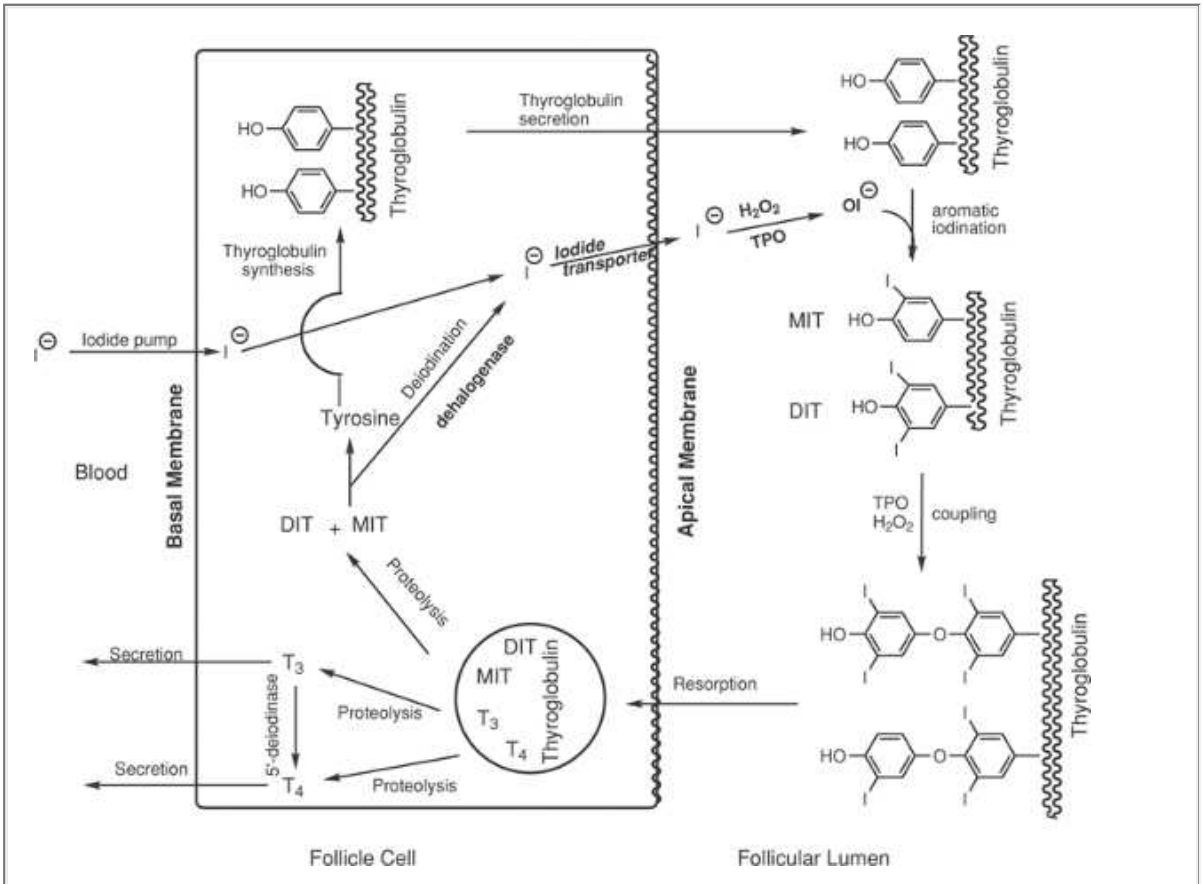

Fig. 34.2. Summary of the major pathways for the biosynthesis and secretion of the thyroid hormones. When thyrotropin (TSH) binds to the TSH receptor at the basal membrane of the follicular cell, the biosynthesis of thyroglobulin (TG) is stimulated, as is that of thyroperoxidase (TPO) and the production of hydrogen peroxide. Noniodinated TG is synthesized by the rough endoplasmic reticulum of the follicular cell and secreted through the apical membrane of the follicular cell into the follicular lumen. Iodide enters the follicular cell by the iodide pump (NIS, sodium iodide symporter) and is then transported into the follicular lumen. In the lumen, the iodide is oxidized by TPO-O (a π-cation radical intermediate formed from TPO and hydrogen peroxide) at the apical membrane to form hypoiodate anion (OI^-), followed by aromatic iodination of selected tyrosyl residues on TG to form diiodotyrosyl (DIT) and monoiodotyrosyl (MIT) residues. The tyrosyl ring of DIT couples with adjacent DIT and MIT residues with an ether linkage to form the outer ring of thyroxine (T_4) and of triiodothyronine (T_3), both of which remain attached to TG. Although shown as a sequential reaction, the iodination and coupling reactions occur simultaneously via TPO and hydrogen peroxide. Hydrogen peroxide is generated by a NADPH/FAD thyroid oxidase (THOX) at the apical membrane. Low plasma levels for T_4 cause the iodinated TG to be resorbed into the follicular cell, where complete proteolysis occurs by lysosomal protease to T_4, T_3, DIT, MIT, and noniodinated amino acids. Both T_4 and T_3 are secreted by the cell into the blood; T_4 is deiodinated to active T_3. Both DIT and MIT are recycled by a dehalogenase (or deiodinase) to free tyrosine and iodide, both of which are recycled back into iodinated thyroglobulin.

In the thyroid follicular cell, intracellular iodide taken up from blood is bound in organic form in a few minutes, so less than 1% of the total iodine of the gland is found as iodide. Therefore, inhibition of the iodide transport system requires blockade of organic binding. This can be achieved by the use of antithyroid drugs, of which n-propyl-6-thiouracil and 1-methyl-2-mercaptoimidazole (methimazole) are the most potent.

Coupling of Iodotyrosine Residues

Coupling is also catalyzed by TPO at the apical membrane, and although shown in Figure 34.2 as sequential steps, they occur simultaneously. This coupling reaction takes place at thyroglobulin and involves the coupling of the two outer rings from DIT residues to become T_4, whereas the coupling of the outer ring from MIT with DIT results in the formation of T_3. During the coupling

reaction as shown in Figure 34.2, a tyrosyl residue donates its iodinated phenyl group as a DIT radical to become the outer ring of the iodothyronine amino acid at an acceptor site, leaving dehydroalanine at the donor site. The location of the iodotyrosyl residues within thyroglobulin creates an optimal spatial alignment, facilitating the coupling reaction. These reactions are catalyzed by TPO and can be blocked by compounds such as thiourea, thiouracils, and sulfonamides.

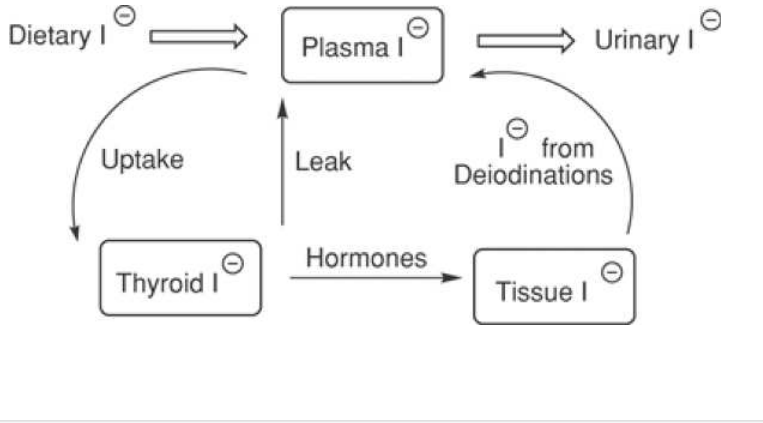

Fig. 34.3. Simplified scheme of iodide metabolism.

Proteolysis of Thyroglobulin and Release of Iodothyronines

In response to demand for thyroid hormones, the release of thyroid hormones from thyroglobulin begins with the resorption of thyroglobulin via endocytosis into the follicular epithelial cells and its subsequent complete proteolysis by the lysosomal digestive enzymes of the follicular cells. Thyroglobulin proteolysis yields MIT, DIT, T_3, and T_4. Although MIT and DIT are formed, they do not leave the thyroid but, instead, are selectively deiodinated to tyrosine and recycled into new thyroglobulin. The iodide is recycled into hypoiodate for subsequent iodination, conserving the essential nutrients for the thyroid gland. Both T_3 and T_4 are secreted by the cell into the circulation. A defect in the recyclization of MIT and DIT can lead to hypothyroidism and goiter by increasing their elimination in the urine.

Conversion of Thyroxine to Triiodothyronine

Although T_4 is by far the major thyroid hormone secreted by the thyroid (~8 to 10 times the rate of T_3), it usually is considered to be a prohormone. Because T_4 has a longer half-life, much higher levels of T_4 than of T_3 are in the circulation. The enzymatic conversion of T_4 to T_3 is an obligate step in the physiological action of thyroid hormones in most extrathyroidal tissues. In the peripheral tissues, approximately 33% of the T_4 secreted undergoes 5′-deiodination to give T_3, and another 40% undergoes deiodination of the inner ring to yield the inactive material rT_3 (13). The deiodination of T_4 is a reductive process catalyzed by a group of enzymes named iodothyronine deiodinases, referred to as deiodinases and symbolized by D, found in a variety of cells. Approximately 80% of the T_3 is derived from circulating T_4.

Three types of deiodinases are currently known, and these are distinguished from each other primarily based on their location, substrate preference, and susceptibility to inhibitors. Type I deiodinase is found in liver and kidney and catalyzes both inner ring and outer ring deiodination (i.e., T_4 to T_3 and rT_3 to 3,3′-T_2). Type II deiodinase catalyzes mainly outer ring deiodination (i.e., T_4 to T_3 and T_3 to 3,3′-T_2) and is found in brain and the pituitary. Type III deiodinase is the principal source of rT_3 and is present in brain, skin, and placenta (14).

Transport of Thyroid Hormones in Blood

The iodothyronines secreted by the thyroid gland into thyroid vein blood are of limited solubility. They equilibrate rapidly, however, through noncovalent association with three major binding proteins: thyroid binding globulin (TBG), transthyretin (TTR; formerly called T_4 binding prealbumin), and albumin. Thyroid

binding globulin is the primary serum binding protein because of its higher affinity for T_4. Under normal conditions, 75% of T_4 is bound to TBG, 10 to 15% to TTR, and 5 to 15% to albumin. When bound, T_4 is not physiologically active but does provide a storage pool of thyroid hormone, which can last 2 to 3 months (mean half-life of T_4, 6.7 days in adults). The plasma proteins involved in thyroid hormone transport and their approximate association constants (K_a) for T_3 and T_4 are shown in Table 34.1. This table indicates that TBG has a high affinity for T_4 ($K_a \sim 10^{10}$ M) and lower affinity for T_3. Additionally, TTR and albumin transport thyroid hormones in the blood; TTR has K_a values of approximately 10^7 and 10^6 M for T_4 and T_3, respectively. The equilibrium between the free hormone and that protein bound hormone determines the accessibility of the free thyroid hormone for the tissue receptors as well as to peripheral sites, where biotransformations take place. The lower binding affinity for T_3 to plasma proteins may be an important factor in the more rapid onset of action and the shorter biological half-life for T_3.

Thyroid hormones are taken into cells by facilitated diffusion or by active transport secondary to a sodium gradient (11). Once in the cell, thyroid hormones bind to cytosolic binding proteins and are not readily available for exchange with plasma hormones. Both T_3 and T_4 are not evenly distributed in body cells: A great part of T_4 is

stored in liver and kidney, whereas most T_3 appears in muscle and brain (11).

Table 34.1. Plasma Proteins Involved in Thyroid Hormone Transport

		Binding of T_4		Binding of T_3	
Protein	**Concentr. (mg/dL)**	**K_a**	**% Bound**	**K_a**	**% Bound**
TBG	1.5	10^{10}	75	10^9	70
TTR	25	10^7	15	10^6	
Albumin	4,000	10^6	10	10^5	30

K_a, approximate association constant; TBG, tyroxine-binding globulin; TTR, transthyretin.

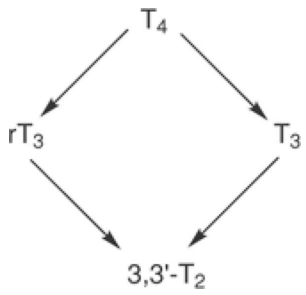

Fig. 34.4. Deiodination of thyroxine (T_4).

Metabolism and Excretion

As discussed earlier, T_4 is considered to be a prohormone, and its peripheral metabolism occurs in two ways: outer ring deiodination by the enzyme 5′-D, which yields T_3, and inner ring deiodination by the enzyme 5-D, which yields rT_3, for which there is no known biological function (Fig. 34.4). In humans, deiodination is the most important metabolic pathway of the hormone, not only because of its dual role in

the activation and inactivation of T_4 but also in quantitative terms.

Degradative metabolism of the thyroid hormones, apart from peripheral deiodination, occurs mainly in the liver, where both T_3 and T_4 are conjugated to form either glucuronide (mainly T_4) or sulfate (mainly T_3) with the phenolic hydroxyl group. The resulting iodothyronine conjugates are excreted via the bile into the intestine, where a portion is hydrolyzed by bacteria. The conjugates also undergo marginal enterohepatic circulation and are excreted unconjugated in feces.

T_4 is conjugated with sulfate in kidney and liver, and T_4-4′-O-sulfate, an excellent substrate for 5′-D (15), is believed to play a role in the regulation of T_4 metabolism.

Additional metabolism, involving side-chain degradation, proceeds by transamination, oxidative deamination, and decarboxylation to yield thyroacetic acid and thyroethanediol; cleavage of the diphenyl ether linkage has been detected as well, both in vitro and in vivo. The reactions through which thyroid hormone is metabolized are summarized in Figure 34.5.

Physiological Actions of Thyroid Hormones—Oxygen Consumption and Calorigenesis

The two most important actions of thyroid hormone are those related to oxygen consumption and those related to protein synthesis. Most effects of thyroid hormones can be related to the activation of genes following the binding of the hormone to high-affinity receptors of cell nuclei, but direct interactions of thyroid hormones with other cellular receptors cannot be excluded (16).

A respiratory component of the action of thyroid hormones was first observed almost a century ago. Respiratory exchange was depressed in patients diagnosed as hypothyroid and increased in patients diagnosed as hyperthyroid (3). The increase in respiration that follows the administration of thyroid hormone reflects an increase in metabolic rate thyroid function has, indeed, long been assessed by measuring the basal or resting metabolic rate (BMR), a test in which the oxygen consumed, as measured in an individual at rest, is used to calculate total body energy production. The BMR of a hyperthyroid individual is above the normal range, or positive, and that of a hypothyroid individual below the normal range, or negative.

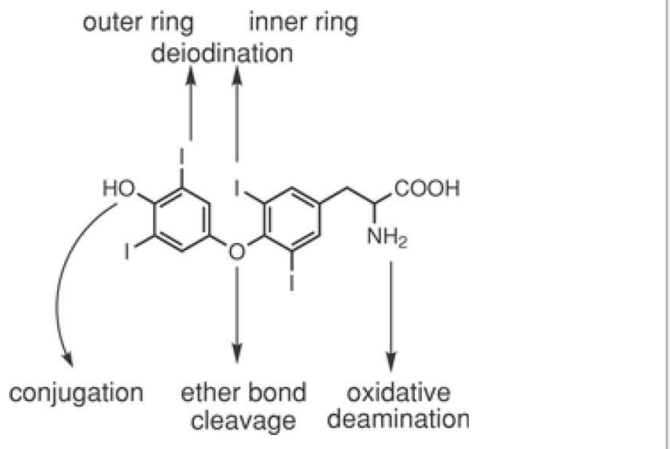

Fig. 34.5. Metabolic pathways for thyroxine.

Thyroid hormones increase the oxygen consumption of most isolated tissues but not of isolated adult brain. This suggests that the behavioral changes seen in abnormal thyroid states (anxiety and nervousness in hyperthyroidism and impaired memory in hypothyroidism) in the adult are not directly linked to overall changes in brain oxygen consumption.

Because most of the energy produced by cellular respiration eventually appears as heat, an increase in cellular respiration necessarily leads to an increase in heat production (i.e., to a thermogenic or calorigenic effect). Thus, to the degree that thyroid hormones control BMR, they also control thermogenesis (17).

Clinically the inability to adjust to environmental temperature is symptomatic of departure from the euthyroid status. Patients with myxedema frequently have subnormal body temperature, have cold and dry skin, and tolerate cold poorly; the thyrotoxic patient, who compensates for excess heat production by sweating (warm, moist hands), does not easily tolerate a warm environment.

Thyroid hormones regulate the turnover of carbohydrates, lipids, and proteins. They promote glucose absorption, hepatic and renal gluconeogenesis, hepatic glycogenolysis, and glucose utilization in muscle and adipose tissue (18). They increase de novo cholesterol synthesis but increase low-density lipoprotein degradation and cholesterol disposal even more, leading to a net decrease in total and in low-density lipoprotein cholesterol plasma levels (19). Thyroid hormones are anabolic when present at normal concentrations; they then stimulate the expression of many key enzymes of metabolism.

Thyroid hormones at the levels present in hyperthyroidism are catabolic; they lead to the mobilization of tissue protein and, especially, of muscle tissue protein for gluconeogenetic processes (20). Thus, the depletion of liver glycogen, the increased breakdown of lipids, and the negative nitrogen balance observed in hyperthyroidism represent toxic effects. The metabolic processes of hypermetabolism are wasteful. In hyperthyroidism, a smaller-than-normal amount of liberated energy is available for useful work, and an excessive amount is wasted as heat.

Because of the role of mitochondria in cellular respiration and energy production, efforts to elucidate the mechanism of thyroid hormone action in metabolism and calorigenesis have focused on mitochondrial studies. Thyroid hormones in vitro are known to uncouple oxidative phosphorylation in isolated mitochondria, but these effects occur at unphysiological doses of T_4. In physiological concentrations, T_4 increases adenosine triphosphate (ATP) formation and the number and inner membrane surface area of mitochondria (21), but T_4 does not reduce the efficiency of oxidative phosphorylation. Furthermore, 2,4-dinitrophenol, a classic uncoupler of oxidative phosphorylation, can neither relieve hypothyroidism nor duplicate other physiological effects of thyroid hormones.

Because in most physiological circumstances oxygen consumption is controlled by energy metabolism, Ismail-Beigi and Edelman (22) proposed that the primary effect of thyroid hormones is to increase the amount of energy expended in translocating cations across cell membranes, probably as a response to an increased passive leak of sodium into, and potassium out of, cells. The extent to which this transport contributes to heat production and ATP utilization is uncertain. The stimulation of futile cycles by thyroid hormones (23) has been suggested to be an additional component of ATP disposal.

The effectiveness of β-blocking agents in treating the symptoms of thyrotoxicosis has led to investigations that have indicated thyroid hormones modulate adrenergic effects by increasing the number of β-adrenergic receptors (24) and, at least in cardiac tissue (25), by increasing the adrenergic receptors that are coupled with a membrane- bound adenylate cyclase (also known as adenyl cyclase) (26); both observations appear to be mutually consistent. The role of thyroid hormones in adaptive thermogenesis (17) could be affected by stimulating an increase in brown adipose tissue β-adrenergic receptors; catecholamines, which are known to activate the β receptor-linked adenylate cyclase in that tissue (23), would then start the lipolysis cascade resulting in heat production.

Differentiation and Protein Synthesis

Stimulation of amphibian metamorphosis by thyroid hormones has been known for a long time (4). Changes in amphibian morphogenesis, such as involution of the tail of *Xenopus* (toads) and metamorphosis of the axolotl (salamanders) and of *Rana* (frogs), have been repeatedly used as end points for the bioassay of thyroid analogues. In young mammals, thyroid hormone is necessary not only for general growth but also for proper differentiation of the central nervous system. The counterpart of amphibian metamorphosis in the developing mammalian brain is myelogenesis and the formation of axons and dendrites (27). Behavioral studies in neonate hypothyroid mammals show that impairment in learning capacity (27) paralleled impairment of proper anatomic development in the brain. A deficiency of thyroid hormone during the critical period when the developing human brain is sensitive to thyroid hormone results in an irreversible clinical entity termed cretinism, which is characterized by stunted growth and mental retardation.

A great deal of attention has been devoted to the events taking place in the roughly 48-hour interval between the administration of thyroid hormone and the manifestation of certain effects caused by that administration. After Tata (28) had observed that the anabolic effects observed in rats given T_4 could be blocked by inhibitors of protein synthesis, further investigations led Tata and Widnell (29) to the conclusion that thyroid hormones were activating protein synthesis at the ribosomal level. Subsequently, Dillmann et al. (30) showed that the T_3-induced formation of α-glycerophosphate dehydrogenase (E.C. 1.1.99.5) could be blocked by α-amanitin, an inhibitor of RNA polymerase II, inferring that thyroid hormones affected the transcription process. In 1972, when the partition of thyroid hormones between plasma and a number of tissues was investigated, Schadlow et al. (31) demonstrated that the uptake of T_3 by unfractionated pituitary tissue was inverse to the dose, suggesting that the pituitary was limited in its capacity to bind T_3. This finding prompted efforts to find the subcellular location of the binding sites and to search for the presence of specific binding sites in other tissues (32). The research revealed that the binding sites were located in cell nuclei and were also present in liver and kidney (32). Eventually, receptors were located in

all mammalian tissues and also in tadpole erythrocytes (33). In cultured pituitary cells, the receptor was described as an acidic, nonhistone, 50,000-Da protein (34) with an equilibrium dissociation (K_d) constant of 2.9×10^{-11} for T_3 and of 2.6×10^{-10} for T_4, indicating that T_3 had a 10 times greater affinity than T_4 for the receptor. There were 6,000 nuclear binding sites in the pituitary, 4,000 in the liver, but only 16 in the testis, a tissue that is not responsive to thyroid hormone (35). The findings by Tata and Widnell (29) of the activation of one RNA polymerase were extended to all RNA polymerases, suggesting that thyroid hormones were involved in all phases of gene activation.

Receptors located on the plasma membrane, in the cytoplasm, and in mitochondria have been described as well (36). Plasma membrane receptors are believed to mediate the transport of hormone into the cell and, possibly, to mediate nonnuclear, immediate effects of thyroid hormone (36). The presence of a large number of low-affinity cytosol binding proteins has been known for

some time (37), but these proteins have not been assigned a specific physiological role. The cytosolic binding proteins have been proposed as a large intracellular thyroid hormone reservoir, delaying the metabolic disposition of thyroid hormone.

Because thyroid hormones immediately increase oxygen uptake and ATP formation and, eventually, lead to an increase in the number, size, and inner membrane surface area of mitochondria as well as to the induction of many mitochondrial enzymes, many efforts to characterize mitochondrial thyroid hormone receptors have been made. Sterling et al. (38) have reported the presence of very high affinity receptors in mitochondria, but their work has not been duplicated. Additionally, many authors believe that most mitochondrial enzymes are synthesized on cytoplasmic ribosomes and then transferred into mitochondria (39).

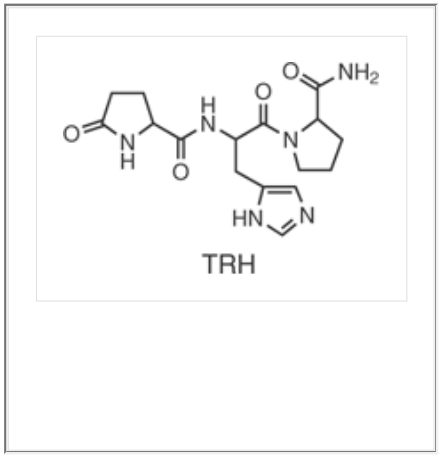
Control of Thyroid Hormone Biosynthesis

The primary role of thyroid is to produce thyroid hormones. The primary regulator of thyroid, both its function and growth, is the pituitary hormone, thyrotropin (TSH). Thyrotropin is a glycoprotein with a molecular weight of approximately 28,000 daltons, which can dissociate into two equally large polypeptide chains: an α-chain, which is also present in other pituitary peptides, and a β-chain, which is present in TSH only. The TSH is produced by and released from the anterior pituitary gland, causing the thyroid hormone to initiate new thyroid hormone synthesis. Increases in iodide uptake, the iodination of thyroglobulin, and endocytosis of colloid are all observed in response to stimulation of TSH. The effects of TSH on the thyroid appear to be the consequence of binding to high-affinity receptors on the capillary membrane of follicular cells and activation of adenylate cyclase and protein kinase enzymes, found on the inner side of the membrane, with subsequent phosphorylation of cellular proteins. It is believed that most, if not all, effects of TSH are mediated through the cyclic adenosine monophosphate (cAMP) formed by adenylate cyclase and, possibly, also by cAMP-activated intracellular phosphokinases.

The amount of thyroid hormone circulating in body fluids and present in tissues remains fairly constant. Accounting for this constancy are the relatively long biological half-life of the thyroid hormones, the regulation of gland activity by the pituitary-hypothalamic system, and the availability of iodide. Thyroid hormone research points toward T_3 as the thyroid hormone; therefore, factors affecting peripheral T_3 formation by the 5′-D enzymes are highly relevant.

The relation of biological half-life to protein binding has already been alluded to. The T_4 is firmly bound to plasma proteins. Only 0.05% of T_4 is not protein bound, and T_4 has a biological half-life of 1 week, as compared to 1 day for the less firmly bound T_3.

The biosynthesis and secretion of TSH is, in turn, regulated by thyrotropin-releasing hormone (TRH) and the quantity of thyroid hormone in circulation through feedback control. The tripeptide pyroglutamylhistidylprolylamide, TRH is formed in the hypothalamus, reaches the thyrotrophs (i.e., the TSH-producing pituitary cells) by way of the hypophyseal portal system, and stimulates TSH release by binding to the TRH receptors of the thyrotrophs (40). The ability of thyroid hormones to prevent the release of TSH is referred to as feedback regulation. It is believed that T_3 prevents the TRH-stimulated release of TSH by stimulating the synthesis of a peptide that would compete with TRH for the TRH receptor sites on the thyrotroph (41). Inhibition of the transcription of the α and β subunits of TSH by thyroid hormone (42) also may contribute to the feedback effect.



The amount of iodide available to the gland for hormone synthesis also is an important regulator of thyroid function. The efficiency of the thyroid pump mechanism and the rate of thyroglobulin and TPO synthesis are all TSH-dependent. In cases of iodide deficiency, the production of thyroid hormone is lowered, and TSH rises through the pituitary feedback mechanism described previously. The effect of the increased TSH is to produce more thyroid hormone by increasing efficiency of the iodide pump and increasing thyroglobulin and TPO synthesis. Thus, in iodide deficiency, there is an increased uptake of iodide (43) are larger MIT-to-DIT ratios, which leads to larger T_3-to-T_4 ratio. The T_3 is the more rapidly acting hormone, mitigating the effect of iodide deficiency. When iodide deficiency is severe, a persistent rise in TSH is observed. This then results in thyroid growth.

In the presence of an excess of circulating iodide, the absolute amount of iodide taken up remains approximately constant. There is a decrease in the fraction of the total iodide taken up and an increase in the amount of iodide leaked from the thyroid gland. In addition, there may be a decrease in organification (i.e., in the formation of iodinated thyroglobulin residues) and in the release of hormones from the gland. The decrease in organification that occurs at excessive physiological doses of iodide has been called the Wolff-Chaikoff block (44). This block may be caused by an interaction of iodide with NADPH (45), which depletes follicular NADPH and, in turn, depletes the H_2O_2 necessary for TPO activity. The decrease in hormone release occurs when iodide is given in pharmacological (mg) quantities; it may last for a few weeks.

The activity of deiodinases reflects thyroid status, general health, and food intake. In hypothyroidism, there is a decrease in hepatic 5′ D-I but an increase in 5′ D-II activity (46). There is a decrease in T_3 and an increase in rT_3 after hepatic disease (47), renal damage (48), chronic

illness (49), and starvation (50), indicating a decrease in the activity of the quantitatively more important 5′ D-I. An increase in deiodinase activity has been observed after overfeeding subjects or after administering a high-carbohydrate or high-fat diet (51) to experimental animals. The mechanism of deiodinase control is presumably intricate, but the inhibiting effects of propranolol on 5′ D-I (52) and of prazosin on the 5′ D-II of BAT (53) infer the involvement of adrenergic components in the regulation. In addition, the rapid change in activity observed after asphyxia points toward a rapid, possibly cAMP-related control (54).

Diseases Involving the Thyroid Gland

Hypothyroidism

Goiter

An enlarged, palpable thyroid gland is referred to as a goiter. When insufficient thyroid hormone is liberated from the thyroid gland, the breakdown of the thyroid-pituitary-hypothalamic feedback mechanism results in the release of excess TSH and in the formation of a thyroid hypertrophy referred to as a nontoxic goiter. The gland enlarges as it tries to take up more iodine, leading to goiter. Endemic goiters are those that occur in a significant segment of a given population. Goiters most frequently are caused by inadequate intake of dietary iodide in regions not reached by iodide-providing sea mists and, occasionally, by the prolonged intake of goitrogens derived from plant sources or aquifers. This condition can be prevented with iodine supplements, and many industrialized countries now iodize salt.

A characteristic sign of hypothyroidism is a decrease in metabolic rate, with a reduction in calorigenic effect and defective thermoregulation. The elevated serum cholesterol level seen in hypothyroidism is the result of a decrease in cholesterol degradation that exceeds the decrease in cholesterol biosynthesis; it reflects a

general slowdown in catabolic processes. Shared symptoms of hypothyroidism and cognitive disorders include fatigue, mental dullness, lethargy, and inattention. Treatment of hypothyroidism includes supplementation of T_4 with the goal of returning TSH levels to normal.

Cretinism

Cretinism, the irreversible clinical entity characterized by defective physical and mental development, appears when thyroid hormone is not available during early childhood for normal bone formation and normal brain growth and differentiation.

Myxedema

Myxedema is used either as a specific term to describe the infiltration of the intercellular spaces of skin and muscle with mucopolysaccharide or as a general term, as in adult myxedema or pituitary myxedema, to denote hypothyroid status.

Hyperthyroidism

The increased metabolic rate of hyperthyroidism results in symptoms opposite to those seen in hypothyroidism. The increased oxygen demand in hyperthyroidism leads to an increased heart rate and increased cardiac output and, thereby, places strain on the heart. Exaggerated catabolic processes lead to decreased serum cholesterol and, possibly, to poor glucose tolerance and glucosuria as well, and the excessive calorigenic effect produced by catabolic processes causes anorexia and poor thermoregulation. Excessive hormone function is expressed by the word “toxic,” as in toxic goiter, toxic adenoma, and thyrotoxicosis. Thyrotoxic crisis or thyroid storm is an emergency caused by a stress-triggered augmentation of the symptoms of thyrotoxicosis (55). Treatment models aim to decrease the overproduction of thyroid hormones using antithyroid medication or radioactive iodine ablation or surgery.

Graves' Disease

Graves' disease is the most frequently encountered form of hyperthyroidism and is caused by a generalized overactivity of the entire thyroid gland. Named after the physician who first described it, Graves' disease is an autoimmune condition in which the body's immune system tricks the thyroid into producing too much thyroid hormone. It is also called diffuse toxic goiter: “diffuse” because the entire thyroid gland is involved in the disease process; “toxic” because the patient appears hot and flushed, as if feverish due to an infection; and “goiter” because the thyroid gland enlarges in this condition. Signs of this disease may include goiter, a protrusion of the eyeballs called exophthalmos, and pretibial myxedema. Hyperthyroidism from Graves' disease is, in general, easily controlled and safely treated.

In the serum of most patients suffering from Graves' disease, an immunoglobulin (IgC) is present that, after a slow onset, elicits a long-lasting stimulation of the thyroid gland. Because the release of the long-acting thyroid stimulator is not controlled by thyroid hormone levels as is TSH, patients with long-acting thyroid stimulator have a hyperplastic, hypertrophied gland that produces and releases an excessive amount of hormone.

The indications are that the exophthalmos is caused by a substance produced by a distinct autoimmune system (56), possibly in response to a modified TSH of pituitary origin.

Hashimoto's Disease

Hashimoto's disease, named after the physician who first described it, is an autoimmune disorder in which plasma cells, lymphocytes, and fibrous tissue attack and destroy the thyroid gland. Pitt-Rivers and Tata (57) suggested that the sequence of events in Hashimoto's disease was initiated by injury to some thyroid structure, following which the normally sequestered thyroglobulin would be released and exposed to immunological mechanisms, thus setting into motion a progressive interaction between

thyroglobulin and circulating autoantibodies. Hashimoto antibodies are present in adult-onset myxedema and in most persons with Graves' disease, but it is recognized that other antigenic factors are involved in these and other autoimmune diseases of the thyroid. Hypothyroidism resulting from Hashimoto's disease requires lifelong treatment with thyroid hormone replacement.

Generalized Resistance to Thyroid Hormone

Generalized resistance to thyroid hormone (GRTH) is a rare form of thyroid disorder and may be a heritable disorder characterized by reduced responsiveness of the pituitary and peripheral tissues to the action of thyroid hormones. Behavioral manifestations include hyperactivity, behavioral problems, and cognitive

deficits. Physical traits representative of GRTH are small goiters, and GRTH is marked by genetic mutation of the thyroid receptor β gene on chromosome 3 (58).

Many have evaluated the association of GRTH to attention-deficit hyperactivity disorder and suggested that similar mechanistic pathways are shared between the two conditions (59,60). In GRTH, T_4 fails to block TSH production, leading to excess levels of T_3 and T_4 with either normal or elevated levels of TSH. In conditions of an improperly functioning thyroid, TH and TSH ratios are unregulated, producing symptoms that are characteristic of attention-deficit hyperactivity disorder.

Thyroid Cancer

Thyroid cancer is a disease in which malignant cells are found in the tissues of the thyroid gland. Four main types of cancer of the thyroid are differentiated based on how the cancer cells look under a microscope: papillary, follicular, medullary, and anaplastic. Follicular and papillary carcinomas have the highest incidence in young women but have low mortality; they represent a different disease than anaplastic types or undifferentiated carcinomas, both of which occur among the older patients and have high death rates. Each year in the United States, approximately 20,000 people are diagnosed with thyroid cancer, and it is more common in women than in men. A study published in Journal of National Cancer Institute (61) predicts that these numbers may rise as individuals who were exposed to radioactive iodine (^{131}I) from nuclear testing in the western states in the 1950s and 1960s reach middle age: A strong dose–response relationship was observed between radiation dose to the thyroid received in childhood and thyroid cancer risk. The risk of radiation-related thyroid cancer was threefold higher in iodine-deficient areas than elsewhere. Administration of potassium iodide as a dietary supplement appear to modify this risk. Treatment of thyroid cancer is straightforward and effective. Follow-up testing can be uncomfortable, however, because it requires a hypothyroid state. Follow-up takes two forms: serum thyroglobulin measurement, and a radioiodine whole-body scan, as described later.

Therapeutic Agents

Thyroid Replacement Therapy

Hormone replacement appears to be the established therapy in the treatment of various forms of hypothyroidism, from the complete absence of thyroid function seen in myxedema to simple goiter and cretinism. Thyroid hormone drugs are natural or synthetic preparations containing T_4 sodium, T_3 sodium, or both. A large number of organic and some inorganic compounds stimulate or prevent thyroid hormone formation by interfering with iodide uptake into follicular cells, inhibiting TPO, preventing thyroid hormone binding to plasma proteins, or acting as effectors of thyroid deiodinases. Some of the agents described in this section are of therapeutic or diagnostic value, some illustrate potential side effects of drugs, and some are experimental compounds designed to achieve unmet therapeutic goals or to define structural parameters necessary for thyroid hormone actions.

Thyroid hormone preparations belong to two categories: natural hormone preparations derived from animal thyroid, and synthetic preparations.

Natural Thyroid Hormone Preparations

Natural preparations include desiccated thyroid and thyroglobulin. Desiccated thyroid and thyroglobulin are derived from thyroid glands of domesticated animals that are used for food by human. The hormones were released from the proteolytic activity of gut enzymes. Potency is based on total iodine content or bioassay and is somewhat variable with different preparations.

Desiccated thyroid preparations (Thyroid USP) are essentially acetone powders of bovine or porcine thyroid glands compressed into oral tablets. A diluent usually is present, because the preparations (especially those of porcine origin) commonly exceed the 0.17 to 0.23% iodine content required by the U.S. Pharmacopeia (USP). Because the iodine of desiccated thyroid is in the form of iodinated tyrosyl and thyronyl residues of the precipitated thyroglobulin, the preparation owes its efficacy to the hormones that eventually are liberated by intestinal proteases. In desiccated preparations, T_3 and T_4 may be present in a ratio of approximately the same as found in humans. Desiccated preparations are less expensive than synthetic hormones but have been shown to produce variable T_4/T_3 blood levels because of inconsistencies both between and within animal sources of the thyroid gland. Most comments regarding desiccated thyroid also apply to partially purified thyroglobulin, because the two preparations differ in their total and their relative amounts of T_4 and T_3.

Synthetic Thyroid Hormones

Synthetic, crystalline thyroid hormones are more uniformly absorbed than biological preparations and

contain more precisely measured amounts of active ingredient in their dosage forms. Of present interest are T_4 (levothyroxine), T_3 (liothyronine), dT_4 (dextrothyroxine), and T_4-T_3 mixtures (Liotrix).

Levothyroxine

Because of its firmer binding to carrier proteins, synthetic crystalline L-T_4 sodium salt (levothyroxine sodium, Synthtoid, Euthyrox) has a slower onset of action than crystalline T_3 or a desiccated thyroid preparation. Its administration leads to a greater increase in serum T_4 but a lesser increase in serum T_3 than compared with Thyroid USP (62). The availability of 11 different tablet strengths, ranging from 25 to 300 µg, allows individual dosing.

Liothyronine

Crystalline T_3 (liothyronine sodium, Cytomel) has a rapid onset and short duration of action. It is the therapy of choice when it is desirable to have rapid onset or cessation of activity, such as in patients with heart disease.

Liotrix

A mixture of the sodium salts of T_4 and T_3 in a 4:1 ratio by weight is distributed as liotrix.

Dextrothyroxine

Dextrothyroxine, the synthetic D-(+)-stereoisomer isomer of L-(–)-T_4, was introduced in hypocholesteremic-hypolipidemic therapy with the premise that it would be void of calorigenic effects. The possibility of trace contamination with and metabolic conversion to T_4 and congeners has restricted its use, however, especially in patients with coronary heart disease.

Thyroid Imaging A gents

Radioiodine

All isotopes of iodine are rapidly taken up in thyroid follicles. So far, only the isotopes ^{131}I and ^{125}I have been used consistently. The isotope ^{131}I, which decays to ^{131}Xe mainly with the emission of 0.6 meV β-particle and approximately 0.3 meV γ-rays, has a half-life of 8 days. The isotope ^{125}I, with a half-life of 60 days, decays to ^{125}Te by electron capture. The major component of its decay is a 27 keV x-rays, and the minor component is a 35.5 keV γ-ray.

The γ-radiation emitted by ^{131}I can be detected by a suitably placed scintillation crystal. This is the basis for the diagnostic use of this isotope in iodine uptake and in thyroid-scanning procedures.

The absorption of ^{131}I β-radiation, which leads to the highly localized destruction of the thyroid follicles in which the isotope is taken up, has promoted radioiodine as a therapeutic alternative to surgical removal of the gland. Advantages of radioiodine therapy over surgery include the simplicity of the procedure, its applicability to patients who are poor surgical risks, and the avoidance of surgical complications, such as hypoparathyroidism. The development of late hypothyroidism (63) and the fear of chromosomal damage are arguments against the use of radioiodine in patients under 20 years of age and during pregnancy.

A review of the use of ^{125}I in thyrotoxicosis has indicated that the potential advantages of the ^{125}I isotope, which are based on its lower penetrability and more localized action, have not been realized in practice (64).

Radioiodine whole-body scan and serum thyroglobulin measurement commonly are used as the follow-up testing in patients with thyroid cancer. Both follow-up tests have limitations and are uncomfortable, because they require a hypothyroid state. For thyroid cells to take up the labeled iodine, thyrotropin must be available, and for the pituitary to supply it, the body must be free of T_3 and T_4. This means that patients must completely stop taking medication for several weeks before the scan day. This results in a severe hypothyroidism, and approximately 25% of patients also produce antibodies against thyroglobulin, rendering the immunoassay useless. To make the follow-up tests easier, the U.S. Food and Drug Administration recently approved the use of Thyrogen (thyrotropin alfa for injection), a recombinant human thyrotropin produced in Chinese hamster ovary cells. Thyrogen has been shown to significantly enhance the sensitivity of thyroglobulin testing in patients maintained on thyroid hormone therapy, and it allows patients with thyroid cancer to avoid the debilitating effects of hypothyroidism when undergoing radioiodine imaging scans.

Perchlorate and Pertechnetate

The ability of large anions to be taken up into the thyroid by way of the iodide pump is linearly related to their molar volume (65). The affinity of iodide for the iodide pump was equal to that of thiocyanate but much smaller than that of the larger perchlorate and pertechnetate ions.

In contrast to iodide and SCN^2, TcO_4^2 and ClO_4^2 do not undergo intrathyroidal metabolism after they are trapped. This property has made TcO_4^2 labeled with the short-lived technetium-99m a widely used radioisotope for thyroid trapping and for thyroid imaging.

Perchlorate, which competitively inhibits the uptake of iodide, has been used in both diagnosis and treatment of thyroid disease. In continental Europe, perchlorate has been used for surgical preparation and in the long-term treatment of thyrotoxicosis. In the United States, the use of perchlorate was drastically curtailed after aplastic anemia and severe renal damage were reported following its use.

Diagnostically, perchlorate is used to assess the intrathyroidal organification of iodine. When perchlorate is administered after a dose of radioactive iodine, perchlorate washes out or discharges intrathyroidal inorganic iodide but does not affect covalently bound organic iodide. When organification is inadequate, there is a sharp decrease in intrathyroidal radioactive iodine after perchlorate administration.

Antithyroid Drugs for the Treatment of Hyperthyroidism

Iodide

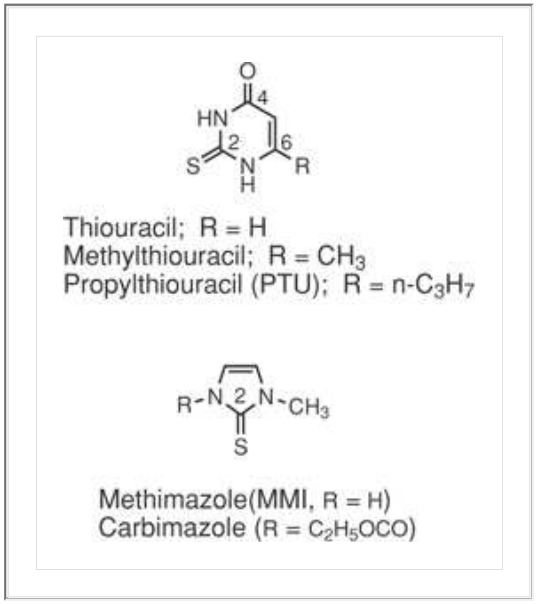
Inhibition of the release of thyroid hormone by iodide is the basis for its use in hyperthyroidism. Iodide decreases the vascularity of the enlarged thyroid gland and also lowers the elevated BMR. It also has been suggested that excess iodide might change the conformation of thyroglobulin, making the protein less susceptible to thyroidal proteolysis (66).

With the use of antithyroid drugs, the role of iodide in hyperthyroidism has been relegated to that of preparation for thyroid surgery. Iodide, as Lugol's solution

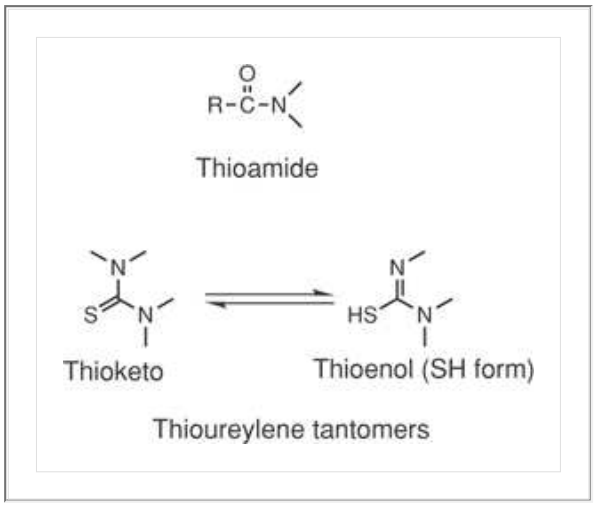
(Strong Iodine Solution USP) or as saturated potassium iodide solution, is administered for approximately 2 weeks to ensure decreased vascularity and firming of the gland. Iodism, a side effect of iodine administration, is apparently an allergic reaction characterized by dermatological and common cold-like symptoms (67).

Methimazole, Propylthiouracil, and Related Compounds

Thionamides are the most important class of antithyroid compounds in clinical practice used in nondestructive therapy of hyperthyroidism. These agents are potent inhibitors of TPO, which is responsible for the iodination of tyrosine residues of thyroglobulin and the coupling of iodotyrosine residues to form iodothyronines. These drugs have no effect on the iodide pump or on thyroid hormone release. The most clinically useful thionamides are thioureylenes, which are five- or six-membered heterocyclic derivatives of thiourea and include the thiouracil 6-n-propyl-2-thiouracil (PTU) and the thioimidazole 1-methyl-2-mercaptoimidazole (methimazole, Tapazole, MMI). The uptake of these drugs into the thyroid gland is stimulated by TSH and inhibited by iodide.



Chemically, the grouping R-CS-N- as been referred to as thioamide, thionamide, thiocarbamide, or if R is N, as it is in thiouracil, PTU, and MMI, it is called a thioureylene. This structure may exist in either the thioketo or thioenol tautomeric forms.



The study of 6-alkylthiouracil showed maximal antithyroid activity with 6-propylthiouracil. 6-Methylthiouracil has less than one-tenth the activity of PTU.

The ability of PTU to inhibit the enzyme 5′-D-I (i.e., the peripheral deiodination of T_4 to T_3, in addition to its intrathyroidal inhibition of thyroid hormone formation) has made PTU the drug of choice in the emergency treatment of thyroid storm (68). Single doses of PTU in excess of 300 mg are capable of almost total blockage of peripheral T_3 production (69).

A number of studies have defined the structure–activity relationships (SARs) of the thiouracils and other related compounds as inhibitors of outer ring deiodinase (70). The C_2 thioketo/thioenol group and an unsubstituted N_1 position are essential for activity. The enolic hydroxyl group at C_4 in PTU and the presence of alkyl group at C_5 and C_6 enhance the inhibitory potency.

Methimazole has more TPO inhibitory activity and is longer-acting than PTU but, in contrast to PTU, is not able to inhibit the peripheral deiodination of T_4, presumably because of the presence of the methyl group at N_1 position. The suggested maintenance dosages listed in USP DI are 50 to 800 mg daily for PTU and 5 to 30 mg daily for MMI.

Efforts to improve the taste and decrease the rate of release of MMI led to the development of 1-carbethoxy-3-methylthioimidazole (carbimazole). Carbimazole, the pro-drug derivative of methimazole, gives rise to methimazole in vivo and is used in the same dosage.

The side effects of thioamides include diarrhea, vomiting, jaundice, skin rashes, and at times, sudden onset of agranulocytosis. There does not appear to be a great difference in toxicity among the compounds currently in use.

Both PTU and MMI are concentrated several-fold by the thyroid gland and inhibit the iodination and coupling reactions of TPO (12). Taurog (71) described the thioureylenes as potent inhibitors of thyroglobulin iodination. He suggested that a thioureylene, such as propylthiouracil (PTU-SH), would irreversibly inhibit TPO-catalyzed iodination of thyroglobulin when the thioureylene-to-iodide ratio was high and reversibly when the PTU-SH-to-iodide ratio was low. In the course of the iodination reaction, the thioureylene PTU-SH would be oxidized (72), possibly to a disulfide dimer, such as PTU-SS-PTU. Drug oxidation is the preferred reaction, and as long as sufficient drug is present, diverting hypoiodate (OI^-) from iodination to drug oxidation. Iodination of tyrosyl residues resumes once oxidation of the drug to disulfide products occurs by either hypoiodate or an enzyme-hypoiodate complex (EOI^-) is complete. Under these conditions, the thioureylenes act as competitive inhibitors by competing with tyrosyls for hypoiodate. Conversely, at high drug concentrations, the thioureylenes are only partially oxidized, and the partially oxidized intermediate can presumably inactivate TPO by covalent binding of an oxidized form of the drug to the prosthetic heme group of TPO to prevent formation of the hydrogen peroxide–TPO complex. As a result, iodination is irreversibly blocked. Data obtained from rats fed an iodide-deficient

diet are consistent with this in vitro model in that intrathyroidal metabolism is radiolabeled PTU and MMI is decreased.

Thioureylene drugs also effectively inhibit the coupling of the DIT/MIT residues on thyroglobulin to yield the T_4 and T_3. This effect has been related to an alteration of the conformation of thyroglobulin brought on by the binding of the thioureylene to thyroglobulin (i.e., by the formation of a compound such as TPO-S-S-PTU) (73).

After the observation that PTU inhibited the peripheral deiodination of T_4 (68,74), attempts to relate deiodinase inhibitory activity to structural parameters were undertaken (74). These studies emphasized the need for tautomerization to a thiol form and for the presence of a polar hydrogen on the nitrogen adjacent to the sulfur-bearing carbon. A study of the relation of chemical structure to 5′-D-I inhibitory activity related to similar studies of structural requirements for TPO inhibition could prove fruitful in the design of improved antithyroid drugs.

Thyrotoxicosis

Because symptoms of thyrotoxicosis resemble those of adrenergic overstimulation, attempts to decrease such symptoms by adrenergic blockade have been undertaken. Reserpine and guanethidine, both of which are depletors of catecholamines, and propranolol, a β-blocking agent, have been used effectively to decrease the tachycardia, tremor, and anxiety of thyrotoxicosis. Because of its less serious side effects, propranolol has become the drug of choice in this adjunctive therapy. Reports of decreased T_3 plasma levels during propranolol treatment suggest that blocking of the peripheral deiodination of T_4 may contribute to the beneficial effects of propranolol. The use of propranolol as a preventive drug in acute thyrotoxicosis has been found to be beneficial by some investigators, but not by others.

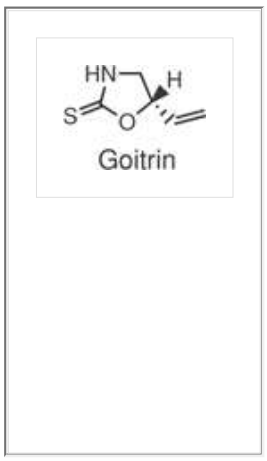
Goitrogens and Drugs Affecting Thyroid Function

The presence of environmental goitrogens was suggested by the resistance of endemic goiters to iodine prophylaxis and iodide treatment in Italy and Colombia. In the past, endemic outbreaks of hypothyroidism have pointed toward calcium as a source of waterborne goitrogenicity, and it is presently believed that calcium is a weak goitrogen able to cause latent hypothyroidism to come to the surface.

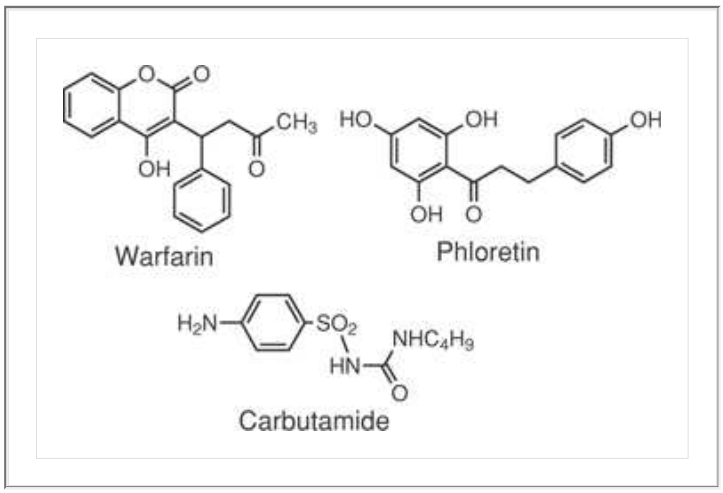
Lithium salts have been used as safe adjuncts in the initial treatment of thyrotoxicosis (75). Lithium is concentrated by the thyroid gland (76), with a thyroid-to-serum ratio of more than 2:1, suggesting active transport. Lithium ion inhibits adenylate cyclase, which forms cAMP. Formed in response to TSH, cAMP is a stimulator of the processes involved in thyroid hormone release from the gland. Inhibition of hormone secretion by lithium has proved to be a useful adjunct in treatment of hyperthyroidism (77).

In view of the role of cysteine residues in the conformation of thyroglobulin, the mode of action of TPO, and the deiodination of T_4, the effect of sulfur-containing compounds on thyroid hormone formation is hardly surprising. Most naturally occurring sulfur compounds are derived from glucosinolates (formerly referred to as thioglucosides) (78), which are present in foods such as cabbage, turnip, mustard seed, salad greens, and radishes (most of these are from the genus *Brassica* or *Cruciferae*) as well as in the milk of cows grazing in areas containing Brassica weeds. Chemically, glucosinolates can give rise to many components, including thiocyanate (CNS^-), isothiocyanate (SCN^-), nitriles (RCN), and thiooxazolidones. Thiocyanate is a large anion that competes with iodide for uptake by the thyroid gland; its goitrogenic effect can be reversed by iodide intake. Goitrin, 5-R-vinyloxazolidine-2-thione, is a potent thyroid peroxidase inhibitor (79) that is claimed to be more effective than PTU in humans (80) and is held to be the cause of a mild goiter endemia in Finland. In rats, goitrin is actively taken up by the thyroid gland and appears to inhibit the coupling of

thyroglobulin diiodotyrosyl residues (81). Many workers, however, believe that the goitrogenic effects of *Brassica* result from the additive effects of all goitrogenic components present.



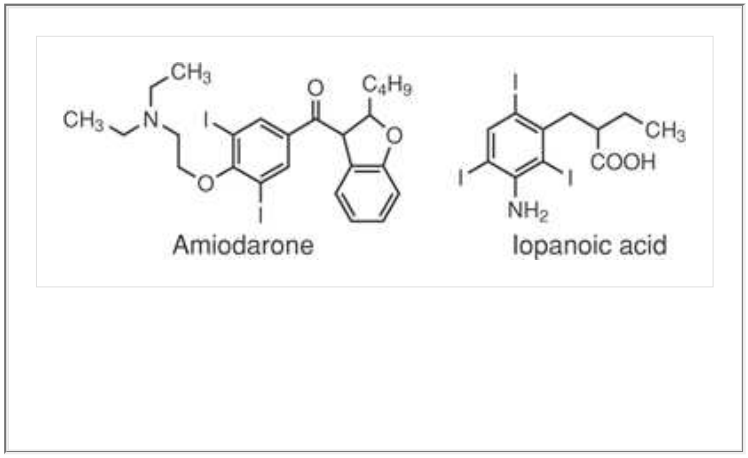
Other compounds affecting thyroid function include sulfonamides, anticoagulants, and oxygenated and iodinated aromatic compounds. The hypoglycemic agent carbutamide and the diuretic Diamox are examples of sulfonamides. Of the anticoagulants, heparin appears to interfere with the binding of T_4 to plasma transport proteins (82), but warfarin (Coumadin) and dicoumarol are competitive inhibitors of the substrate T_4 or rT_3 in the 5′-D reaction, with a dissociation constant (K_i) in the micromolar range (83). Other oxygenated compounds affecting the 5′-D include resorcinol, long known to be a goitrogen, and phloretin, a dihydrochalocone with an IC_{50} of 4 M.



The ability of oxidation products of 3,4-dihydroxycinnamic acid to prevent the binding of TSH to human

thyroid membranes (84) suggests that other oxygenated phenols may interfere with thyroid hormone function in more than one way. Examples of iodinated drugs affecting thyroid function are the antiarrhythmic agent amiodarone and the radiocontrasting agents iopanoic acid and ipodoic acid. All of these compounds interfere with the peripheral deiodination of T_4 and are being tested as adjuncts in the treatment of hyperthyroidism.

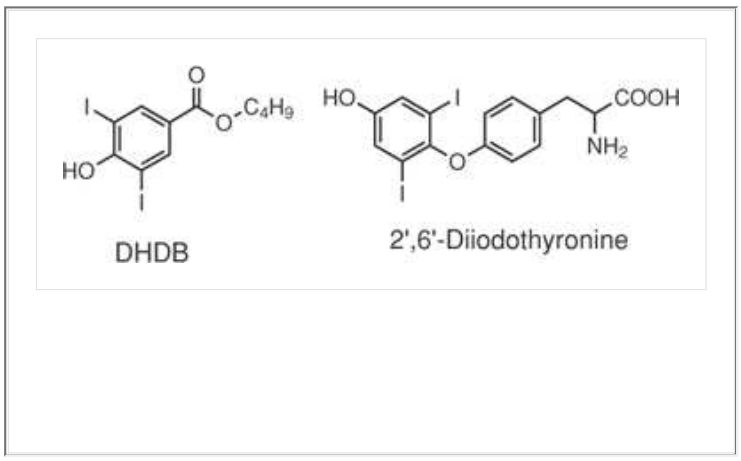
The binding of thyroid hormones to plasma carrier proteins is affected by endogenous agents or by drugs that can change the concentration of these proteins or compete with thyroid hormones for binding sites. Examples of the first group are testosterone (and related anabolic agents) that are able to decrease and estrogens (and related contraceptive agents) that are able to increase the concentration of T_4 binding globulin. Salicylates, diphenylhydantoin, and heparin are members of the large group competing with thyroid hormones for binding sites. Alterations in the binding of T_3 and T_4 are of no large physiological consequence, because the steady-state concentrations of free hormone are rapidly restored by homeostatic mechanisms. Knowledge regarding the presence of agents affecting thyroid hormone binding, however, is important for the interpretation of diagnostic tests assessing the presence of free or total hormone in plasma.



Thyroid Hormone Analogues

The search for thyroid hormone analogues was prompted by the desire to establish SARs for the hormone and by the need for a safe, specific antagonist able to block thyroid action without delay at a peripheral site. The reader will recall that TPO inhibitors, such as PTU, do not affect the extensive amount of hormone stored in thyroidal thyroglobulin.

Some early analogues designed as antagonists were butyl-3,5-diiodo-4-hydroxybenzoate (BHDB), which was designed as a deiodinase inhibitor and is, to a degree, effective as such, and 2′6′-diiodothyronine, which has a small antithyroid effect.



When the activity of T_3 was discovered in 1955, and when none of the many analogues tabulated by Selenkow and Asper (85) demonstrated significant antithyroid activity, efforts were made to redefine the structural requirements for thyroid-like activity to provide a better rationale for the design of a peripheral thyroid antagonist. The biological assay methods used for the newer compounds included measurements of in vivo oxygen uptake, of hepatic lipogenic enzyme activity, of goiter formation, of the rate of amphibian metamorphosis, and more recently, of the binding to nuclear receptors.

The measurement of oxygen uptake provides a direct index of metabolic rate; this measurement can be done simply by placing experimental animals in a calibrated vessel maintained at constant temperature and connected to an oxygen analyzer (86). Repeatedly used as an index of thyromimetic activity have been the in vitro assay of oxygen uptake by suspended mitochondria and the spectrophotometric assays of rat liver mitochondrial α-glycerophosphate dehydrogenase (87) and of cytoplasmic malic enzyme (88).

In the “goiter” or “antigoiter” assay, goiter formation is induced by the administration of a TPO inhibitor, such as thiouracil. The inhibitor is blended with the food or added to the drinking water and given to experimental animals for 10 to 14 days. The increase in gland weight caused by the TPO inhibitor can be reversed by T_4 or by a test compound with thyromimetic activity. The effect of a given dose of thyromimetic agent compared with that of a given dose of T_4 yields the “antigoitrogenic effect” of the compound. Furthermore, when both a test compound and T_4 are given to an animal receiving a TPO inhibitor, the ability of the test compound to antagonize T_4, or the “antithyroid effect'' of the test compound, can be assessed.

Discrepancies have been seen between the results obtained with amphibian metamorphosis and those obtained with other assays. These discrepancies have been attributed to the ability of test animals, such as

tadpoles, to concentrate test compounds and, especially, lipophilic test compounds from the medium (89). The binding affinity of thyroid analogues to nuclear receptors correlates well with the effectiveness of these analogues in the antigoiter assay, provided that the metabolism of the analogues is taken into consideration (89).

Structure–Activity Relationships of Thyroid Analogues

The synthesis and biological evaluation of a wide variety of T_4 and T_3 analogues allowed a significant correlation of structural features with their relative importance in the production of hormonal responses. The key findings are summarized in Table 34.2. In general, only compounds with the appropriately substituted phenyl-X-phenyl nucleus (as depicted at the top of Table 34.2) have shown significant thyroid hormonal activities. Both single ring compounds such as DIT and a variety of its aliphatic and alicyclic ether derivatives showed no T_4-like activity in the rat antigoiter test (90), the method most often used in determining thyromimetic activity in vivo (91). The SARs

are discussed in terms of single structural variations of T_4 in the 1) alanine side chain, 2) 3- and 5-positions of the inner ring, 3) the bridging atom, 4) 3′- and 5′-positions of the outer ring, and 5) the 4′-phenolic hydroxyl group.

Table 34.2. Some Properties and Pharmacokinetics for Levothyroxine and Liothyroninea

Parameters	L-Thyroxine	Liothyronine
Trade name	Synthroid, Levothroid, Levoxyl	Cytomel
pK_a (phenolic)	6.7	8.4
Oral bioavailability (%)	50–80b	95
Peak response	Several weeks (hypothyroid)	2–3 days (hypothyroid)
Duration of action	Several weeks (hypothyroid)	Several days (hypothyroid)
Protein binding (%)	99% (weakly)	Weakly bound
Time to peak concentration (hours)	2–4	1–2
Volume of distribution (L/kg)	8.7–9.7	41–45
Elimination half-life (days)	6–7 euthyroid	1 euthyroid
	9–10 hypothyroid	1–2 hypothyroid
	3–4 hyperthyroid	1 hyperthyroid
Excretion (%)	50 urine 50 feces	urine

Aliphatic Side Chain

The naturally occurring hormones are biosynthesized from L-tyrosine and possess the L-alanine side chain. The L-isomers of T_4 and T_3 (compounds 1 and 3 in Table 34.2) are more active than the D-isomers (compounds 2 and 4) (Table 34.2). The carboxylate ion and the number of atoms connecting it to the ring are more important for activity than is the intact zwitterionic alanine side chain. In the carboxylate series, the activity is maximum with the two-carbon acetic acid side chain (compounds 7 and 8) but decreases with either the shorter formic acid (compounds 5 and 6) or the longer propionic and butyric acid analogues (compounds 9-12). The ethylamine side chain analogues of T_4 and T_3 (compounds 13 and 14) are less active than the corresponding carboxylic acid analogues. In addition, isomers of T_3 in which the alanine side chain is transposed with the 3-iodine or occupies the 2-position were inactive in the rat antigoiter test (92), indicating a critical location for the side chain in the 1-position of the inner ring.

Alanine-Bearing Ring

The phenyl ring bearing the alanine side chain, called the inner ring or α-ring, is substituted with iodine in the 3- and 5-positions in T_4 and T_3. As shown in Table 34.2, removal of both iodine atoms from the inner ring to form 3′,5′-T_2 (compound 15) or 3′-T_1 (compound 16) produces analogues devoid of T_4-like activity, primarily because of the loss of the perpendicular orientation of diphenyl ether conformation. Retention of activity observed on replacement of the 3- and 5-iodine atoms with bromine (compounds 17 and 18) implies that iodine does not play a unique role in thyroid hormone activity. Moreover, a broad range of hormone activity found with halogen free analogues (compounds 19 and 20) indicates that a halogen atom is not essential for activity. In contrast to T_3, 3′-isopropyl-3,6-dimethyl-L-thyronine (compound 20) has the capacity to cross the placental membrane and exerts thyromimetic effects in the fetus after administration to the mother. This could prove to be useful in treating fetal thyroid hormone deficiencies or in stimulating lung development (by stimulating lung to synthesize special phospholipids [surfactant], which ensure sufficient functioning of the infant's lungs at birth) immediately before premature birth (93). Substitution in the 3- and 5-positions by alkyl groups significantly larger and less symmetric than methyl groups, such as isopropyl and secondary butyl moieties, produces inactive analogues (compounds 21 and 22). These results show that 3,5-disubstitution by symmetric, lipophilic groups not exceeding the size of iodine is required for activity.

Bridging Atom

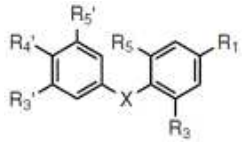
Several analogues have been synthesized in which the ether oxygen bridge has been removed or replaced by other atoms. The biphenyl analogue of T_4 (compound 23 in Table 34.2), formed by removal of the oxygen bridge, is inactive in the rat antigoiter test. The linear biphenyl structure is a drastic change from the normal diphenyl ether conformation found in the naturally occurring hormones. Replacement of the bridging oxygen atom by sulfur (compound 24) or by a methylene group (compound 25) produces highly active analogues. This provides evidence against the Niemann quinoid theory, which postulates that the ability of a compound to form a quinoid structure in the phenolic ring is essential for thyromimetic activity, and emphasizes the importance of the three-dimensional structure and receptor fit of the hormones. Attempts to prepare amino- and carbonyl-bridged analogues of T_3 and T_4 have been unsuccessful (94,95).

Phenolic Ring

The phenolic ring, also called the outer or β-ring, of the thyronine nucleus is required for hormonal activity. Variations in 3′- or 3′,5′-substituents on the phenolic ring have dramatic effects on biological activity and affinity for the nuclear receptor. The unsubstituted parent structure of this series L-T_2 (compound 26 in Table 34.2) possesses low activity. Substitution at the 3′-position by polar hydroxyl or nitro groups (compounds 27 and 28) causes a decrease in activity as a consequence of both lowered lipophilicity and intramolecular hydrogen bonding with the 4′-hydroxyl (96). Conversely, substitution by nonpolar halogen or alkyl groups results in an increase in activity in direct relation to the bulk and lipophilicity of the substituent—for example, F < Cl < Br < I (compounds 29-31) and CH_3 < CH_2CH_3 < $CH(CH_3)_2$ (compounds 32–34). Although 3′-isopropylthyronine (compound 34) is the most potent analogue

known, being approximately 1.4 times as active as L-T_3, n-propylthyronine (compound 35) is only about one-fourth as active as isopropyl, apparently because of its less compact structure. As the series is further ascended, activity decreases with a further reduction for the more bulky 3′-phenyl substituent (compound 36). Substitution in both 3′- and 5′-positions by the same halogen produces less active hormones (compounds 37 and 38) than the corresponding 3′-monosubstituted analogues (compounds 29 and 30). The decrease in activity has been explained as resulting from the increase in phenolic hydroxyl ionization and the resulting increase in binding to TBG (the primary carrier of thyroid hormones in human plasma) (97). In general, a second substituent adjacent to the phenolic hydroxyl (5′-position) reduces activity in direct proportion to its size.

Table 34.3. Relative Rat Antigoiter Activity of Thyroxine Derivatives



Compound	R_1	R_3	R_5	X	$R_{3'}$	$R_{5'}$	$R_{4'}$	Antigoiter Activity[a]
1. L-T_4	L-Ala	I	I	O	I	I	OH	100

[a]See Ekins et al. (107) and Ahmad et al. (108). In vivo activity in rats relative to L-T_4 = 100% or DL-T_4 = 100% for goiter prevention.

Phenolic Hydroxyl Group

A weakly ionized phenolic hydroxyl group at the 4′-position is essential for optimum hormonal activity. Replacement of the 4′-hydroxyl with an amino group (compound 39 in Table 34.2)

results in a substantial decrease in activity, presumably as a result of the weak hydrogen bonding ability of the latter group. The retention of activity observed with the 4′-unsubstituted compound (compound 40) provides direct evidence for metabolic 4′-hydroxylation as an activating step. Introduction of a 4′-substituent that cannot mimic the functional role of a phenolic group, such as a methyl group (compound 41), and that is not metabolically converted into a functional residue results in complete loss of hormonal activity. The thyromimetic activity of the 4′-methyl ether (compound 42) was ascribed to the ready metabolic cleavage to form an active 4′-hydroxyl analogue. The pK_a of 4′-phenolic hydroxyl group is 6.7 for T_4 (90% ionized at pH 7.4) and 8.5 for T_3 (~approximately 10% ionized). The greater acidity for T_4 is reflective of its stronger affinity for plasma proteins and, consequently, of its longer plasma half-life.

Conformational Properties of Thyroid Hormones and Analogues

The importance of the diphenyl ether conformation for biological activity was first proposed by Zenker and Jorgensen (98,99). Through molecular models, they showed that a perpendicular orientation of the planes of the aromatic rings of 3,5-diiodothyronines would be favored to minimize interactions between the bulky 3,5-iodines and the 2′,6′-hydrogens. In this orientation, the 3′- and 5′-positions of the ring are not conformationally equivalent, and the 3′-iodine of T_3 could be oriented either distal (away from) or 5′ proximal (closer) to the side chain–bearing ring (Fig. 34.6). Because the activity of compounds such as 3′,5′-dimethyl-3,5-diiodothyronine had demonstrated that alkyl groups could replace the 3′- and 5′-iodine substituents, model compounds bearing alkyl groups in the 3′-position and alkyl or iodine substituents in the 5′-position (in addition to the blocking 2′-methyl group) were synthesized for biological evaluation (99).

Biological evaluation of 2′,3′- and 2′,5′-substituted diiodothyronines (100) revealed that 3′-substitution was favorable for thyromimetic activity but that 5′-substitution was not. The structures of representative distal analogues, 2′,3′-dimethyl-3,5-DL-diiodothyronine (compound I) and O-(4′-hydroxy-1′-naphthyl)-3,5-DL-diiodotyrosine (compound II), and of the proximal analogues, 2′,5′-dimethyl-3,5-DL-diiodothyronine (compound III) and 2′-methyl-3, 5,5′-DL-triiodothyronine (compound IV), are given in Figure 34.6. The effectiveness of these compounds in rat antigoiter assay (101) is presented in Table 34.4. These results clearly indicate that in 2′-blocked analogues, a distal 3′-substitution is favorable for thyromimetic activity, but a proximal 5′-substitution is not.

Table 34.4. Effectiveness of Distal and Proximal Compounds Antigoiter Assay

Compounda	Dose (mg/kg/day)	% T_4 activity
I	0.025	50

II	0.013	>100
III	2.3	<1
IV	0.5	2

[a]See text for specific descriptions of compounds I–IV.

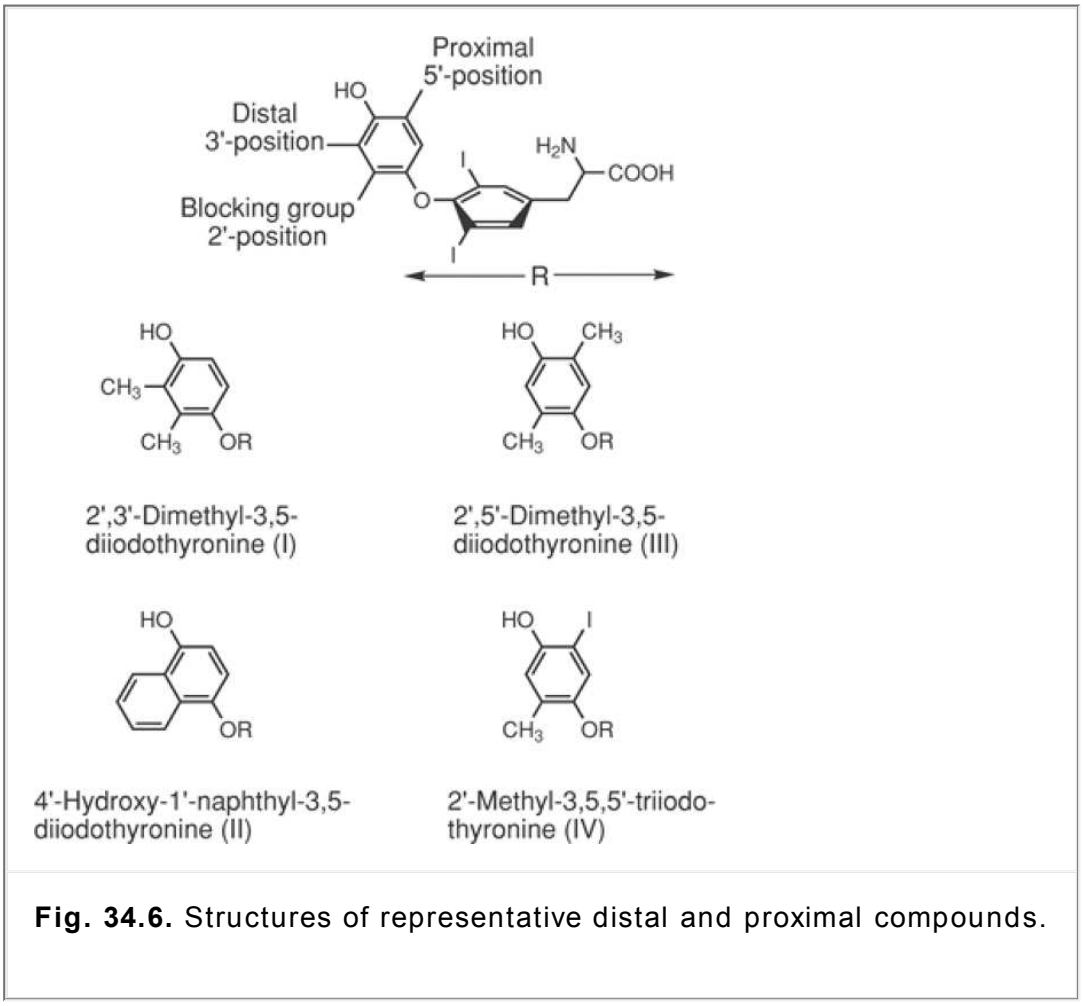

Fig. 34.6. Structures of representative distal and proximal compounds.

The perpendicular orientation of the rings of 3,5-diiodothyronines, which was postulated from molecular models, has been confirmed by x-ray crystallographic studies (102), molecular orbital calculations (103), and nuclear magnetic resonance studies (104,105).

In addition to being perpendicular to the inner ring, the outer phenolic ring can adopt conformations relative to the alanine side chain, which would be *cis* or *trans*. In other words, the cisoid and transoid conformations result from the methine group in the alanine side chain being either *cis* or *trans* to the phenolic ring (Fig. 34.7). Although the bioactive conformation of the alanine side chain in thyroid hormone analogues has not yet been defined, these conformations appear to be similar in energy, because both are found in thyroactive structures as determined by x-ray crystallography (106). The synthesis of conformationally fixed cyclic or unsaturated analogues may allow evaluation of the bioactivity of the two conformers.

Transthyretin Receptor Model

An additional tool in structural analysis and analogue design has been TTR (formerly called T_4 binding prealbumin), a plasma protein that binds as much as 27% of plasma T_3 (107). The amino acid sequence of the TTR T_3 binding site is known, and the protein has therefore served as a model, although admittedly an approximate model, for the T_3 receptor. The TTR model portrays the T_3 molecule as placed in an envelope

near the axis of symmetry of the TTR dimer. In this envelope, hydrophobic

residues, such as those of leucine, lysine, and alanine, are near pockets accommodating the 3,5,3′- and 5′-positions of T_3, whereas the hydrophilic groups of serine and threonine (hydrogen bonded to water), are between the 3′-substituent and the 4′-phenolic group. Taking this model into account, Ahmad et al. (108) suggested that 3′-acetyl-3,5-diiodothyronine might be a good analogue or a good inhibitor of T_3, because the carbonyl group of the 3′ acetyl substituent would form a strong hydrogen bond with the 4′ phenolic hydrogen, preventing thereby its bonding with the hydrated residue of the putative receptor.

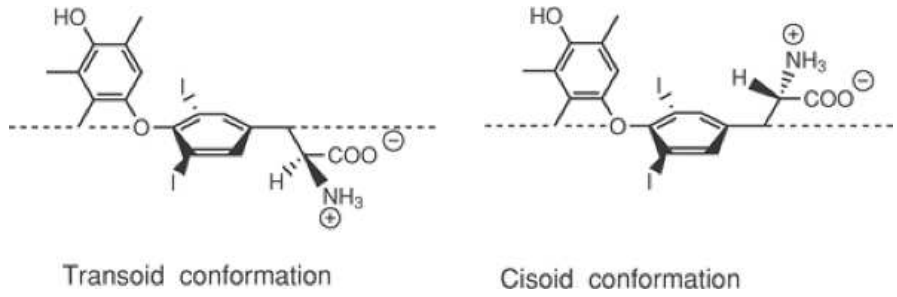

Fig. 34.7. Side-chain conformations of thyroid hormones: transoid (left), and cisoid (right).

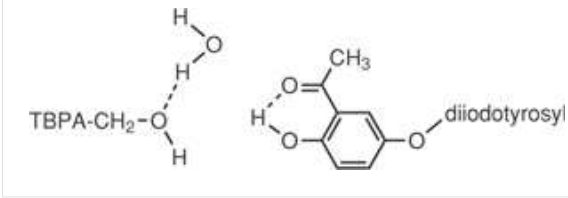

This compound, prepared by Benson et al. (109), was found to be indistinguishable from T_3 in oxygen uptake and glycerophosphate activity tests and to be half as active as T_3 in displacing labeled T_3 from rat liver nuclei in specific in vivo conditions.

Problems

What organs and functions of the body are regulated by thyroid hormones?

Thyroid hormones regulate the body's metabolism and organ function, affecting heart rate, cholesterol level, body weight, energy level, muscle strength, skin condition, menstrual regularity, memory and many other conditions.

List classes of drugs that interact (interfere) with thyroid hormones therapy.

- *Oral anticoagulants*—Thyroid hormones increase catabolism of vitamin K–dependent clotting factors.
- *Insulin or oral hypoglycemics*—Initiating thyroid replacement therapy causes increases in insulin or oral hypoglycemic requirements. The effects seen are poorly understood and depend on a variety of factors, such as endocrine status of the patient and type of thyroid preparations.

- *Cholestyramine*—Cholestyramine binds both T_4 and T_3 in the intestine, thus impairing absorption of these thyroid hormones.
- *Estrogen, oral contraceptives*—Estrogens tend to increase serum thyroxine-binding globulin (TBG), thus increasing thyroid requirements.
- Antidepressant drugs

Why is the use of thyroid hormones in therapy for obesity unjustified?

Drugs with thyroid hormone activity, either alone or together with other therapeutic agents, have been used for treatment of obesity. In euthyroid patients, doses within the range of daily hormonal requirements are ineffective for weight reduction. Larger doses may produce serious or even life-threatening manifestation of toxicity, particularly when given in association with sympathomimetic amines, such as those used for their anorectic effects.

What is the purpose of prescribing β-blockers along with thyroid drugs in treatment of hyperthyroidism?

β-Adrenergic blocking agents, such as atenolol, nadolol, metoprolol, or propranolol, block the action of circulating thyroid hormone on the body tissues, slowing heart rate and lessening nervousness. These drugs may be extremely helpful in reducing symptoms until one of the other forms of treatment have a chance to take effect. They are not used, however, in patients who have asthma or heart failure, which may be worsened with these drugs.

Patients with hypothyroidism and organic depression may need both levothyroxine and antidepressant drug therapy. In levothyroxine-treated patients with hypothyroidism who were treated with sertraline, there was an elevated serum thyrotropin concentration, indicative of a decrease in the efficacy of levothyroxine. What is the possible mechanism of interaction between the two drugs?

Sertraline may interfere by increasing the clearance of thyroxine.

Shelton RC, Winn S, Ekhatore N, et al. The effects of antidepressants on the thyroid axis in depression. Biol Psychiatry 1993;33:120–126.

What are the tests for checking the thyroid function?

1. *Total serum T_4*. This includes both bound and free T_4 concentration.
2. *T_3 resin uptake (T_3RU)*. The T_3 resin uptake test measures the amount of unsaturated binding sites on the thyroid hormone transport proteins. A proportion of the labeled T_3 will bind to available sites on the serum TBG; any excess will bind to the resin. Resin uptake is inversely proportional to the number of vacant binding sites and, therefore, inversely proportional to the total TBG.

   In thyrotoxicosis, fewer vacant binding sites are available on thyroxine binding globulin because of the high circulating levels of thyroid hormone. This means less radioactive T_3 will be able to bind to TBG and more will bind to the resin. Hence, resin uptake is higher in hyperthyroid patients than in normal patients. The converse is true in hypothyroid states. In high TBG states, such as pregnancy or estrogen therapy, the T_3RU will be low; however, the physiologically active free T_4 level will still be normal.
3. *Free thyroxine Index (FT_4I)*. The FT_4I is a reflection of the amount of free T_4 in most situations. It is a calculated value and corrects for changes in TBG concentrations by using the following formula:

   FTI = (total T_4) × (T_3 resin uptake/T_3RU control)

   Mean normal T_3RU for the particular assay (normal range, 25–35%; mean normal, 30%). With extreme changes in TBG concentrations, acute medical illness, heparin therapy, or low protein states secondary to nephrotic syndrome, the FT_4I may not accurately reflect the

amount of free T_4 concentrations.

4. *TSH test*. Measuring the serum TSH has become the screen test of choice for thyroid disease. Primary hypothyroidism produces elevated TSH levels, whereas patients with primary hyperthyroidism (i.e., Graves' disease) should have undetectable TSH values. This relationship is true only in individuals with an intact hypothalamic-pituitary-thyroid axis. Patients who present with a normal or detectable TSH level and elevated thyroid hormone concentrations require further evaluation to exclude central causes of hyperthyroidism.
5. *TRH test*. The administration of TRH causes a rise in TSH concentration in normal subjects (TSH, 2-30 mU/L). An exaggerated response occurs in primary hypothyroid subjects (TSH often is >30 mU/L, depending on the baseline TSH elevation.) Hyperthyroid patients have a mild or absent TSH response (TSH, <2 mU/L), because the suppressed TSH cannot be stimulated by exogenous TRH. The introduction of sensitive TSH assays that can detect low suppressed TSH levels, identifying patients with primary hyperthyroidism, has made the TRH stimulation test virtually obsolete.
6. *Iodine test*. Plasma iodine in the form of iodide is concentrated (trapped) in the thyroid cells by an energy-requiring active transport mechanism, where it is incorporated into T_3 and T_4 via organification. Therefore, iodine measures both trapping and organification by the thyroid gland.

What conditions are associated with decreased and increased levels of TBG?

TBG is synthesized by the liver under the influence of estrogen. An increase in TBG concentration in response to higher estrogen levels may result in higher measured total T_4 concentration. The amount of free T_4 concentration remains constant, however, and the patient remains clinically euthyroid.

Conditions associated with increased levels of TBG:

- *Estrogen effects*—pregnancy, oral contraceptives
- *Infectious hepatitis*
- *Biliary cirrhosis*
- *Genetic determination*

In contrast, factors that cause a decrease in TBG concentration or a lower affinity for T_4 binding to TBG may result in low measured total T_4 concentration without affecting free T_4 levels.

Conditions associated with decreased binding of T_4 by TBG:

- *Androgens and anabolic steroids*
- *Large doses of glucocorticoids*
- *Nephrotic syndrome*
- *Major systemic nonthyroidal illness*
- *Active acromegaly*
- *Chronic liver disease*
- *Drugs*—dilantin, tegretol
- *Genetic determination*

Considering that T_3 does not cross the placental membrane and, therefore, cannot be useful in treating fetal thyroid hormone deficiencies or in stimulating lung development immediately before premature birth, what would be your solution to overcome this problem?

(Refer to the *Structure-Activity Relationship of Thyroid Analogues* section)

3′-Isopropyl-3,6-dimethyl-L-thyronine has the capacity to cross the placental membrane and exerts thyromimetic effects in the fetus after administration to the mother.

List the major pathways for the metabolism of T_4.

1. Outer ring deiodination by the enzyme 5′-D, which yields T_3.
2. Inner ring deiodination by the enzyme 5-D, which yields rT_3.
3. Glucuronide conjugation through the phenolic hydroxy group, which yields T_4-4′-O-glucuronide.

4. Sulfate conjugation through the phenolic hydroxy group, which yields T_4-4′-O-sulfate.
5. Side-chain oxidative deamination and decarboxylation, which yields thyroacetic acid and thyroethanediol.

Case Study

Victoria F. Roche

S. William Zito

GS is a 56-year-old women who, on her most recent visit to her physician, complains of always feeling cold. She says it is causing strife at home, because she always wants to turn up the thermostat and her husband wants to turn it down. In addition, she has been feeling tired for the last 6 months, and her skin has been dry and itchy. On further questioning, she reveals that she has been "grouchy" at work and finds it difficult to cope with the ordinary stresses of her job. Laboratory tests indicate elevated TSH (11 mIU/ml) and low levels of free T_4 (0.6 ng/dL). The physical and laboratory findings are consistent with a diagnosis of hypothyroidism. Her physician wants to treat the hypothyroidism with hormone replacement therapy. Evaluate the given structures for use in this case.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented SAR analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 35

Calcium Homeostasis

Robin M. Zavod

Introduction

Three primary hormones—calcitonin, parathyroid hormone, and vitamin D—control the homeostatic regulation of calcium and its principle counterion, inorganic phosphate. Homeostatic control of these ions is essential not only for the moderation of longitudinal bone growth and bone remodeling but also for blood coagulation, neuromuscular excitability, plasma membrane structure and function, muscle contraction, glycogen and adenosine triphosphate (ATP) metabolism, neurotransmitter/hormone secretion, and enzyme catalysis (1). In an average 70-kg adult, approximately 1 kg of calcium is found, 99% of which is located in the bone. The principle calcium salt contained in the hydroxyapatite crystalline lattice of teeth and bones is $Ca_{10}(PO_4)_6(OH)_2$. Similarly, approximately 500 to 600 g of phosphate are present, 85% of which is found in the bone. The normal plasma concentration of calcium is approximately 4.5 to 5.7 mEq/L, 50% of which is protein bound. The remainder of the calcium is either complexed to corresponding counterions (46%) or exists in its ionized form (4%). It is only the ionized form of calcium that is tightly hormonally regulated (varies less than 5–10%) (1,2). Because serum calcium concentrations fluctuate, so do the plasma levels of the hormones associated with calcium homeostasis. Serum phosphorous levels vary with age, diet, and hormonal status. The most common form of phosphate in the blood (pH 7.4) is HPO_4^{2-}.

The bone is composed of two distinct tissue structures: cortical (compact) bone, and trabecular (cancellous) bone (3). Eighty percent of the skeleton is composed of cortical bone (e.g., long bones such as the humerus, radius, and ulna) (4,5), which is a relatively dense tissue (80–90% calcified) (4) that provides structure and support (3). Bone marrow cavities, flat bones, and the ends of long bones are all composed of trabecular bone, which is considerably more porous (5–20% calcified) (4,5). To maintain healthy, well-mineralized bone, a continuous process of bone resorption (loss of ionic calcium from bone) and formation occurs along the bone surface. Cortical bone is remodeled at the rate of 3% per year, whereas 25% of trabecular bone, which has considerably higher surface area, is remodeled annually (3). In terms of calcium turnover in bone, approximately 500 mg are removed and replaced on a daily basis.

Both inorganic and organic components are present in the bone. The highly crystalline inorganic component is hydroxyapatite, and the collagen matrix comprises the major portion (90%) of the organic component. The collagen matrix serves as the foundation for hydroxyapatite mineralization. Osteocalcin and osteonectin are minor organic constituents that promote binding of hydroxyapatite and calcium to the collagen matrix and regulate the rate of bone mineralization, respectively (5).

In general, peak bone mass occurs between 30 and 40 years of age (3,6) and is dependent on genetic factors as well as proper intake of calcium, maintenance of quality nutrition, and participation in weight-bearing exercise (6). Thereafter, peak bone mass progressively declines at the rate of 0.3 to 0.5% of cortical bone per year (3). After menopause, bone loss is accelerated (2% per year in the spine) (6) for a period of 5 to 10 years because of the loss of estrogen. This can result in up to a 30% decrease in bone mineral density.

Hormonal Regulation of Serum Calcium Levels

Arnaud (7) has developed a “butterfly model” that provides a diagrammatic view of the complex interrelationships among the three hormones (parathyroid, calcitonin, and vitamin D) that control calcium homeostasis (serum concentrations of ionic calcium) and their target organs (bone, kidney, and intestine) (Fig. 35.1). The right side (B loops) of the butterfly model describes the processes that increase the serum calcium concentration in response to hypocalcemia; the left side (A loops) depicts the events that occur in response to hypercalcemia.

Clinical Significance

As our knowledge about the development and risk factors associated with disruptions in calcium homeostasis has increased, so too have the modalities available to prevent and/or treat these disease processes. In general, disorders of calcium homeostasis involve the development of bone disease and/or alterations in serum calcium concentration. In the most basic sense, the development of bone disease is simply an inequity between bone breakdown and bone formation, which also may result in an altered serum calcium concentration. In addition to bone disease, disruptions in normal serum calcium concentrations may be related to an imbalance in calcium intake and renal calcium elimination. These disturbances can result from various factors, including increased activity of cells that cause bone breakdown, decreased activity of cells that form new bone, decreased absorption of calcium, or irregularities in levels of hormones that affect calcium absorption and influence cells involved in bone maintenance. Our understanding of these physiologic processes has led to the development of multiple classes of agents targeting the different mechanisms for evolution of these disease processes, including selective estrogen receptor modulators, bisphosphonates, and various calcium salts.

Application of the principles of medicinal chemistry has resulted in formulation of agents with additional routes of administration, increased potency, and decreased frequency of dosing. These advances have increased the utility of these agents and improved the quality of life for countless individuals affected by calcium homeostasis disorders. Understanding the development of individual disease processes involved in disorders of calcium homeostasis (e.g., osteoporosis, osteopetrosis, hyperparathyroidism, and Paget's disease) and the pharmacodynamic effects of individual compounds used to treat these disorders is paramount for the practitioner making therapeutic decisions. Incorporation of these factors into the therapeutic plan is necessary to target the valued pharmacodynamic effects of these agents while minimizing unwanted or harmful effects. An example would be the selection of raloxifene to treat osteoporosis in a patient with severe gastroesophageal reflux disease instead of an oral bisphosphonate, which could increase the likelihood of developing erosive esophagitis. Finally, it is also important for the clinician to recognize the capacity of certain entities used to treat calcium disorders to be allergenic or more prone to produce adverse effects so that selection of the best agent for an individual patient is facilitated.

Kathryn Neill Pharm.D.

Assistant Professor, Critical Care Specialist, Department of Pharmacy Practice, College of Pharmacy, University of Arkansas for Medical Sciences

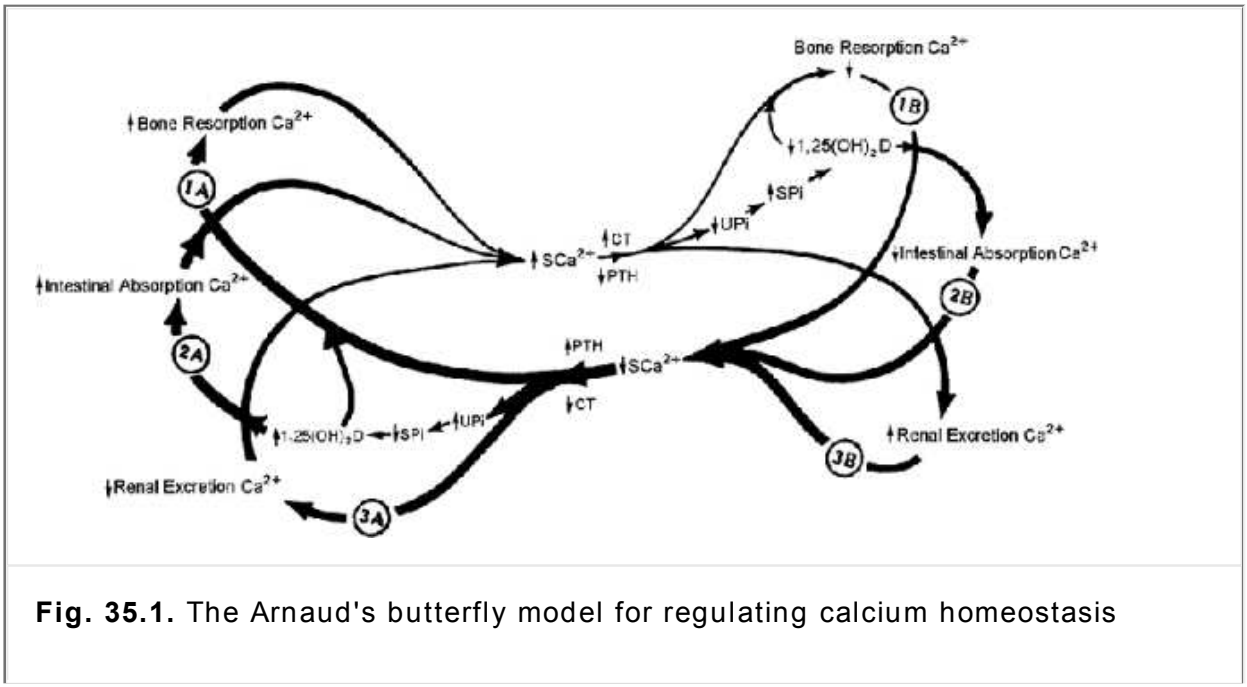

Fig. 35.1. The Arnaud's butterfly model for regulating calcium homeostasis

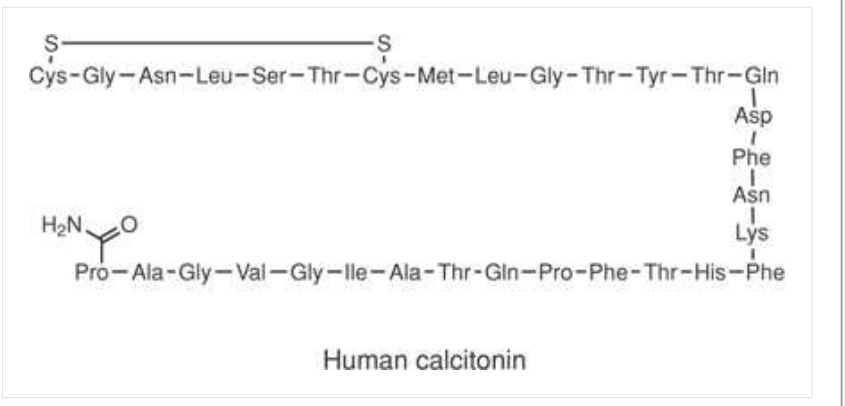
consists of three overlapping loops that interlock and relate to one another through the serum concentrations of ionic calcium (SCa), parathyroid hormone (PTH), and calcitonin (CT). The right side (B loops, where B refers to the effects of CT) of the model describes the physiologic processes that increase the serum calcium concentration in response to hypocalcemia; the left side (A loops, where A refers to the effects of PTH) of the model depicts the events that decrease the serum calcium concentration in response to hypercalcemia. Loop 1 bone resorption; loop 2 intestinal absorption; loop 3 renal excretion; SPi, serium inorganic phosphate; UPi, urinary inorganic phosphate. (Adapted from Arnaud CD. Calcium homeostasis: regulatory elements and their integration. Fed Proc 1978; 37:2557-2560; with permission).

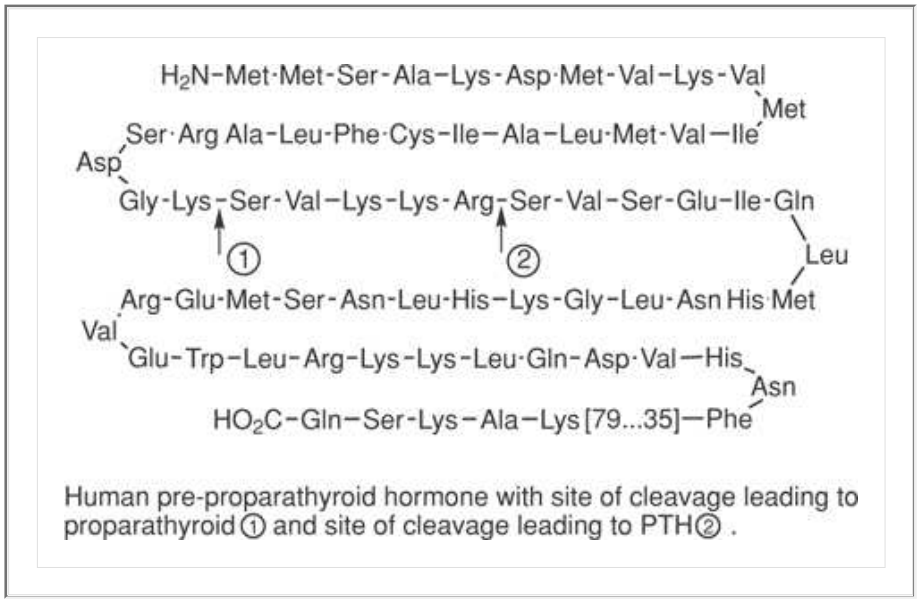
Calcitonin



Human calcitonin

Human calcitonin is a 32-amino-acid peptide (molecular weight, 3,527 dalton) biosynthesized in the parafollicular “C” cells found within the thyroid gland. This hormone contains a critical disulfide bridge between residues 1 and 7, with the entire amino acid sequence required for biological activity. The carboxy terminal residue is a proline amide. “Pro-calcitonin,” a precursor peptide, has been identified and proposed to facilitate intracellular transport and secretion. Calcitonin is secreted in response to elevated serum calcium concentrations (>9 mg/100 mL) and serves to oppose the hormonal effects of parathyroid hormone. In response to a hypercalcemic state (Fig. 35.1, B loops), increased calcitonin secretion drives serum calcium concentrations down via stimulation of urinary excretion of both calcium and phosphate (loop 3B), prevention of calcium resorption from the bone via inhibition of osteoclast activity (loop 1B), and inhibition of intestinal absorption of calcium (loop 2B). When serum calcium concentrations are low (hypocalcemia), the release of calcitonin is slowed, thereby activating loops 1A, 2A, and 3A.

Parathyroid Hormone



Human pre-proparathyroid hormone with site of cleavage leading to proparathyroid ① and site of cleavage leading to PTH ② .

Parathyroid hormone (PTH) is biosynthesized as a 115-amino-acid preprohormone in the rough endoplasmic reticulum of the parathyroid gland and is cleaved to the prohormone (84 amino acids) in the cisternal space of the reticulum. The active hormone is finally produced (34 amino acids; molecular weight, 9,500 dalton) in the Golgi complex and is stored in secretory granules in the parathyroid gland. This gland is exquisitely sensitive to serum calcium concentrations and is able to monitor these levels via calcium-sensing receptors (CaSR). These cell surface receptors help cells to react to micromolar changes in the concentration of ionized calcium in the serum (8). Binding of calcium to these receptors facilitates activation of phospholipase C and, ultimately, inhibition of PTH secretion. The relatively short-acting PTH is secreted from the parathyroid gland chief cells in response to a hypocalcemic state and serves to oppose the hormonal effects of calcitonin (1). Unlike calcitonin, the biological activity of PTH resides solely in residues 1 to 34 in the amino terminus. Parathyroid hormone decreases renal excretion of calcium (Fig. 35.1, loop 3A), indirectly stimulates intestinal absorption of calcium (Fig. 35.1, loop 2A), and in combination with active vitamin D, promotes bone resorption (Fig. 35.1, loop 1A) by a complex, unknown mechanism, thereby elevating serum calcium concentrations. In addition, the secretion of PTH stimulates the biosynthesis and release of the third hormone associated with calcium homeostasis, vitamin D. When serum calcium concentrations are high, the release of PTH is inhibited.

Vitamin D

Derived from cholesterol, vitamin D is biosynthesized from its prohormone cholecalciferol (D_3), the product of solar ultraviolet irradiation of 7-dehydrocholesterol in the skin (2). In 1966, it was first recognized that vitamin D must undergo activation *via* two oxidative metabolic steps (Fig. 35.2). The first oxidation to 25-hydroxycholecalciferol (25(OH)D_3: calcifediol; Calderol) occurs in the endoplasmic reticulum of the liver and is catalyzed by vitamin D 25-hydroxylase. This activation step is not

regulated by plasma calcium concentrations. The major circulating form (10–80 μg/mL) is 25(OH)D_3, which also is the primary storage form of vitamin D (2). In response to a hypocalcemic state and the secretion of PTH, a second oxidation step is activated in the mitochondria of the kidney, catalyzed by vitamin D 1α-hydroxylase (2,9). The product of this reaction, 1,25-dihydroxycholecalciferol (1,25$(OH)_2D_3$: 1,25-calcitriol; Rocaltrol, Calcijex) is the active form of vitamin D. Its concentration in the blood is 1/500 that of its monohydroxylated precursor. The biosynthesis of vitamin D is tightly regulated based on the serum concentrations of calcium, phosphate, PTH, and active vitamin D (2).

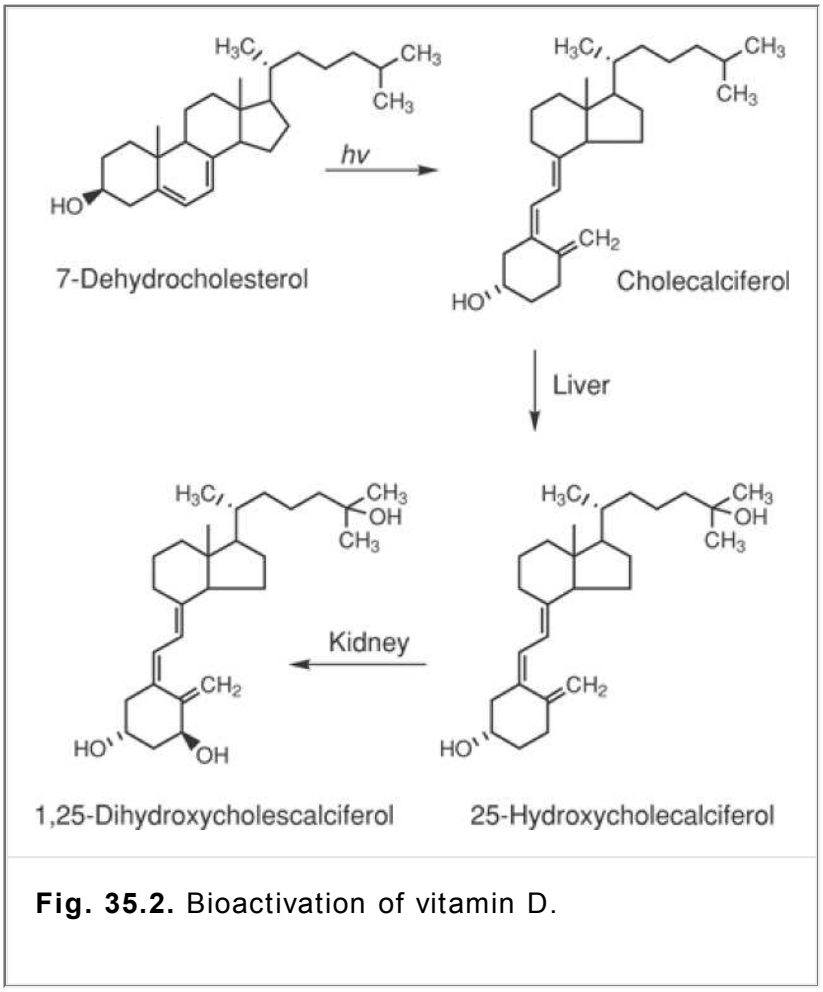


Fig. 35.2. Bioactivation of vitamin D.

Sterol-specific cytoplasmic receptor proteins (vitamin D receptor) mediate the biological action of vitamin D (9). The active hormone is transported from the cytoplasm to the nucleus via the vitamin D receptor, and as a result of the interaction of the hormone with target genes, a variety of proteins are produced that stimulate the transport of calcium in each of the target tissues. Active vitamin D works in concert with PTH to enhance active intestinal absorption of calcium, to stimulate bone resorption, and to prohibit renal excretion of calcium (2,9). If serum calcium or 1,25-calcitriol concentrations are elevated, then vitamin D 24-hydroxylase (in renal mitochondria) is activated to oxidize 25(OH)D_3 to inactive 24,25-dihydroxy-cholecalciferol and to further oxidize active vitamin D to the inactive 1,24,25-trihydroxylated derivative. Both the 1,24,25-trihydroxylated and the 24,25-dihydroxylated products have been found to suppress PTH secretion as well. Several factors have been identified in the regulation of the biosynthesis of vitamin D, including low phosphate concentrations (stimulatory) as well as pregnancy and lactation (stimulatory).

Normal Physiology

During growth periods in childhood and early adulthood, bone formation characteristically exceeds bone loss. In young adulthood, bone formation and bone resorption are nearly equal. After the age of 40 years, however, bone resorption is slightly greater than bone formation, and this results in a gradual decline in skeletal mass. Osteoblasts, osteoclasts, and osteocytes are the three types of cells that make up the bone remodeling unit (3) or bone metabolizing unit (4) and, therefore, are largely responsible for the bone remodeling process.

Osteoblasts, which are of mesenchymal origin and are formed in the bone marrow, stimulate bone formation (6). In the maturation process, osteoblasts undergo multiple cell divisions and, in so doing, express the gene products that are needed to form the bone matrix or osteoid (3) as well as those products responsible for mineralization of that tissue (6). Multiple endogenous substances are involved in osteoblast maturation, including many cytokines (interleukins and granulocyte-macrophage colony-stimulating-factor) (3) as well as hormones and growth factors (6). It is in the rough endoplasmic reticulum that the biosynthesis of the bone matrix protein occurs (4).

Osteoclasts are the large multinucleated cells of hemopoietic origin (6) that are responsible for carrying out the

bone resorption or destroying process. Cytokines, PTH, and the active form of vitamin D activate these cells. Bone lining flat cells, derived from "retired" osteoclasts and osteoblasts, are located on the bone surface (3). The function of these flat cells is thought to serve to identify areas of the bone that have become weakened or misshapen and to send a signal to the bone remodeling unit to prepare the bone. Lining cells then digest the outer layer of the bone matrix in preparation for bone remodeling. The osteoclast membrane then comes into contact with the bone surface and forms an impermeable "sealing zone" of approximately 500 to 1,000 μm in size (2,6). The H^+ ATPase-rich osteoclast membrane that is in contact with the bone surface forms a ruffled border, the sealing zone becomes acidified, and ultimately, the bone minerals dissolve (6). Several types of lysosomal enzymes have been proposed to then digest the collagen matrix (3), thereby pitting the bone surface to a depth of 50 μm (4,5,6). Only calcitonin acts directly on the osteoclast to prevent bone resorption.

Yet another type of cell is found deep within the bone matrix, the osteocyte. The role of this type of cell has yet to be elucidated, but it has been proposed that it may be responsible for maintaining bone integrity (3) and for providing nutrition to the bone.

Parathyroid hormone stimulates bone resorption by several mechanisms: 1) Transformation of osteoprogenitor cells into osteoclasts is stimulated in the presence of PTH, 2) PTH promotes the deep osteocytes to mobilize calcium from perilacunar bone, and 3) surface osteocytes are stimulated by PTH to increase the flow of calcium out of the bone.

Quantification of bone mineral density (BMD) can be measured by noninvasive radiographic tests, such as single-photon (3) or dual-photon absorptiometry (spine, hip, and total body) (10), dual-energy x-ray absorptiometry (3,10,11) (spine, hip, total and body), peripheral dual-energy x-ray absorptiometry (wrist, heel, and finger), single energy x-ray absorptiometry (wrist or heel) (12), quantitative computed tomography (spine) and peripheral quantitative computed tomography (wrist) (10), and quantitative ultrasound (heel, shin bone, and knee cap) (12). Dual-energy x-ray absorptiometry is considered to be the gold standard for measuring bone density and has an accuracy that exceeds 95% (4). These techniques measure the attenuation of x-rays or gamma rays as they cross the spine, hip, or radius before they reach the detector (6). Other methods under development that measure BMD include ultrasound, traditional x-rays, and blood/urine tests (6). Traditional x-rays can identify the site of fracture, but they cannot measure BMD (3). Blood/urine tests can identify if the patient is suffering from a medical condition (3) that is contributing to the loss of BMD and can identify important biochemical markers that can assess the rate of

bone resorption and bone turnover. The measurement of serum calcium, phosphorous, and vitamin D levels also may provide insight regarding the cause of decreased BMD (3). Often, patients suffer from multiple vertebral compression fractures (3) without seeking treatment other than an over-the-counter analgesic, and the diagnosis of osteoporosis occurs only after the patient has already lost significant (as much as 30%) bone mass.

Table 35.1. Classification of Osteoporosis (14)

Etiology	Type I (postmenopausal) Increased Osteoclast Activity and Bone Resorption	Type II (senile) Decreased Osteoblast Activity and Bone Formation; Decreased GI Ca Absorption	Type III (secondary) Drug Therapies; Disease States
Typical age at diagnosis	50–75	>70	any age
Gender ratio	6:1 women/men	2:1 women/men	1:1 women/men
Typical fracture site	vertebrae, distal radius	femoral, neck, hip	vertebrae, hip, extremities

Bone morphology	decreased trabecular	decreased trabecular and normal cortical bone	decreased cortical bone
Rate of bone loss	2–3% per year	0.3–0.5% per year	variable

Disease States Associated With Abnormal Calcium Homeostasis

Osteoporosis

Osteoporosis is a skeletal disease that is characterized by loss of bone mass as well as microarchitectural deterioration of the bone tissue. This disease is associated with increased bone fragility and susceptibility to fracture. It is a condition that is characterized not by inadequate bone formation but, rather, by a deficiency in the production of well-mineralized bone mass. Whereas no medical cause typically is evident in primary osteoporosis (3), secondary osteoporosis classically stems from medical illness or medication use. There are two types of primary adult osteoporosis, type I, or postmenopausal, and type II, or senile (Table 35.1). In type I osteoporosis, there is an accelerated rate of bone loss via enhanced resorption at the onset of menopause. In this form of the disease, the loss of trabecular bone is threefold greater than the loss of cortical bone. This disproportionate loss of bone mass is the primary cause of the vertebral crush fractures and the wrist and ankle fractures experienced by postmenopausal women. In type II osteoporosis, which is associated with aging, the degree of bone loss is similar in both trabecular and cortical bone (5) and is caused by decreased bone formation by the osteoblasts.

Drug- or disease-induced, or type III, osteoporosis (Table 35.2) accounts for up to 30% of the cases of vertebral fractures reported annually. It can be caused by a variety of factors, including long-term suppression of osteoblast function, an inhibition of calcium absorption from the gut, or excessive loss of calcium in the urine, as a result of estrogen deficiency, hyperparathyroidism (6,11), hyperthyroidism (6,11), hypogonadism (11,13), renal disease (6), depression, and treatment with glucocorticoids (13), thyroid hormone, anticonvulsants, methotrexate (13), cyclosporine (13), warfarin, lithium, or immunosuppressive therapy (6). Warfarin impairs the vitamin K–dependent biosynthesis of osteocalcin (13), it prevents the recycling of oxidized vitamin K to its active reduced form via inhibition of vitamin K epoxide reductase and vitamin K reductase. Long-term therapy with glucocorticoids has been shown to directly suppress osteoblast function and reduce calcium absorption from the gut (13). Vitamin D deficiency, as the cause of pseudohyperparathyroidism, is a common cause of osteoporosis in elder persons who are institutionalized and lack adequate sunlight exposure (2).

Osteoporosis is the cause of nearly 1.5 million fractures annually in the United States (3), including 250,000 hip fractures and 550,000 vertebral fractures. As it relates to the percentage of women older than 50 years who are at risk for developing osteoporosis because of low bone mass, the statistics are sobering: 52% of Caucasian and Asian women, 35% of African-American women, and 49% of Hispanic women. It has been predicted that one in every three women who live to the age of 90 years will experience a hip fracture (3,15). It has been estimated that 15 to 35% of hip fracture patients will require long-term nursing home care. A surprising 60% of hip fracture patients do not regain full function, and within 3 to 4

months of hip fracture, as many as 25% die as a result of secondary complications (e.g., pneumonia or infection). Mortality also is increased 17% after both femoral and vertebral fractures. The risk factors associated with osteoporosis are presented in Table 35.3. Given these statistics, osteoporosis should be considered a significant health problem that only stands to worsen unless appropriate interventions are pursued.

Table 35.2. Causes of Secondary (Type III) Osteoporosis (13,15)

Alcohol	Hypopituitarism
Algodystrophy	Mastocytosis
Anorexia nervosa	Mylenoma
Celiac disease	Organ transplant
Crohn's disease	Osteogenesis imperfecta
Diabetes mellitus	Primary biliary cirrhosis
Drug-induced	Pregnancy
(corticosteroids, heparin, warfarin)	Rheumatic diseases Thyrotoxicosis/thyroid replacement
Exercise induced amenorrhea	
Gastrectomy	Turner's syndrome
Hyperparathyroidism	Ulcerative colitis
Hypogonadism	

Table 35.3. Risk Factors for Osteoporosis (3)

Lifestyle Factors	Genetic Factors	Medical Disorders	Drugs
Smoking	White or Asian	Cushing's syndrome	Glucocorticoids
Sedentary lifestyle	Female	Hyperthyroidism	Thyroid hormone
Calcium intake	Family history	Congenital hypogonadism	Phenytoin
Milk intolerance	Small frame	Primary biliary cirrhosis	Carbamazepine

Excessive caffeine	Early menopause	Malabsorption syndromes	Heparin
Excessive alcohol		Gastrointestinal resection	Aluminum antacids
Nulliparity		Primary hyperparathyroidism	GnRH agonists
High protein intake		Anorexia nervosa Multiple myeloma Depression	Furosemide

GnRH, gonadotropin-releasing hormone.

Osteopetrosis

Osteopetrosis, also known as marble bone disease, describes a group of heritable disorders that are centered on a defect in osteoclast-mediated bone resorption. There are four autosomal recessive and one autosomal dominant forms of osteopetrosis (Table 35.4) (16). It generally is characterized by abnormally dense, brittle bone and increased skeletal mass. Unlike osteoporosis, this disorder results from decreased osteoclast activity, which has an effect on both the shape and structure of the bone. In very extreme cases, the medullary cavity, which houses bone marrow, fills with new bone, and production of hematopoietic cells is hampered. Like osteoporosis, this disease can be detected radiographically and appears as though there is a "bone within a bone." There is limited evidence that bisphosphonates can induce osteopetrosis via their inhibition of osteoclast activity (17).

Hypocalcemia

Hypocalcemia can be caused by PTH deficiency, vitamin D deficiency, various pharmacological agents, and miscellaneous disorders (Table 35.5) (18). A state of hypocalcemia will inhibit calcitonin release. This results in an elevation of PTH biosynthesis and release and indirectly causes an increase in the production of vitamin D. The left wing of Arnaud's butterfly model (Fig. 35.1) would be activated to increase serum calcium concentrations. In the absence of calcitonin, osteoclast activity is unregulated; therefore, bone resorption is accelerated. In acute cases of hypocalcemia, specifically in the case of hypocalcemic tetany, PTH is administered to correct the hormonal imbalance.

Hypercalcemia

A state of hypercalcemia (Table 35.6) will promote calcitonin biosynthesis and release. As a result, PTH biosynthesis and its secretion are inhibited, as is the production of vitamin D. The right wings of Arnaud's butterfly model (Fig. 35.1, B loops) would be activated to decrease serum calcium concentrations. In the presence of calcitonin,

osteoclast activity is inhibited, so bone resorption is slowed. In acute cases of hypercalcemia, calcitonin is administered to reestablish calcium homeostasis. Hypercalcemia also can be treated with sulfate salts, ethylenediaminetetraacetic acid, furosemide, ethacrynic acid, glucocorticoids, and plicamycin.

Table 35.4. Human Osteopetrosis Genotypes

Gene Involved	Function of Gene	Clinical Symptoms	% Patients Affected

Autosomal Recessive Disorders			
CAII	Carbonic acid and proton production	Less severe: may improve with age, short stature, no hematologic failure	<5%
TCIRG1	Proton pump	Severe: apparent in infancy, visual impairment, hypocalcemia, death by 10 years of age	~60%
CLCN7	Chloride channel	Severe: apparent in infancy, similar to TCIRG1 symptoms Intermediate: apparent in infancy but less aggressive, osteomyelitis, fractures	~15%
gl/gl	Unknown	Extremely severe: death within months	<5%
Autosomal Dominant Disorder			
CLCN7	Chloride channel	Frequent fractures, osteomyelitis, some more severe (like recessive disorders)	

Table 35.5. Causes for Hypocalcemia

PTH Deficiency	Vitamin D Deficiency	Drugs	Miscellaneous
Hypoparathyroidism	Nutritional deficiency	Chemotherapeutic agents	Osteoblastic metastases
Pseudohypoparathyroidism	Gastrointestinal malabsorption	Diuretics • Furosemide	Phosphate infusion
Hypomagnesemia	Renal • Failure • Tubule disorders • Nephrotic syndrome Hepatobiliary disease (decreased synthesis)	Inhibitors of bone resorption • Calcitonin • Bisphosphonates • Estrogens Antiviral •Foscarnet Antifungal •Ketoconazole	Rapid infusion of citrate buffered plasma or blood or large amounts of albumin

	Pancreatic disease (malabsorption) Anticonvulsant therapy (malabsorption, abnormal metabolism)		

Hypoparathyroidism

Hypoparathyroidism is caused by decreased serum PTH concentrations. It is characterized by hypocalcemia, hyperphosphatemia, and reduced levels of circulating vitamin D. The right wings of Arnaud's butterfly model is predominant (Fig. 35.1), and serum calcium concentrations precipitously decrease. Administration of intravenous (IV) calcium gluconate and PTH serves to acutely correct plasma calcium levels. Chronic oral administration of active vitamin D as well as calcium supplements has been effective in maintaining appropriate serum calcium concentrations.

Pseudohypoparathyroidism

In this disease state, levels of PTH are normal or even elevated; however, serum calcium concentrations are low. End-organ insensitivity to PTH has been proposed to be the cause of the hypocalcemic state. Treatment of this condition with calcium and vitamin D has proven to be successful.

Hyperparathyroidism

Increased levels of PTH leads to moderately to severely elevated serum calcium concentrations (2) and, as a result, a significant loss of calcium from the bone. Deposits of calcium salts in soft tissue as well as formation of renal calculi also can result from this hormonal imbalance. Treatment of this condition with salmon calcitonin, loop diuretics, or other classical treatments for hypercalcemia has been favorable. The IV vitamin D analogue paricalcitol, which is used for both prevention and treatment of hyperparathyroidism secondary to chronic renal failure, has been shown to reduce parathyroid levels by an average of 30% after 6 weeks of treatment. Whereas paricalcitol is a fully active form of vitamin D, doxercalciferol requires activation by the liver. This analogue also is indicated for the treatment of secondary hyperparathyroidism. Doxercalciferol capsules should be administered three times weekly at the time of dialysis along with close monitoring of calcium and phosphate levels. Treatment of secondary hyperparathyroidism with vitamin D therapy is problematic, however, because it often leads to

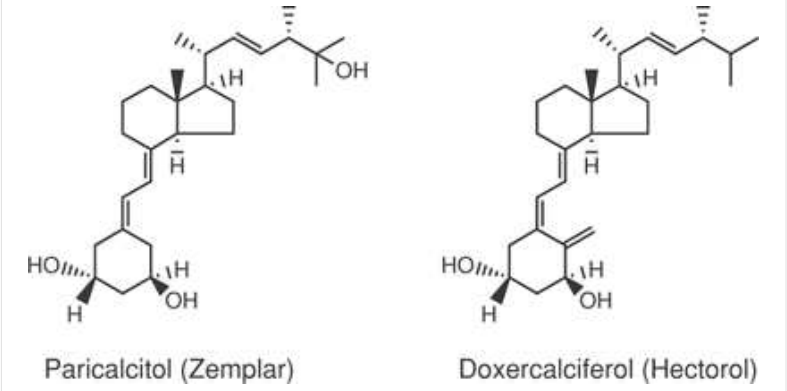
hypercalcemia, hyperphosphatemia, or both because of increased intestinal absorption of both calcium and phosphorous (19). In patients with chronic renal failure, CaSR agonists are able to limit progression of hyperparathyroidism and growth of the parathyroid gland.

Table 35.6. Calcium Homeostasis-Related Disorders

Type of Disorder	Treatment	Examples
Disorders leading to hypercalcemia	Fluids, low calcium diet, sulfate, loop diuretics, glucocorticoids, calcitonin, EDTA	Hyperparathyroidism Hypervitaminosis D Sarcoidosis Neoplasia Hyperthyroidism Immobilization Paget's disease of the bone

		Osteoporosis
Disorders of bone remodeling	Bisphosphonates, calcitonin, estrogen, calcitonin, calcium, fluoride, PTH + vitamin D	

EDTA, ethylenediaminetetra-acetic acid; PTH, parathyroid hormone.



Rickets and Osteomalacia

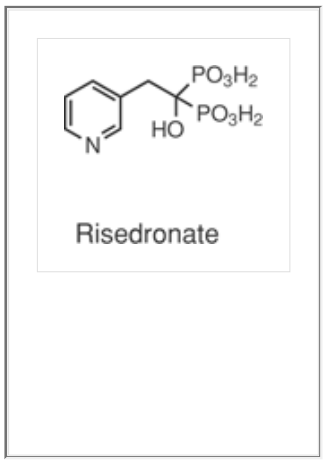
During the Industrial Revolution, there was widespread incidence of rickets in both children and adults, because inadequate exposure to sunlight prevented the biosynthesis of active vitamin D in the skin. Both rickets and osteomalacia are metabolic bone diseases that are characterized by poor bone mineralization. Without adequate plasma levels of vitamin D and calcium, deposition of the calcium salts in the bone markedly decreases. Vitamin D supplementation (to improve intestinal absorption of calcium and mineralization of the bone) as well as oral calcium supplementation are required to treat these diseases once established. The incidence of rickets in the United States dropped dramatically through vitamin D–supplemented food programs. The increased use of milk substitutes (e.g., soy) and reduced exposure to sunlight has recently led to a rise in rickets. Rickets is still considered to be a worldwide health problem.

In addition to the classical environmental or nutritional cause of these diseases, both osteomalacia and rickets can have a pharmacological origin via chronic treatment with anticonvulsants (phenobarbital and phenytoin) or glucocorticoids. These agents interfere with intestinal absorption of calcium and, thereby, cause pseudohyperparathyroidism. As a result, an increase in bone turnover and a decrease in the formation of appropriately mineralized bone is observed. In these patients, treatment with vitamin D improves calcium absorption, ultimately enhancing mineralization of the bone.

Paget's Disease

Paget's disease (Table 35.6) is characterized by excessive bone resorption, followed by replacement of the normally mineralized bone with soft, poorly mineralized tissue (20). It has been determined that the osteoclasts have an abnormal structure, are hyperactive, and are present at elevated levels (20). Patients afflicted with this painful condition often suffer from multiple compression fractures. Administration of calcitonin and oral calcium and phosphate supplements had been the treatment of choice until the bisphosphonate risedronate was approved by the U.S. Food and Drug Administration (FDA). Daily administration of risedronate results in a decreased rate of bone turnover and a decrease in the levels of serum alkaline phosphatase and urinary hydroxyproline, two biochemical markers of bone turnover (4,20). A significant advantage to treatment with the bisphosphonates is long-term suppression of the disease (20). Calcium supplementation, which often is necessary in these patients, must be dosed separately from risedronate, because calcium- and aluminum- or

magnesium-containing antacids interfere with absorption of the bisphosphonates.



Drug Therapies Used to Treat Osteoporosis

Agents used in the treatment and prevention of osteoporosis are categorized as antiresorptive agents, or bone-forming agents depending on the primary mechanism of action (21). For most effective therapies, bone mass increases for the first few years of treatment. Eventually, however, all the pits or lacunae will be filled in with new bone, and no additional increase in bone mass will occur. Antiresorptive agents have been shown to increase bone mass by as much as 8 to 9% at the lumbar spine and 3 to 6% in the femoral neck. Once a diagnosis of osteoporosis and the likely cause has been established, it is important to gather both patient fracture history and general medical history. This information is essential to select the appropriate treatment for a given patient (Table 35.7) (22).

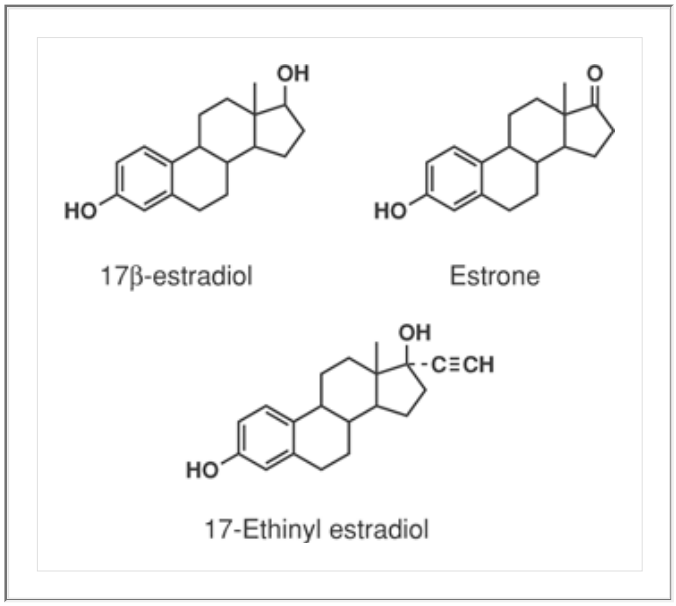
Antiresorptive Agents

Estrogen Analogues—Estrogen Replacement Therapy

Mechanism of action

The precise mechanism by which estrogen prevents bone resorption has not been elucidated; however, it has been proposed to be associated with inhibition of osteoclast activity. Limited evidence supports the presence of estrogen-specific receptors (present on osteoclasts) having a biochemical role in the regulation of

bone remodeling (14). Estrogen improves calcium absorption, promotes calcitonin biosynthesis, and increases the vitamin D receptors on osteoclasts. Although the primary mechanism of action remains unclear and its use is controversial at best, hormone replacement therapy is considered to be second-line therapy for the prevention of osteoporosis (23). Estrogen receptor therapy (ERT; e.g., 17β-estradiol, estrone sodium sulfate, or 17-ethinyl estradiol) (21) is classified as antiresorptive therapy in the prevention of osteoporosis. The pharmacokinetics of the estrogens is covered in detail in Chapter 46.



Patient Data	Alendronate	Risedronate	Raloxifene	Calcitonin	Teriparatide
PM women: (+) osteoporosis/(+) fracture	√	√	√	√	√
PM women: (+) osteoporosis/(–) fracture	√				
Men: (+) osteoporosis	√				√
Corticosteroid induced osteoporosis	√		√		
(+) Esophageal or upper GI disorder	(–)	(–)	√	√	
(+) Vasomotor symptoms	√	√	(–)	√	
(+) Venous thromboembolic event	√	√	(–)	√	
(+) Vertebral compression fracture pain				√	

√ = Recommended; (–) = Not recommended

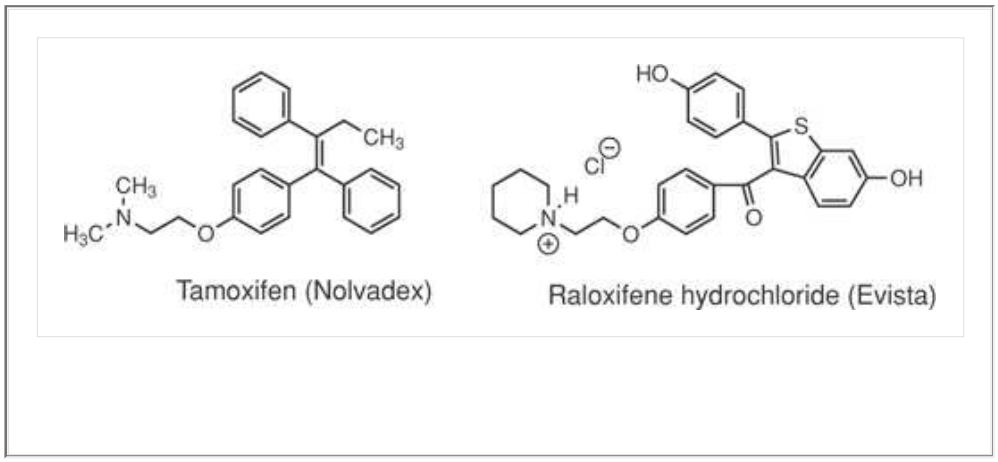
Table 35.7. Osteoporosis Treatment Selection Criteria (22)

Therapeutic effects

Fractures of the spine, wrist, and hips decrease by 50 to 70%, and spinal bone density increases by 5% (24), in those women treated with estrogen within 3 years of the onset of menopause and for 5 to 10 years thereafter (5,11,25). The minimum dose required and that which is considered to be standard therapy is 0.625 mg/day of conjugated estrogens (Premarin); however, a 0.3 mg/day dose of esterified estrogen (Estratab) has been shown to be adequate for the prevention of osteoporosis (5). Estrogen replacement therapy is available in several types of formulations, including transdermal patches (Climera, Estraderm, Menostar, or Vivelle).

Initiated at the onset of menopause, this therapy also has favorable effects on serum cholesterol levels (reduces low-density lipoprotein and elevates high-density lipoprotein levels). Women taking ERT have found relief from hot flashes, vaginal dryness, and urinary stress incontinence (21). It is recommended that the estrogen be combined with a progestin for those women with an intact uterus so as to decrease the risk of

endometrial cancer (14). Hormone replacement therapy is not necessarily the treatment of choice for all women, because some are intolerant to this type of therapy or have a disease state in which ERT is contraindicated (e.g., breast cancer, liver disease, or active thromboembolic disease) (3).



Selective Estrogen Receptor Modulators

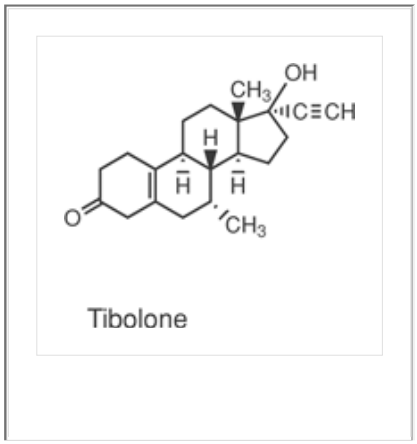
Raloxifene

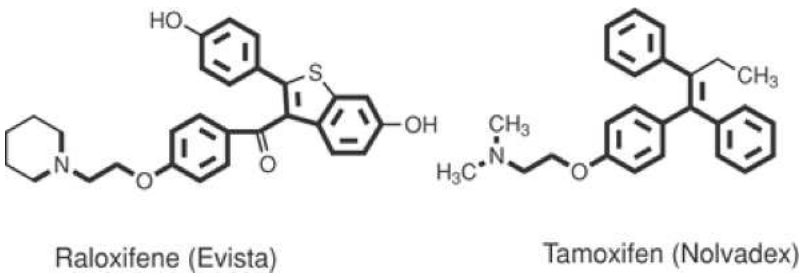
Tamoxifen citrate, which is classified chemically as a triarylethylene, was developed as an antiestrogenic drug and as a selective estrogen receptor modulator (SERM). It is prescribed for the treatment of metastatic breast cancer. Raloxifene hydrochloride, a benzothiophene

P.944

derivative (24), also may be considered to be a semirigid analogue of tamoxifen (Fig. 35.3). The two drugs are similar in that they both possess agonist activity in certain tissues (e.g., bone and cardiovascular) and antagonist activity in others (e.g., breast and uterus) (6,21) (see Chapter 46). Raloxifene, the first SERM approved for the prevention of osteoporosis in postmenopausal women, acts as an estrogen agonist on receptors in osteoblasts and osteoclasts but as an antagonist at breast and uterine estrogen receptors. This selective action means that this agent does not increase the risk of endometrial or breast cancer, as is the case with long-term tamoxifen therapy. Because this agent does not have a stimulatory effect at its receptors on most tissues, it does not prevent the hot flashes and other symptoms of menopause as estrogen does (5).

Tibolone is a synthetic steroid that has been shown to increase bone mineral density similar to alendronate. The U.S. FDA approval is pending; overseas, this agent is used for the treatment of menopausal symptoms as well as the prevention of osteoporosis. It is considered to be a viable alternative to conjugated equine estrogen plus micronized progesterone. With the 2.5-mg dose and calcium supplementation (800 mg/day), an increase in the lumbar spine and femoral neck bone density has been demonstrated. The ability of tibolone to prevent bone loss is proposed to be mediated through its estrogenic metabolites via the estrogen receptor (26). The most common reason for patient withdrawal from clinical trials was vaginal bleeding (also a common side effect when estrogen therapy is used).





Raloxifene (Evista) Tamoxifen (Nolvadex)

Fig. 35.3. Structures of raloxifene and tamoxifen, highlighting the similarity between the two drugs.

Therapeutic Action

Clinical trials have shown that raloxifene, in combination with oral calcium supplementation, decreases the risk of vertebral fracture and promotes bone formation, albeit to a lesser extent than with estrogen. Raloxifene has been shown to have a beneficial effect on lipid profiles (11). Raloxifene should not be administered in combination with cholestyramine (decreased absorption), coumadin (prothrombin times and international normalized ratios must be monitored more closely), and those drugs that are highly protein bound, such as clofibrate, diazepam, ibuprofen, indomethacin, and naproxen.

Structure–Activity Relationship

From a structural perspective, the only pure antiestrogens are 7α-substituted estrogens (21). In the triarylethylene class of agents, the A ring phenol is critical for binding to the estrogen receptor, because it mimics the essential 3-phenolic group in estrogens (21). The orientation of the three aryl rings in a propeller type of arrangement also is important for tight receptor binding and biological activity (21).

Pharmacokinetics

Raloxifene is rapidly absorbed following oral administration, with an estimated 60% absorption, but it has a very low bioavailability (2%), associated with extensive phase II metabolism. The metabolites are excreted via the bile, with potential enterohepatic recycling that could account for the interaction with cholestyramine. Supportive of the enterohepatic recycling is the half-life of 28 hours. Metabolism of raloxifene occurs to a great extent in the intestine and consists of glucuronide conjugation catalyzed by uridine diphosphate glucuronosyltransferase (UGT) (27,28,29). The UGT1A family is responsible for intestinal human metabolism, as shown in Figure 35.4. Efflux by intestinal cells of the resulting glucuronide occurs via P-glycoprotein and multidrug resistance–related protein. The combination of rapid metabolism and efflux can account for the low bioavailability.

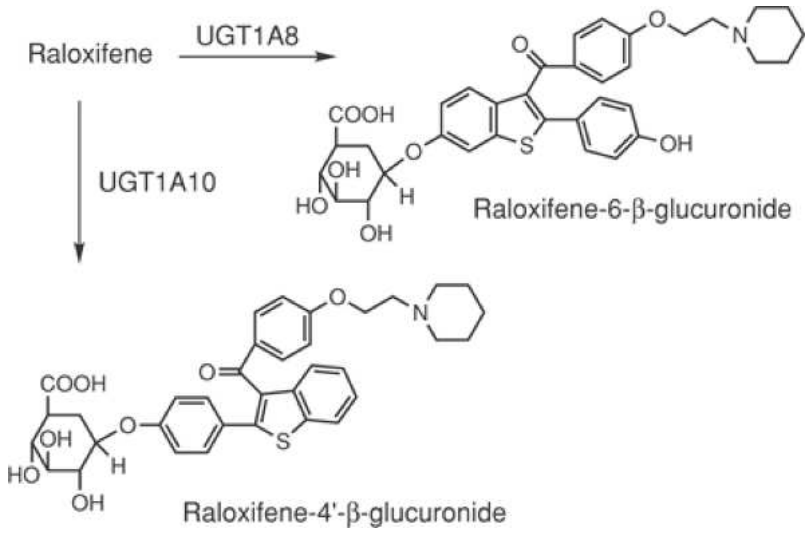


Fig. 35.4. Metabolism of raloxifene.

Lasofoxifene

Lasofoxifene is a very potent second-generation SERM currently in phase III clinical trials for the treatment and prevention of osteoporosis in postmenopausal women (Fig. 35.5). At low doses, this agent has been shown to prevent bone loss and decrease serum cholesterol (dose range, 0.01–20.0 mg/day). In early clinical trials, lasofoxifene improved BMD in the lumbar spine by 3% (after 12 months of therapy), which is twice the improvement observed with similar treatment using raloxifene. Improvement in hip BMD was similar for both agents. Interestingly, a more pronounced reduction

in low-density lipoprotein cholesterol was observed with lasofoxifene treatment than with raloxifene treatment. As of September 2005, the U.S. FDA had rejected an New Drug Application (NDA) for lasofoxifene for undisclosed reasons.

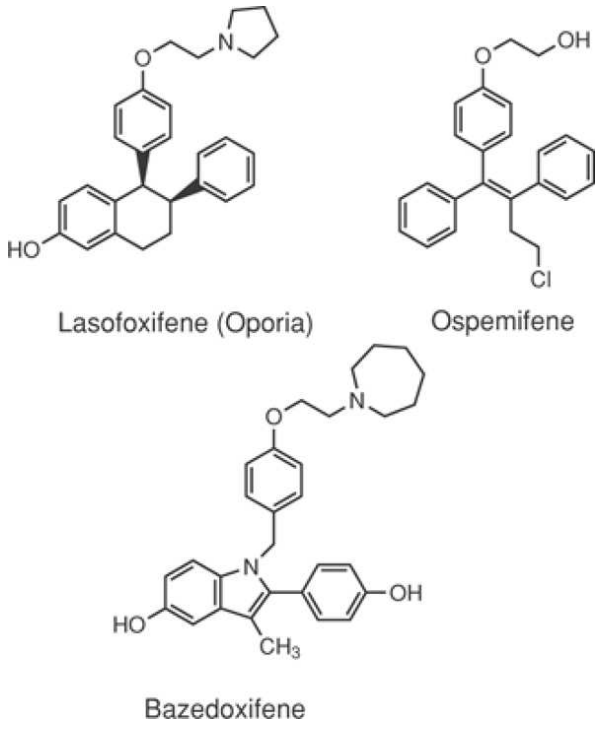

Fig. 35.5. Investigational second-generation selective estrogen receptor modulators.

Ospemifene is a SERM that is currently in Phase II/III clinical trials for the treatment of postmenopausal osteoporosis and urogenital atrophy (Fig. 35.5). It is a known metabolite of toremifene, a triphenylethylene derivative used to treat breast cancer. Ospemifene has been shown to have beneficial effects on the bone without significant estrogen-related side effects. The beneficial effect observed on bone stems from this agent's ability to increase osteoblast proliferation and, as a result, to enhance bone mineralization as well as bone formation. Unlike tamoxifen, ospemifene does not induce osteocyte apoptosis (30).

Bazedoxifene is an indole-based SERM that is under investigation for the treatment and prevention of postmenopausal osteoporosis (Fig. 35.5). It also is being evaluated in combination with Premarin (conjugated estrogens). Bazedoxifene displaces 17β-estradiol from estrogen receptors and has excellent binding affinity for the receptor itself. Unlike raloxifene, this agent does not cause hot flashes at the doses required to have a beneficial effect on bone. In addition, it does not cause uterine or mammary gland stimulation (31).

Bisphosphonates

Mechanism of action

The bisphosphonates are synthetic in origin and are designed to mimic pyrophosphate, where the oxygen in P-O-P is replaced with a carbon atom to create a nonhydrolyzable backbone (24,25) (Fig. 35.6). Because pyrophosphate is a normal constituent of bone, these analogues selectively bind to the hydroxyapatite portion of the bone (25,32). The bisphosphonates (Fig. 35.7) effectively inhibit osteoclast proliferation, decrease osteoclast activity, reduce osteoclast life span, and as a result, decrease the number of sites along the bone surface where bone resorption occurs (25). By these three mechanisms, the bisphosphonates are able to limit bone turnover and allow the osteoblasts to form well-mineralized bone without opposition (3). The precise mechanisms of action of these antiresorptive agents has not been elucidated; it is equally uncertain whether all the bisphosphonates act by a similar mechanism (25). To date, cell surface receptors have not been identified, nor has a second messenger system been detected.

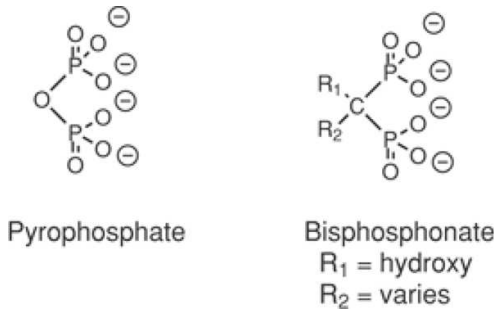

Fig. 35.6. Bisphosphonate structure–activity relationships.

Structure–activity relationships

From a structural perspective, the bisphosphonates have been proposed to have specific molecular interactions with their biological target for drug action, even though precise structure–activity relationships (SARs) have not been elucidated. In fact, the exact molecular target is still under investigation. The central carbon of the geminal phosphonate has been substituted with a variety of functional groups to yield a large family of compounds with differing physicochemical and biological properties (25). The SAR studies (Fig. 35.6) have concluded that a hydroxyl substituent (R_1) maximizes the affinity of the agent for the hydroxyapatite

as well as improves the antiresorptive character of the agent (21,33). The character of the R_2 substituent varies widely and clearly has a significant influence on the potency of this class of compounds (Fig. 35.7). The R_2 amino–substituted bisphosphonates (pamidronate, alendronate, and neridronate) are more potent than etidronate and clodronate (not available in the United States). The R_2 4-carbon amino linear chain for alendronate is more potent than the R_2 3-carbon derivative pamidronate and the R_2 6-carbon analogue neridronate (21). Alkylation of the amine functional group improving potency as is demonstrated by compounds with branched amine substituents at R_2 (e.g., olpadronate and ibandronate) and those that contain rings at R_2 (e.g., risedronate, incandronate, tiludronate, and zoledronate). The third-generation analogues contain a basic heterocyclic side chain at R_2 tethered to the central carbon by a variety of linkages (potency: NH > CH_2 > S > O) (21,33). Because structural variation of R_2 has a significant effect on potency, it can be surmised that R_2 interacts at an “active site” and participates in a specific molecular interaction. The bisphosphonate itself as well as the hydroxyl group at R_1 also should be included as critical SAR features (21).

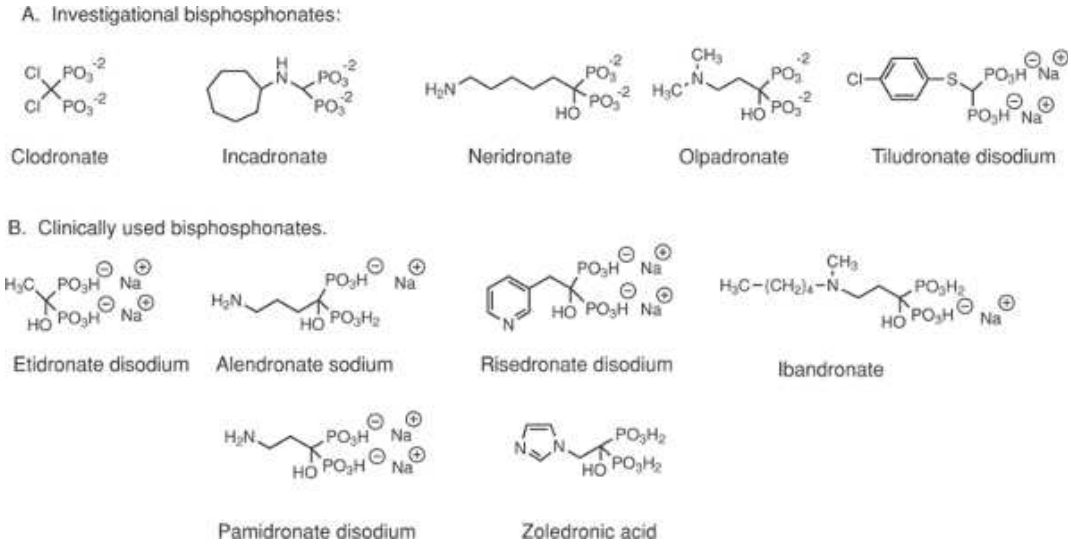

Fig. 35.7. Bisphosphonates, both investigational and clinically used.

Pharmacokinetics

To date, four generations of bisphosphonates have been developed for the treatment of osteoporosis (Fig. 35.7). Absorption of these agents from the gut is quite poor (1–5%) (11) because of their polar nature, and as a therapeutic class, they have limited cellular penetration. Up to 50% of the actual absorbed dose is taken up specifically by the bone within 4 to 6 hours, and the rest is exclusively excreted by the kidney (6,24). Uptake of these agents in the bone is concentrated in areas of the bone that are actively undergoing remodeling (32). Between the selective uptake and the rapid rate of clearance, the bisphosphonates enjoy a short circulating half-life and very limited drug exposure to nontarget tissues (25). Because the bisphosphonates are only released from the bone when the bone is resorbed, they have a tissue half-life of 1 to 10 years; however, these agents remain pharmacologically active only while they are exposed on bone resorption surfaces (32).

Specific Drugs

Etidronate Disodium (Didronel)

Agents in the first generation (e.g., etidronate disodium and tiludronate) that were dosed continuously produced poorly mineralized bone (3), because there was no interval for appropriate bone mineralization to occur. Subsequent studies that used a cyclic dosing schedule (400 mg/day for 2 weeks, followed by 2.5 months of calcium supplementation only) showed improvement in bone mineralization (11,30). Etidronate has been approved for treatment of Paget's disease of the bone but not for treatment of osteoporosis (5). Tiludronate (6) is approximately 10-fold more potent than etidronate and, when given orally for 6 months (200, 400, or 800 mg/day), increases BMD by 2%. No further bone loss was detected in patients 6 months after cessation of therapy.

Alendronate Sodium (Fosamax)

The second-generation agent alendronate sodium was the first bisphosphonate agent approved by the U.S. FDA for the prevention and treatment of osteoporosis and Paget's disease of the bone (32,34) and is 1,000-fold more potent than etidronate. This derivative, when dosed continuously (5–10 mg/day for osteoporosis and 40 mg/day for Paget's disease) and given with oral calcium supplements (500 mg/day), produced well-mineralized bone and significantly improved BMD (7% in the spine and 4% in the hip) within 18 months (6). In addition, the vertebral fracture rate was shown to decrease by 47%. A side effect associated with alendronate, chemical esophagitis (2,3,11,24), has been attributed to inadequate intake of water and lying down after taking the medication. Specific patient instructions were developed to limit the incidence of upper gastrointestinal problems and include: 1) taking the medication with 6 to 8 ounces of water on arising in the morning, 2)

remaining in an upright position for at least 30 minutes after taking the medication, and 3) delaying drinking other liquids/eating for at least 30 minutes, if not 1 to 2 hours, to allow maximal absorption of the agent (3). To enhance absorption, calcium supplements and any aluminum- or magnesium-containing antacids should be dosed separately from the agents in this class. These agents are not recommended in patients with renal impairment (serum creatinine, <2.5 mg/dL), a history of esophageal disease, gastritis, or peptic ulcer (5).

Risedronate Disodium (Actonel)

The third-generation agent risedronate disodium has been approved not only for the treatment of osteoporosis but also for the treatment of Paget's disease of the bone and glucocorticoid-induced osteoporosis. Risedronate is 1,000- to 5,000-fold more potent than etidronate. At the end of an 18-month study, 53% of those patients that took risedronate for 2 months remained in remission, as compared to 14% of the patients that took etidronate, an earlier-generation bisphosphonate, for 6 months. Oral administration of this agent suffers from the same problems as that of other bisphosphonate agents. Risedronate should not be given to patients with creatinine clearance of less than 30 mL/min.

A new formulation of alendronate, FOSAMAX PLUS D, was approved by the U.S. FDA in April 2005. This formulation includes 70 mg of alendronate and 2,800 IU of vitamin D_3 (i.e., a 7-day supply of both the bisphosphonate and vitamin D). This formulation should not be used in patients with severe kidney disease or low serum calcium levels and should not be the only therapy used to correct a vitamin D deficiency.

Risedronate with calcium, which was approved by the U.S. FDA in August 2005, represents a novel type of packaging for this class of agents. It addresses the Surgeon General's Report on Bone Health and Osteoporosis, which states that treatments for osteoporosis need to be made simpler and more structured. Sold in units that contain a 1-month supply, each week of therapy includes a total of seven tablets, including one 35-mg tablet of risedronate and six 500-mg tablets of calcium carbonate.

Ibandronate Sodium (Boniva)

Ibandronate sodium was approved in May 2003 for the treatment and prevention of osteoporosis in postmenopausal women. Its mechanism of action is identical to the other bisphosphonate agents. Administered daily (2.5 mg), ibandronate has been clinically shown to reduce the risk of vertebral fractures by 62% (35). If administered on an intermittent basis (20 mg), it reduces the risk of vertebral fractures by 50%. Ibandronate (2.5 mg daily), along with 500 mg of supplemental calcium, has been clinically shown to increase BMD in the hip (1.8%), femoral neck (2.0%), and lumbar spine (3.1%). The 150-mg formulation approved in March 2005 represents the first oral therapy for a chronic disease to be administered once monthly.

The oral bioavailability of this agent is extremely poor (0.6%) and is adversely affected by the presence of food, beverages other than water, and other medications, including calcium or vitamin D supplements and antacids. Because of the increased calcium content in mineral water, patients should not take this medication with this type of water. Drugs that inhibit gastric acid secretion (e.g., H_2 antagonists and proton-pump inhibitors) actually promote ibandronate absorption. Like the others in this therapeutic class, ibandronate is not metabolized, and that which is not bound to the bone (40–50% of the absorbed dose) is eliminated renally unchanged. It does not inhibit the cytochrome P450 (CYP450) isozymes. This agent does not require any dosage adjustment for patients with hepatic impairment or mild to moderate renal impairment (creatinine clearance, >30 mL/min). Ibandronate should not be prescribed for patients with severe renal impairment (creatinine clearance, <30 mL/min).

Osteonecrosis of the jaw has been reported in patients receiving IV bisphosphonate therapy. The majority of the patients who developed osteonecrosis of the jaw were undergoing chemotherapy, taking corticosteroids, and had undergone a dental procedure (e.g., tooth extraction). The U.S. FDA recommends that patients receive a thorough dental examination before initiation of IV bisphosphonate therapy and that they avoid invasive dental work during treatment.

The remaining two bisphosphonates, pamidronate and zoledronic acid, are approved for treatment of hypercalcemia of malignancy as well as other cancer conditions and will be discussed later in the chapter.

Calcitonin (Calcimar [IV, SC]; Miacalcin and Fertical [nasal spray])

Calcitonin (see earlier discussion in this chapter) has been approved for the treatment of postmenopausal osteoporosis, hypercalcemia of malignancy, and Paget's disease of the bone. Several sources are available (e.g., eel, human, salmon, and porcine). The calcitonin isolated from salmon is the preferred source, because it has greater receptor affinity and a longer half-life than the human hormone (3,7). Calcitonin is commercially available as synthetic calcitonin-salmon, which contains the same linear sequence of 32 amino acids, as occurs in natural calcitonin-salmon. Calcitonin-salmon differs structurally from human calcitonin at 16 of 32 amino acids (see Fig. 7.16 for primary structure differences between human and salmon calcitonin). The pharmacological activity of these calcitonins is the same, but calcitonin-salmon is approximately 50-fold more potent on a weight basis than human calcitonin with a longer duration of action. The duration of action for calcitonin salmon is 8 to 24 hours following intramuscular (IM) or subcutaneous (SC) administration and 0.5 to 12.0 hours following IV administration. The parenteral dose required for the treatment of osteoporosis is 100 IU/day (33). Initially only available by IM or SC injection, the peptide hormone calcitonin-salmon is available as a nasal spray (Miacalcin) and as a rectal suppository (6). A recombinant DNA form of calcitonin salmon was approved by the U.S. FDA in 2005 and is available as a nasal spray. The bioavailability of calcitonin-salmon nasal spray shows great variability (range, 0.3–30.6% of an IM dose). It is absorbed rapidly from the nasal mucosa, with peak plasma concentrations appearing 30 to 40 minutes after nasal administration, compared with 16 to 25 minutes following parental dosing. Calcitonin-salmon is readily metabolized in the kidney, with an elimination half-life calculated at 43 minutes. As a result, the intranasal dose required is 200 IU/day (3). Once the Miacalcin nasal pump has been activated, the bottle may be kept at room temperature until the medication is finished (2 weeks).

Therapeutic application

Calcitonin therapy requires the concomitant oral administration of elemental calcium (500 mg/day). Clinical studies have shown that the combination of intranasal calcitonin salmon (200 IU/day), oral calcium supplementation (>1,000 mg/day of elemental calcium), and vitamin D (400 IU/day) has decreased the rate of new fractures by more than 75% and has improved vertebral BMD by as much as 3% annually (3). Calcitonin prevents the abnormal bone turnover characteristic of Paget's disease of the bone and has antiresorptive activity. In the presence of calcitonin, the osteoclast brush borders disappear, and the osteoclasts move away from the bone surface undergoing remodeling (36). Side effects are significantly more pronounced when calcitonin-salmon is administered by injection and can include nausea, vomiting, anorexia, and flushing. Because calcitonin-salmon is protein in nature, the possibility of a systemic allergic reaction should be considered,

and appropriate measures for treatment of hypersensitivity reaction should be readily available. Although calcitonin-salmon does not cross the placenta, it may pass into breast milk. Calcitonin-salmon is a possible alternative to ERT; however, only limited evidence suggests that it has efficacy in women who already have fractures. Resistance to calcitonin-salmon can result from the development of neutralizing antibodies (37).

In addition to its antiresorptive action via suppression of osteoclast activity, calcitonin-salmon exhibits a potent analgesic effect and has provided considerable relief to those patients suffering from the pain associated with Paget's disease and osteoporosis. This analgesic effect is a result of calcitonin-stimulated endogenous opioid release. The potency of this analgesic effect has been demonstrated to be 30- to 50-fold that of morphine in selected patients. Calcitonin is preferred over estrogen and the bisphosphonates when treatment of both osteoporosis and related bone pain is warranted.

Bone-Forming Agents

Teriparatide (Forteo)

In 2002, the U.S. FDA approved teriparatide for the treatment of postmenopausal osteoporosis in patients who have a high risk of fracture as well as to increase bone mass in men with primary or hypogonadal osteoporosis who have a high risk of fracture (38). Teriparatide is recombinant human PTH 1-34 (see p. 937), the biologically active portion of the endogenously produced preprohormone. Unlike the bisphosphonates, which are classified as bone restorative agents, teriparatide is the first approved bone-forming agent. Bone formation is possible because of the ability of this agent to increase the number of osteoblasts. Although teriparatide enhances the function of both osteoclasts and osteoblasts, the exposure incidence dictates its effect on the skeleton. If administered once daily or intermittently, teriparatide preferentially enhances osteoblastic function,

and bone formation occurs. Continuous exposure to endogenous PTH may result in poor skeletal composition because of enhanced osteoclast-mediated bone resorption (36). After 18 months of treatment, lumbar BMD increased up to 12% in postmenopausal women. After 10 months of treatment, 53% of men had an increase of 5% or greater in spine BMD. The risk for developing new vertebral fractures was reduced by 65% after 21 months of treatment, and the number of nonvertebral fragility fractures was reduced by 53% (23).

An New Drug Application (NDA) for a full-length recombinant human parathyroid hormone (Preos) is currently under review by the U.S. FDA.

Administered as a once-daily, 20-µg SC injection in the thigh or abdominal wall, teriparatide is a clear, colorless liquid that is available as a 750 µg/3 mL, prefilled, disposable pen that requires refrigeration. Concurrent calcium (1,000 mg) and vitamin D (400 IU) supplementation is recommended. Treatment for longer than 2 years is not recommended. Teriparatide is rapidly absorbed, demonstrates 95% bioavailability, and is quickly eliminated via both hepatic and extrahepatic routes. The half life is 1 hour when administered SC. Metabolic studies have not been performed on teriparatide; however, the entire PTH preprohormone has been shown to undergo enzyme-mediated transformations in the liver. Dizziness and leg cramps are the most commonly reported adverse side effects.

Temporary increases in serum calcium levels occur following administration of teriparatide. As a result, this agent is contraindicated in patients who are predisposed to hypercalcemia. Some evidence suggests that these elevations in serum calcium levels may cause a patient who is taking digitalis to experience digitalis toxicity (39). Teriparatide should not be prescribed to patients with Paget's disease, children, young adults, women who are pregnant or nursing, and those patients who have received skeletal radiation therapy (36). Because of an increased incidence of osteosarcoma (malignant bone tumors) observed in rats, teriparatide also carries a black box warning.

Inorganic Salts

Calcium salts

Appropriate intake of calcium during childhood, adolescence, and early adulthood increases peak BMD and may reduce the overall risk of developing osteoporosis. For those who are at low risk of developing osteoporosis and have adequate BMD, consumption of the recommended amounts of calcium (1,200–1,500 mg of elemental calcium per day for teenagers, 1,000 mg/day for premenopausal women and men, up to 1,500 mg/day for postmenopausal women not taking ERT, and 1,000 mg/day for postmenopausal women taking ERT) typically is sufficient to prevent bone loss (15). This often can be accomplished by eating a well-balanced diet. For those patients with established osteoporosis or areas of poorly mineralized bone, calcium supplementation alone is not sufficient to reverse the bone loss or to significantly improve mineralization of the bone (11).

The actual amount of elemental calcium that is present in the available calcium salts varies considerably; however, no one particular salt has been identified as an exceptional source of elemental calcium (Table 35.8). Absorption of calcium from the gastrointestinal tract (25–40%) improves under acidic conditions; therefore, those medications that change the acidic environment of the stomach (e.g., H_2 antagonists and proton-pump inhibitors) have an adverse effect on calcium absorption (3). Total daily doses of elemental calcium that exceed 500 mg should be spaced out over the day to improve absorption (5,15). The more water soluble and, therefore, more easily absorbed salts (e.g., citrate, lactate, and

gluconate) are less dependent on the acidic environment for appropriate absorption and would be appropriate alternatives for patients who produce low levels of acid. Calcium carbonate is a poorly soluble form of calcium, but it is inexpensive and only requires the patient to take a few tablets per day with acidic food or beverages like citrus juice (15).

Table 35.8. Percent of Elemental Calcium Content in Various Salts (3)

Salt	Calcium (%)	Elemental Calcium (mg/tablet)
Calcium carbonate	40	

Tums (500 mg chewable)		200 mg
Titrilac (1 g/5 mL suspension)		400 mg/5 mL
Alka-Mints (850 mg chewable)		340 mg
Os-Cal 500 (1,250 mg table)		500 mg
Viactive (1,250 mg chewable)		500 mg
Tricalcium phosphate	39	
Calcium chloride	27	
Tribasic calcium phosphate	23	
Posture (1,565.2 mg tablets)		600 mg
Calcium citrate	21	
Citrical (950 mg tablets)		200 mg
Citrical Liquitab (2,376 mg effervescent tabs)		500 mg
Calcium lactate	13	
Generics (325 mg tablets)		42 mg
Generics (650 mg tablets)		84 mg
Calcium gluconate	9	
Neo-Calglucon (1.8 g/5 mL syrup)		115 mg/5 mL

Sodium fluoride

Sodium fluoride (NaF) promotes the proliferation and activity of osteoblasts and is classified as a nonhormonal bone-forming agent. Because treatment with NaF induces bone formation, it is essential that this therapy be coupled with oral calcium supplementation (1,000 mg/day). Additionally, NaF exhibits moderate antiresorptive activity, because it inhibits osteoclastic activity when it is absorbed into the bone matrix. In the treatment of osteoporosis, the therapeutic window for this agent is fairly narrow: Doses less than 45 mg/day are subtherapeutic, and doses in excess of 75 mg/day impair bone mineralization. In addition, the bone that is formed in the presence of NaF is neither as well mineralized nor as strong as normal bone tissue. In fact, some

studies have demonstrated that patients taking sodium fluoride have increased bone fragility despite the increase in bone mass and, as a result, have an increased nonvertebral fracture rate as compared to the placebo group (5,21,33). As a result, its use in the treatment of osteoporosis has not been approved and is considered to be somewhat controversial. Several studies have examined the benefits of continuous versus cyclic dosing of NaF in the treatment of osteoporosis. Intermittent dosing (25 mg b.i.d. for 12 months, followed by 2 months of calcium supplementation alone) of a slow-release formulation of sodium fluoride (SR-NaF; Neosten) with 400 mg of calcium citrate was shown to effectively improve bone mass (vertebra, 5% per year; femoral neck, 2% per year) as well as to decrease the number of vertebral fractures (40,41).

Miscellaneous Therapies

Various classes of drugs, such as thiazide diuretics, proton-pump inhibitors, androgens, PTH, statins, and human monoclonal antibody, have been shown to have beneficial effects in treatment of diseases associated with abnormal calcium homeostasis through various mechanisms.

The thiazide diuretics, which reduce urinary calcium excretion, also may reduce the rate of bone loss (33). This protective effect has been shown to vanish within 4 to 5 months after discontinuation of the thiazide.

Elevated concentrations of proton-pump inhibitors, such as omeprazole, have been shown to inhibit bone resorption via inhibition of H^+,K^+-ATPase, a potential energy pump located in the osteoclast ruffled border (30).

Androgens such as stanozolol (11), nandrolone (11), methandrostenolone, and the testosterone patch have been shown to increase bone mass by 5 to 10% and may be appropriate for men with a deficiency in testosterone.

An increase in trabecular bone mass by as much as 50% has been demonstrated in patients treated with low doses of PTH, but it comes at the expense of the cortical bone (1,11,25). Treatment with high doses of PTH is correlated with stimulation of bone resorption (20). Cyclical therapy with PTH and calcitonin has been shown to improve BMD in the spine without adverse effects in the cortical bone (11). When given in combination with estrogen, PTH promoted the formation of well-mineralized trabecular bone.

Strontium ranelate is an orally active agent that can be classified as both an antiresorptive agent and a bone-forming agent (42,43). It is able not only to stimulate replication of preosteoblastic cells to promote bone formation but also is able to decrease osteoclastic activity to prevent bone resorption. Biochemical markers for bone formation (e.g., bone-specific alkaline phosphatase), which normally decrease in the presence of antiresorptive therapy, are elevated in the presence of strontium ranelate (44). Lumbar spine BMD increased 11.4% in patients treated with this new agent.

The hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors, otherwise known as the statins, have been found to increase bone formation via enhanced activity of the bone morphogenic protein 2 (*BMP-2*) gene. This gene increases osteoblast differentiation. In addition, by inhibiting HMG-CoA reductase, the statins not only prevent the biosynthesis of cholesterol but also prevent the formation of compounds associated with osteoclast activation (45). Unfortunately, clinical data

from several large studies conflict, and further study is warranted before the statins can be considered as a viable treatment for osteoporosis (46).

AMG-162 (Amgen) is a fully human monoclonal antibody to the receptor activator of nuclear factor κB ligand (RANKL). Its receptor is located on the surface of osteoclasts and osteoclast precursors. When bound to its receptor, RANKL promotes the formation and activation of osteoclasts. To balance the effects of RANKL, the body produces osteopotegerin, which binds to RANKL and prevents it from binding to and activating its receptor, modulating the production and activation of osteoclasts (47). When an individual develops osteoporosis, this balance is “disrupted,” and RANKL overwhelms osteopotegerin activity, causing significant bone loss. AMG-162 was designed to mimic the biochemical effects of osteopotegerin. Studies show that AMG-162 is more effective in improving BMD (4–7%) than weekly administration of alendronate (5%) (47). It is anticipated that this agent will be administered SC biannually. The most commonly reported adverse effect is dyspepsia.

There are a number of agents in the pipeline (Table 35.9), some with very novel mechanisms of action, including inhibitors of cathepsin B and protein tyrosine kinase Src, as well as antagonists at $\alpha_v\beta_3$ integrin receptors (48).

Drug Therapies Used to Treat Hyperparathyroidism

Increased levels of PTH leads to moderately to severely elevated serum calcium concentrations (2) and alterations in phosphorous metabolism. To modulate the levels of PTH released from the parathyroid gland chief cells, regulation of CaSR sensitivity is required. An agonist at this receptor, a calcimimetic, serves to activate the receptor, whereas an antagonist at this receptor is classified as a calcilytic. There are two types of calcimimetic agents: those that activate the CaSR directly (type I), and those that require the presence of a cation, such as calcium or magnesium (type II) for activation (49). Type I calcimimetics are polycations (e.g., magnesium and neomycin). The first- and second-generation of type II calcimimetics are phenylalkylamine based. They have an indirect/allosteric action on CaSR mediated by a conformational alteration of these receptors.

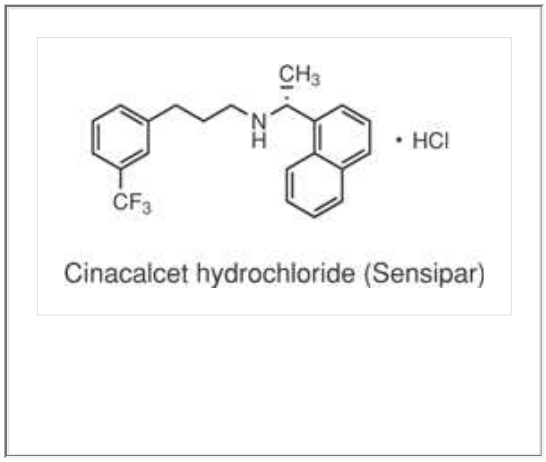
Cinacalcet Hydrochloride (Sensipar)

Cinacalcet is the first type II calcimimetic agent approved that improves CaSR sensitivity to calcium (19,50). When calcium is bound to the CaSR, phospholipase C is activated, and the secretion of PTH is inhibited. In the presence of cinacalcet, not only is a drop in

PTH levels observed but also a decrease in serum calcium and phosphorous levels. This represents a significant therapeutic advantage over vitamin D–based treatments for secondary hyperparathyroidism (19). Cinacalcet hydrochloride is a second-generation calcimimetic approved for the treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis and for the treatment of hypercalcemia in patients with parathyroid cancer. It can be used alone, with vitamin D, and/or with a phosphate binder (51).

Drug	Chemical Structure	Mechanism of Action	Stage of Clinical Trial
Precos (recombinant PTH)	34 amino acids	Treatment of osteoporosis	Phase III
SB-357114		Cathepsin K inhibitor	Phase I
Osteoprotegerin	—	Inhibitor of osteoclast differentiation and function	Phase II
Nitroflurbiprofen (HC–1026)		Nitrosylated nonsteroidal anti-inflammatory—decreases bone resorption	Phase II
CGP-77675 and AP 23588	 —	Protein tyrosine kinase Src inhibitor—decreases osteoclast mediated bone resorption	Preclinical
SB-265123		$\alpha_v\beta_3$ Integrin receptor antagonist	Preclinical

Table 35.9. Experimental Agents for Treatment of Abnormal Calcium Homeostatis



Cinacalcet hydrochloride (Sensipar)

Drug Therapies Used to Treat Hypercalcemia of Malignancy

Zoledronic Acid (Zometa)

Zoledronic acid, a bisphosphonate, was approved by the U.S. FDA in 2001 for the treatment of hypercalcemia of malignancy, a metabolic complication that can be life-threatening (Fig. 35.7). Hypercalcemia of malignancy can occur in up to 50% of patients diagnosed with advanced breast cancer, multiple myeloma, and nonsmall cell lung cancer. This condition arises when chemical moieties produced by the tumor cause overstimulation of osteoclasts. When there is an increase in bone degradation, there is a concomitant release of calcium into the plasma. When serum concentrations of calcium rapidly elevate, the kidneys are unable to handle the overload, and hypercalcemia results. This can lead to dehydration, nausea, vomiting, fatigue, and confusion. Zoledronic acid effectively decreases plasma calcium concentrations via inhibition of bone resorption (inhibition of osteoclastic activity and induction of osteoclast apoptosis). It also prevents the increase in osteoclastic activity caused by tumor-based stimulatory factors. Additionally zoledronic acid has been approved by the U.S. FDA for the treatment of multiple myeloma and bone metastases associated with solid tumor–based cancers (e.g., prostrate and lung). This agent is currently in late-stage clinical trials for the treatment and prevention of osteoporosis and, if approved, will be formulated as a 5-mg, once-yearly IV infusion.

The maximum recommended dose for the treatment of hypercalcemia of malignancy is 4 mg. A clinically significant deterioration in renal function occurs when single doses of this agent exceed 4 mg and the infusion duration is less than 15 minutes (52). It is recommended that patients be well hydrated before infusion. If serum calcium levels do not fall to normal levels, retreatment is appropriate, but retreatment is not recommended until 7 days have elapsed from the initial treatment. For the treatment of multiple myeloma and metastatic bone lesions, a 4-mg initial dose is recommended, followed by additional doses every 3 to 4 weeks for 9 to 15 months (prostate cancer, 15 months; breast cancer, 12 months; other solid tumors, 9 months).

Zoledronic acid is a white, crystalline powder that is available in vials for reconstitution for IV infusion over at least 15 minutes. It does not undergo metabolic transformation and does not inhibit CYP450 enzymes. Clearance of this agent is dependent on the patient's creatinine clearance, not on dose. Serum creatinine levels should be evaluated before every treatment. Zolendronic acid is contraindicated in patients with severe renal impairment.

Zolendronic acid should not be mixed with infusion solutions that contain calcium (e.g., lactated Ringer's) and should be administered via IV infusion in its own line. Because of the possibility of a serious deterioration in renal function, the manufacturer requires strict adherence to the infusion duration being no less than 15 minutes.

Pamidronate Disodium (Aredia)

Pamidronate, a second-generation bisphosphonate, is 100-fold more potent than etidronate (Fig. 35.7) (6). It has been approved for the treatment of hypercalcemia of malignancy, for Paget's disease, and for osteolytic bone metastases of breast cancer and osteolytic lesions of multiple myeloma. When used to treat bone metastases, pamidronate decreases osteoclast recruitment, decreases osteoclast activity and increases osteoclast apoptosis (53). Erosive esophagitis has been reported with the use of pamidronate sodium.

Gallium Nitrate (Ganite)

Gallium nitrate (Ganite) has been approved for the treatment of hypercalcemia of malignancy (33) in patients that do not respond to hydration. Its effectiveness stems from its ability to inhibit bone resorption despite the presence of tumor-derived factors that promote calcium loss from the bone. Administered by infusion over 24 hours, the typical dose is 200 mg/m^2/day for five consecutive days. A lower dose is recommended if the symptoms of hypercalcemia are mild (100 mg/m^2/day for 5 days). Steady state is achieved in 24 to 48 hours. Maintenance of patient hydration is essential during treatment. Gallium nitrate is not significantly metabolized and is largely excreted through the kidneys. It is contraindicated in patients with severe renal impairment. Renal function should be closely monitored in all patients receiving this agent.

Case Study

Victoria F. Roche

S. William Zito

PA is a 62-year-old Caucasian female who presents to the emergency room with a complaint of persistent lower back pain for the past 2 weeks. She says that she "just woke up one morning with the back pain." While having her history taken, PA reveals that she was diagnosed with rheumatoid arthritis 6 years ago, which was 3 months after her second mastectomy for breast cancer. PA went through menopause 10 years ago, has not undergone hysterectomy, and has been on Synthroid (25 µg/daily) since she was surgically treated for hyperthyroidism at the age of 25. PA claims that her thyroid function was normal at her last visit to her endocrinologist. Currently, PA is being treated with the following drugs for her RA:

Sulfasalazine	(500-mg tablets, three tablets b.i.d.)
Oxycodone	(5-mg tablets; as needed for pain)
Methotrexate	(2.5-mg tablets, eight tablets weekly)
Prednisone	(10-mg tablets, one tablet daily for flare-ups)
Hydrochlorthiazide	(12.5-mg tablets; one tablet daily for ankle edema)

On further questioning, PA reports that flare-ups requiring her to go on prednisone have occurred at least twice a year since she was first diagnosed with rheumatoid arthritis. The emergency room physician ordered a dual-energy x-ray absorptiometry scan of the spine and requested a lateral spine image to be done at the same time. A diagnosis of osteoporosis was made based on the presence of vertebral fracture and a T value for bone mass density (BMD) of 2.0 standard deviations below the young adult mean. In addition to calcium carbonate (500 mg t.i.d.) and vitamin D (400 U q.d.), the physician wants to prescribe calcium antiresorptive therapy for PA, and you have the following drugs available from the hospital formulary. Make a recommendation.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.

5. Counsel your patient.

Chapter 36

Nonsteroidal Anti-Inflammatory Drugs

Ronald Borne

Mark Levi

Norman Wilson

Drugs covered in this chapter:

Antipyretic analgesics

- Acetaminophen

Anti-inflamatory analgesics

- Aspirin and other salicylates
- Diflunisal
- Indomethacin
- Diclofenac
- Etodolac
- Nabumetone
- Sulindac
- Tolmetin
- Ibuprofen
- Fenoprofen
- Flurbiprofen
- Ketoprofen
- Ketoraloc
- Naproxen
- Oxaprozin
- Suprofen
- Mefenamic acid
- Meclofenamic acid
- Piroxicam
- Meloxicam

COX-2 inhibitors

- Celecoxib
- Rofecoxib
- Valdecoxib
- Etoricoxib
- Lumiracoxib

Drugs for arthritis

- Gold salts
- Hydroxychloroquine
- Methotrexate
- Leflunomide
- Etanercept
- Infliximab

- Adalimumab
- Rituximab
- Anakinra
- Abatacept

Drugs for the treatment of gout

- Colchicine
- Probenecid
- Sulfinpyrazone
- Allopurinol

Introduction

The classification of drugs covered in this chapter as nonsteroidal anti-inflammatory drugs (NSAIDs) is somewhat misleading, because many of these entities possess antipyretic and analgetic properties in addition to anti-inflammatory properties, which are useful in the treatment of a number of rheumatic disorders. On the other hand, there are drugs that possess analgetic/antipyretic properties but are essentially devoid of anti-inflammatory activity. Additionally, drugs that possess uricosuric properties useful in the treatment of gout will be covered here. The prototype agent of this class is acetylsalicylic acid, aspirin, which has therapeutically useful analgetic, antipyretic, and anti-inflammatory actions; other drugs to be covered may possess only one or two of these properties. Steroids that are useful anti-inflammatory drugs are covered separately in Chapter 33.

Nonsteroidal anti-inflammatory drugs continue to be one of the more widely used groups of therapeutic drugs. The medicinal drugs covered in this chapter represent a major market in both prescription and nonprescription drugs. Other than caffeine or ethyl alcohol, aspirin may be the most widely used drug in the world (1). An estimated 70 to 100 million prescriptions are written annually for NSAIDs, with over-the-counter (OTC) use accounting for an additional use that may be up to sevenfold higher. Rheumatic diseases, which have been classified by the Arthritis Foundation (Table 36.1) (2), are inflammatory disorders affecting more individuals than any chronic illness. The Centers for Disease Control and Prevention estimates that more than 40 million Americans have some form of arthritis or chronic joint disorder. Approximately 7 million Americans suffer from arthritis in its most debilitating forms (3,4). Osteoarthritis is the most common form of arthritis in the United States, affecting about 12% of Americans between the ages of 25 and 74. Rheumatoid arthritis is thought to affect well over 2 million Americans (two to three times more females more than males), whereas juvenile arthritis affects 71,000 children under 16 years of age, 61,000 of whom are females. In addition, nonrheumatoid osteoporosis affects 24 million females (half of all women older than 45 years and 90% of all women older than 75 years) (3,4) and 16 million males. Because more than 80% of the U.S. population older than 55 years have joint abnormalities that are detectable radiographically (5), the use of NSAIDs will increase as Americans experience a greater life expectancy. It is not surprising, therefore, that the development of new NSAIDs continues at a steady pace—a pace slowed down by the recent controversies surrounding selective cyclooxygenase (COX)-2 inhibitors.

The diseases mentioned are considered to be host defense mechanisms. Inflammation is a normal and essential response to any noxious stimulus that threatens the host and may vary from a localized response to a generalized response (6). The resulting inflammation can be summarized as follows: 1) Initial injury causing release

of inflammatory mediators (e.g., histamine, serotonin, leukokinins, SRS-A, lysosomal enzymes, lymphokinins, and prostaglandins); 2) vasodilation; 3) increased vascular permeability and exudation; 4) leukocyte migration, chemotaxis, and phagocytosis; and 5) proliferation of connective tissue cells. The most common sources of chemical mediators include neutrophils, basophils, mast cells, platelets, macrophages, and lymphocytes (6). The etiology of inflammatory and arthritic diseases has received a great deal of recent attention but remains, for the most part, unresolved, hindering the development of new agents that are curative in nature. Currently available drugs relieve the symptoms of the disease but are not curative.

Clinical Significance

The arachidonic acid pathway leading to the production of inflammatory mediators provides several targets for intervention on inflammation. The most widely used nonsteroidal anti-inflammatory drugs (NSAIDs) in practice

today are drugs like aspirin, naproxen, ibuprofen, diclofenac, and others that inhibit the cyclooxygenase (COX) enzymes. Although specific NSAIDs have found their niches in particular disease states, the NSAIDs generally work by the same mechanism with little exception. Aspirin, a salicylate, is somewhat different from the other agents in that its property of irreversibly inhibiting platelet homeostasis works to its advantage and broadens its use in coronary artery disease prophylaxis, in which it has been shown to reduce mortality whereas the others have not. Other salicylate varieties lack the ability to irreversibly inhibit platelet function and, therefore, are not clinically useful this way.

Variations on the molecular structures have provided improved side effect profiles of agents used. For example, although phenacetin and acetaminophen are not anti-inflammatory agents, they are included in this chapter, because they are analgesics and antipyretics and illustrate the point that improvement in molecular structure from phenacetin to acetaminophen helped to reduce the hepatotoxicity and risk for drug-induced hemolytic anemia with which phenacetin was associated when it was on the market in the past.

Changes to the currently available NSAIDs are constantly being produced, hence the abundance of "me-too" drugs. With gastrointestinal (GI) bleeding and complications being the most feared consequence of taking these drugs, an emphasis on minimizing these risks has been one of the motivations to develop less offensive agents. Gastrointestinal side effects are believed to be related to indirect toxic effects (inhibiting COX enzymes) and direct toxic effects (local irritation to the GI mucosa). Molecular changes have been made to the various NSAIDs to produce more potent compounds, to reduce the direct irritant effects, and to create pro-drugs that lack the direct irritant effect altogether. Other changes have resulted in compounds with no more potency but with lower incidence of GI side effects, which still represents a therapeutic advantage.

As can be seen, a thorough understanding and appreciation of the chemical nature of the NSAIDs is directly linked to clinically significant end points and positive therapeutic outcomes.

Jill T. Johnson Pharm.D., BCPS
Associate Professor, Department of Pharmacy Practice, College of Pharmacy, University of Arkansas for Medical Sciences

Anti-inflammatory drugs may act by interfering with any one of several mechanisms, including immunological mechanisms such as antibody production or antigen–antibody complexation, activation of complement, cellular activities such as phagocytosis, interference with the formation and release of the chemical mediators of inflammation, or stabilization of lysosomal membranes. The role of complement in inflammation is of considerable interest (7,8,9). The complement system is one component of the host defense system that aids in the elimination of various microorganisms and antigens from blood and tissues. Although complement normally plays a functional role in the development of disease states, excessive complement activation, by promoting inflammation locally, is detrimental. Individuals with a deficiency of individual complement proteins, however, either acquired or hereditary, are more susceptible to infections caused by pyrogenic bacteria and diseases resulting from the generation of autoantibodies and immune complexes. Complement proteins are numbered C1 to C9, and their cleavage products are indicated by the suffixes a, b, and so on. The complement system consists of two activating pathways (an antibody-mediated classical pathway and a nonimmunologically activated alternate pathway), a single termination pathway, regulatory proteins, and complement receptors and involves approximately 30 membrane and plasma proteins (8). A major function of complement is to mark antigens and microorganisms with C3 fragments that direct them to cells containing C3 receptors, such as phagocytic cells (8). Complement has been implicated in numerous diseases, including allergic, hematologic, dermatologic, infectious, renal, hepatic inflammatory (rheumatoid arthritis and systemic lupus erythematosus), pulmonary, and others (e.g., multiple sclerosis and myasthenia gravis). Complement activation can induce the synthesis or release of inflammatory mediators, such as interleukin-1 (a potent proinflammatory cytokine) and prostaglandins (e.g., *PGE_2). Leukotrienes (e.g., LTB_4) and thromboxanes also are released. Complement*

also aids the immigration of phagocytes associated with inflammation. Thus, inhibition of the complement system by controlling its activation or inhibiting those active fragments that are produced should be beneficial in reducing or eliminating tissue damage associated with inflammatory diseases.

Table 36.1. Classification of Rheumatic Diseases

- A. Acute and chronic polyarthritis and other synovial diseases
  - Rheumatoid arthritis
- B. Infection-related rheumatic diseases

- Septic arthritis
- Osteomyelitis
- Lyme disease
- Rheumatic fever

- C. Spondyloarthropathies
  - Ankylosing spondylitis
  - Reactive arthritis
  - Psoriatic arthritis
  - Enteropathic spondyloarthropathy (arthritis of inflammatory bowel disease)
- D. Osteoarthritis and related degenerative related diseases
- E. Crystal-induced arthropathies
  - Gout (monosodium urate)
  - Calcium pyrophosphate dehydrate, apatite, and other calcium crystals deposited in the joint
- G. Metabolic bone disease
  - Osteoporosis
- H. Connective tissue disease
  - Systemic lupus erythematosus
  - Scleroderma/polymyositis
  - Mixed connective tissue disease
- I. Musculoskeletal diseases (regional pain syndromes)
  - Neck, lower back and lumbar spine stenosis, shoulder, elbow, wrist and hand, hip, and knee
- J. Inflammatory muscle (nonarticular) diseases
  - Fibromyalgia
  - Bursitis
  - Tendinitis
- K. Vasculitis
  - Polymyalgia rheumatica
- L. Sjogren's syndrome
- M. Neoplasms
- N. Drug-induced rheumatologic syndromes
  - Systemic lupus erythematosus
  - Glucocorticoid-induced arthritis
  - Scleroderma (acrosclerosis)
  - Vasculitis
  - Statin-induced myositis

From Klippel JH, Wayand CM, Wortmann R, et al., eds. Primer on the Rheumatic Diseases. 12th Ed. Atlanta: Arthritis Foundation, 2001; with permission.

Connective tissue diseases include the following states: rheumatoid arthritis, ankylosing spondylitis, systemic lupus erythematosus, polyarteritis nodosa, gout, rheumatic fever, and osteoarthritis, with the most common forms of which are rheumatoid arthritis, osteoporosis, and gout. Rheumatoid arthritis is a chronic, nonsuppurative inflammatory disease of unknown cause affecting primarily peripheral synovial joints. The onset is usually insidious, with immunological reactions playing a major role. The pathogenesis of rheumatoid arthritis has been summarized as follows (10): 1) An unknown initiation factor in the synovial joint causes the production of antigenic immunoglobulin (Ig) G, which stimulates the synthesis of the rheumatoid factors IgM and IgG, forming immune complexes; 2) IgG aggregates activate the complement system, leading to the generation of chemotactic factors (cytokines) that attract polymorphonuclear leukocytes into the articular cavity; 3) the polymorphonuclear leukocytes ingest immune complexes to become rheumatoid arthritis cells, which discharge hydrolases from lysosomal granules that, in turn, degrade extracellular tissue components, polysaccharides, and collagens in cartilage, thus provoking an inflammatory response in rheumatoid joints; and 4) all of which induce expression of cyclooxygenase. Clinical symptoms characteristically include symmetric swelling of at least three joints, accompanied by soft tissue swelling

with tenderness, erythema, morning stiffness lasting at least an hour, and pain. The joints primarily involved are those of the extremities, and the patient often suffers a low-grade fever accompanied by malaise, anorexia, and fatigue. Serum protein irregularities and abnormal amounts of rheumatoid factors are common. It often is difficult to distinguish rheumatoid arthritis from other connective tissues disorders because of lack of definitive diagnostic features. Because bone erosions, uniform joint-space narrowing, and osteopenia (decreased bone density) develop within 6 months in about 40% of those with early rheumatoid arthritis, it is more effective to treat early rheumatoid arthritis with disease modifying drug therapy (DMARDs) before structural damage develops than attempting to correct the damage. Corticosteroids are used for controlling the symptoms, not disease modifying.

Osteoarthritis is a degenerative joint disease, and is the most common form of arthritis. It is characterized by degeneration of cartilage and hypertrophy of bone at the articular margin. Secondary inflammation of synovial tissue is common. The most common symptoms involve joint pain associated with movement, joints lose range-of-motion, minimal swelling of the involved joint, and, sometimes, bone enlargement. Weight-bearing joints and joints of the hands and fingers generally are involved. Treatment usually involves exercise and pain medication. Aspirin is considered first-choice therapy, with acetaminophen and NSAIDs being employed in patients who do not tolerate salicylates. Nutritional supplements such as glucosamine and hyaluronic acid have been shown to possibly slow progression of osteoarthritis.

Gout is a metabolic disease characterized by recurrent episodes of acute arthritis, usually monoarticular, and is associated with abnormal levels of uric acid in the body, particularly the presence of monosodium urate crystals in synovial fluid. Primary gout is a hereditary disease in which hyperuricemia is caused by an error in uric acid metabolism—either overproduction or an inability to excrete uric acid. Secondary gout refers to those cases in which hyperuricemia is caused by an acquired disease or disorder, such as chronic renal disease, lead poisoning, or myeloproliferative disorders. Gout generally occurs in

mid-life and affects males significantly more than females (9:1). Treatment usually involves the use of uricosuric drugs, colchicine, NSAIDs, or corticosteroids.

The search for new and effective treatment modalities requires the availability of adequate screening tests. Although no model adequately reflects the events that occur in human arthritic conditions, several in vivo and in vitro assays are used. The most common in vivo animal assays measure the ability of anti-inflammatory drugs to inhibit edema induced in the rat paw by carrageenan (a mucopolysaccharide derived from a sea moss of the *Chondrus* species), to inhibit adjuvant arthritis in rats induced by *Mycobacterium butyricum* or *M. tuberculosis*, to inhibit granuloma formation usually induced by the implantation of a cotton pellet beneath the abdominal skin of rats, or to inhibit erythema of guinea pig skin as a result of exposure to ultraviolet radiation. In vitro techniques include the ability of NSAIDs to stabilize erythrocyte membranes or, more commonly, to inhibit the biosynthesis of prostaglandins, particularly in cultured human synoviocytes and chondrocytes, and monocyte culture fluid stimulated bovine synoviocytes and chondrocytes.

Role of Chemical Mediators in Inflammation

As indicated previously, a number of chemical mediators have been postulated to play important roles in the inflammatory process. Before 1971, the proposal by Shen (11,12) that the NSAIDs exert their effects by interacting with a hypothetical anti-inflammatory receptor was widely accepted. The topography of the proposed receptor was based on known structure–activity relationships primarily within the series of indole acetic acid derivatives, of which indomethacin was the prototype. Most NSAIDs, whether they be salicylates, arylalkanoic acids, oxicams, or anthranilic acid derivatives, possess the common structural features of an acidic center, an aromatic or heteroaromatic ring, and an additional center of lipophilicity in the form of either an alkyl chain or an additional aromatic ring. The proposed receptor to which indomethacin was postulated to bind consisted of a cationic site to which the carboxylate anion would bind, a flat area to which the indole ring would bind through van der Waals forces, and an out-of-the-plane trough to which the benzene ring of the p-chlorobenzoyl group would bind through hydrophobic or charge-transfer interactions. Additional binding sites for the methoxy and carbonyl groups also were suggested. In 1971, Vane (13) published a classic paper in which he reported that indomethacin, aspirin, and salicylate, in this descending order of potency, inhibited the biosynthesis of prostaglandins from arachidonic acid using cell-free preparations of guinea pig lung, and he further suggested that the clinical actions of these drugs resulted from this inhibition. This theory has become the most widely accepted mechanism of action of NSAIDs. Gund and Shen (14) subsequently modified this hypothesis and proposed that the earlier anti-inflammatory receptor model actually described the active site of the key enzyme in prostaglandin biosynthesis (i.e., prostaglandin cyclooxygenase) (Fig. 36.1).

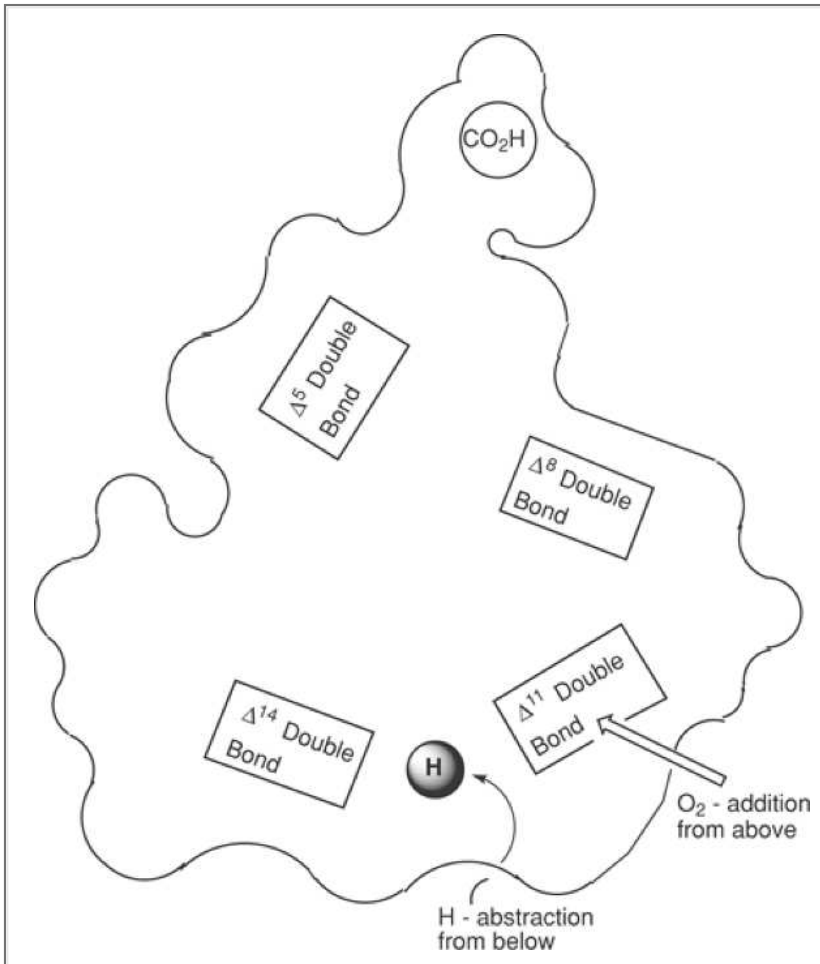

Fig. 36.1. Shen's proposed model of the fatty acid substrate binding site of prostaglandin synthetase. (Modified from Gund P, Shen TY. A model for the prostaglandin synthetase cyclooxygenation site and its inhibition by anti-inflammatory arylacetic acids. J Med Chem 1977;20:1146–1152; with permission.)

Prostaglandins, Thromboxanes, Prostacyclin, and Leukotrienes

Prostaglandins are naturally occurring, 20-carbon, cyclopentano–fatty acid derivatives produced in mammalian tissue from polyunsaturated fatty acids. They belong to the class of eicosanoids, a member of the group of autocoids derived from membrane phospholipids. The eicosanoids are derived from unsaturated fatty acids and include the following groups of compounds: prostaglandins, thromboxanes, prostacyclin, and leukotrienes. They have been found in essentially every compartment of the body. In 1931, Kurzrok and Lieb (15) reported that human seminal fluid possessed potent contractile and relaxant effects on uterine smooth muscle. Shortly thereafter, Goldblatt (16) in England and von Euler (17) in Sweden independently reported vasodepressor and smooth muscle–contracting properties in seminal fluid; von Euler identified the active constituent as a lipophilic acidic substance, which

he termed “prostaglandin.” These observations attracted little attention during World War II, but shortly thereafter, primarily through the efforts of Bergstrom and Samuelsson (18), it was realized that von Euler's prostaglandin was actually a mixture of a number of structurally related fatty acids. The first report of the structure of the prostaglandins in 1962 stimulated several studies relating to the chemical and biological properties of these potent substances.

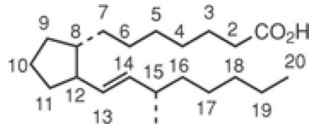

Fig. 36.2. General structure of the prostaglandins.

The general structure of the prostaglandins is shown in Figure 36.2. All naturally occurring prostaglandins possess this substitution pattern, a 15α-hydroxy group and a *trans* double bond at C-13. Unless a double bond occurs at the C-8, C-12 positions, the two side chains (the carboxyl-bearing chain termed the α-chain and the hydroxyl-bearing chain termed the β-chain) are of the *trans* stereochemistry depicted. The prostaglandins are classified by the capital letters A, B, C. D, E, F, G, H, and I (e.g., PGA, PGB, and so on) depending on the nature and stereochemistry of oxygen substituents at the 9- and 11-positions. For example, members of the PGE series possess a keto function at C-9 and an α-hydroxyl group at C-11, whereas members of the PGF series possess α-hydroxyl groups at both of these positions. Members of the PGG and PGH series are cycloendoperoxide intermediates in the biosynthesis of prostaglandins, as depicted in Figure 36.3. The number of double bonds in the side chains connected to the cyclopentane ring is designated by subscripts 1, 2, or 3, indicative of the nature of the fatty acid precursor. The subscript 2 indicates an additional *cis* double bond at the C-5, C-6 positions, and the subscript 3 indicates a third double bond of *cis* stereo-chemistry at the C-17, C-18 positions.

Prostaglandins are derived biosynthetically from unsaturated fatty acid precursors. The number of double bonds contained in the naturally occurring prostaglandins reflects the nature of the biosynthetic precursors. Those containing one double bond are derived from 8,11,14-eicosatrienoic acid, those with two double bonds from arachidonic acid (5,8,11,14-eicosatetraenoic acid), and those with three double bonds from 5,8,11,14,17-eicosapentenoic acid. The most common of these fatty acids in humans is arachidonic acid; hence, prostaglandins of the 2 series play an important biological role. Arachidonic acid is derived from dietary linoleic acid or is ingested from the diet (19) and esterified to phospholipids (primarily phosphatidylethanolamine or phosphatidylcholine) in cell membranes. Various initiating factors interact with membrane receptors coupled to G proteins (guanine nucleotide–binding regulatory proteins) activating phospholipase A_2, which in turn hydrolyzes membrane phospholipids resulting in the release of arachidonic acid. Other phospholipases (e.g., phospholipase C) also are involved. Phospholipase C differs from phospholipase A_2 by inducing the formation of 1,2-diglycerides from phospholipids with the subsequent release of arachidonic acid by the actions of mono- and diglyceride lipases on the diglyceride (17). A polypeptide produced by leukocytes, interleukin-1, which mediates inflammation, increases phospholipase activity and, thus, prostaglandin biosynthesis. The steroidal anti-inflammatory drugs (corticosteroids) appear to act, in part, by inhibiting these phospholipases, particularly phospholipase A_2. The liberated arachidonic acid may then be acted on by two major enzyme systems: by arachidonic acid cyclooxygenase (prostaglandin endoperoxide synthetase, COX) to produce prostaglandins, thromboxanes, and prostacyclin, or by lipoxygenases to produce leukotrienes.

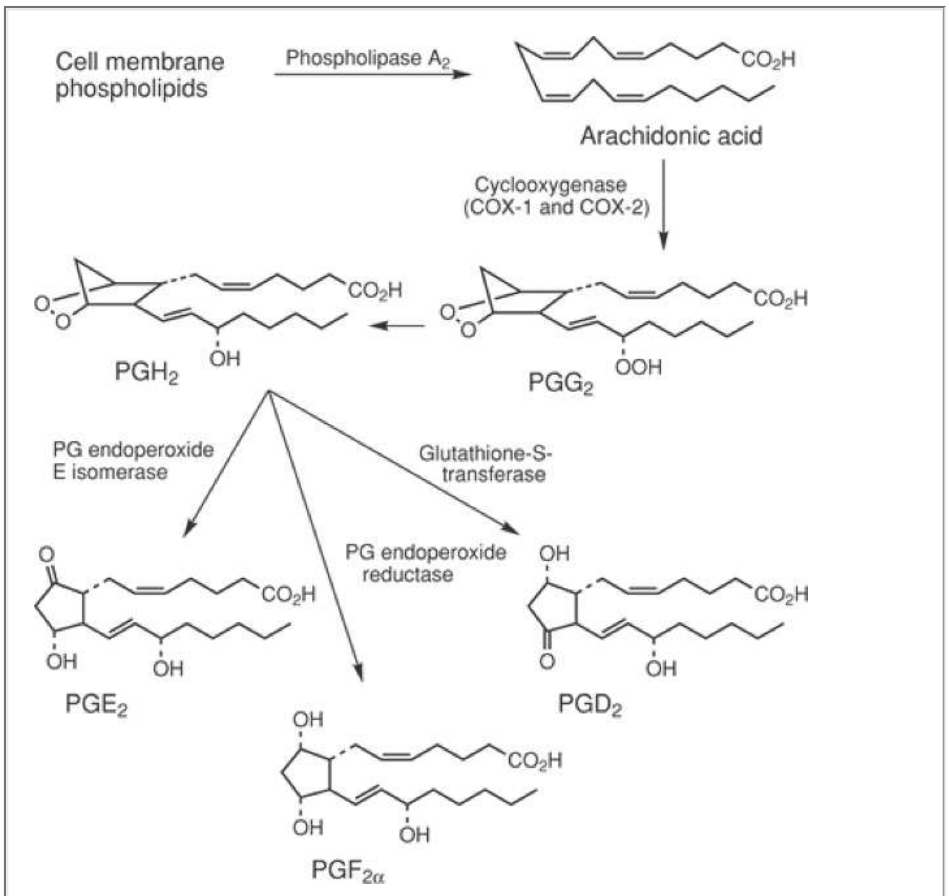

Fig. 36.3. Biosynthesis of prostaglandins from arachidonic acid.

Interaction of arachidonic acid with cyclooxygenase (COX) in the presence of oxygen and heme produces, first, the cyclic endoperoxide, PGG_2, and then, through its peroxidase activity, PGH_2, both of which are chemically unstable and decompose rapidly (half-life, 5 minutes). The PGE_2 is formed by the action of PGE isomerase and PGD_2 by the actions of isomerases or glutathione-S-transferase on PGH_2, whereas $PGF_{2\alpha}$ is formed from PGH_2 via an endoperoxide reductase system (Fig. 36.3). It is the cyclooxygenase step at which the NSAIDs inhibit prostaglandin biosynthesis, preventing inflammation. Because PGG_2 and PGH_2 themselves may possess the ability to mediate the pain responses and produce vasoconstriction, and because PGG_2 may mediate the

inflammatory response, cyclooxygenase inhibition would have a profound effect on the reduction of inflammation.

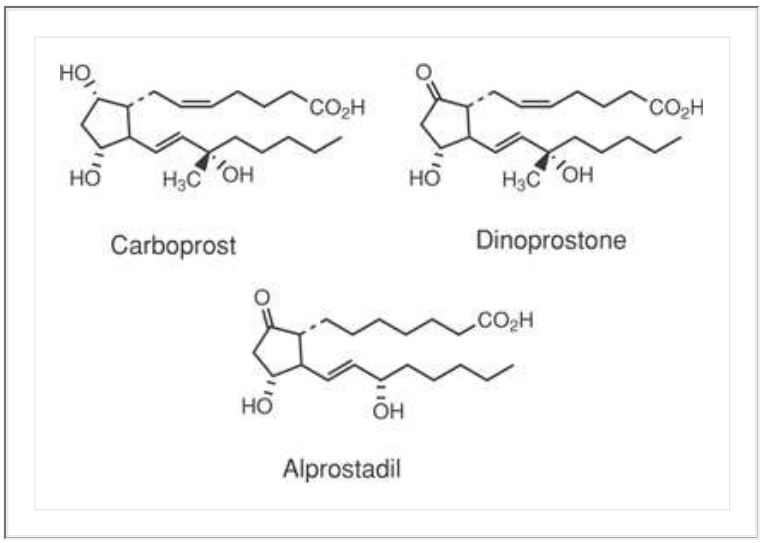
Three isoforms of COX have been identified: COX-1, COX-2, and COX-3. COX was first purified in 1976 and first cloned in 1988. Among the more significant advances of the past decade was the isolation of a second isoform of the COX enzyme, COX-2, the expression of which is inducible by cytokines and growth factors (20,21,22,23,24). A third distinct COX isoform, COX-3, has recently been reported in addition to two smaller COX-1–derived proteins (partial COX-1, or PCOX-1, proteins, termed PCOX-1α and PCOX-1β). It has been long known that acetaminophen possesses analgetic and antipyretic activity but little, if any, anti-inflammatory activity. Thus, the identification of this third isoform of the COX enzyme may be of importance, because COX-3 is selectively inhibited by analgetic/antipyretic drugs and is potently inhibited by some NSAIDs. Inhibition of COX-3 may represent a primary central mechanism by which acetaminophen decreases pain and fever (discussed later).

Both COX-1 and COX-2 are very similar in structure and almost identical in length, varying from 599 (human) to 602 (mice) amino acids for COX-1 and from 603 (mice) to 604 (human) for COX-2. Both isoforms possess molecular masses of 70 to 74 kDa and contain just over 600 amino acids, with an approximately 60% homology within the same species (25,26). Cyclooxygenase-2 contains an 18-amino-acid insert near the C-terminal end of the enzyme that is not present in COX-1, but all other residues that have been previously identified as being essential to the catalytic activity of COX-1 are present in COX-2. Both isoforms have been cloned from various species, including human, and are heme-containing membrane proteins that exist as dimers (25). The three-dimensional radiographic crystal structure of COX-2 derived from human or murine sources can be superimposed on that of COX-1. Residues that form

the substrate binding channel, the catalytic sites, and those residues immediately adjacent are essentially identical with the exception of two minor differences. The isoleucine at positions 434 and 523 in COX-1 is exchanged for valine in COX-2. The smaller size of Val-523 in COX-2 allows inhibitor access to a side pocket off the main substrate channel, whereas the longer side chain of Ile in COX-1 sterically blocks inhibitor access. A major difference between COX-1 and COX-2 is that compared to COX-1, COX-2 lacks a sequence of 17 amino acids from the N-terminus but contains a sequence of 18 amino acids at the C-terminus. This causes a difference in the numbering systems of the two isoforms such that the serine residue acetylated by aspirin in COX-1 is numbered Ser-530, whereas in COX-2, the serine residue acetylated is Ser-516. Yet, the amino acid residues that are thought to be responsible for providing the catalytic role are the same, with both isoforms displaying similar ability to convert arachidonic acid to PGH_2. Cyclooxygenase-1 appears to be more specific than COX-2 for fatty acid substrates, because COX-2 accepts a wider range of fatty acid substrates than COX-1. Cyclooxygenase-1 primarily metabolizes arachidonic acid, and COX-2 metabolizes C-18 and C-20 fatty acid substrates. Selective inhibitors of COX-2 do not bind to Arg-120, which is used by the —COOH of arachidonic acid and the carboxylic acid selective or nonselective COX-1 inhibitors.

From a therapeutic viewpoint, the major difference between COX-1 and COX-2 lies in physiological function rather than in structure. Little COX-2 is present in resting cells, but its expression can be induced by cytokines in vascular smooth muscle, fibroblasts, and epithelial cells, leading to the suggestion that COX-1 functions to produce prostaglandins that are involved in normal cellular activity (protection of gastric mucosa, maintenance of kidney function) and COX-2 to produce prostglandins at inflammatory sites (27). Inducible COX-2 linked to inflammatory cell types and tissues is believed to be the target enzyme in the treatment of inflammatory disorders by NSAIDs. Until recently, most NSAIDs inhibited both COX-1 and COX-2, but with varying degrees of selectivity. Selective COX-2 inhibitors may eliminate side effects associated with NSAIDs because of COX-1 inhibition, such as gastric and renal effects.

Prostaglandins are rapidly metabolized and inactivated by various oxidative and reductive pathways. The initial step involves rapid oxidation of the 15α-OH to the corresponding ketone by the prostaglandin-specific enzyme, prostaglandin 15-OH dehydrogenase. This is followed by reduction of the C-13, C-14 double bond by prostaglandin Δ^{13}-reductase to the corresponding dihydro ketone, which for PGE_2 represents the major metabolite in plasma. Subsequently, enzymes normally involved in β- and ω-oxidation of fatty acids more slowly cleave the α-chain and oxidize the C-20 terminal methyl group to the carboxylic acid derivative, respectively. Hence, dicarboxylic acid derivatives containing only 16 carbon atoms are the major excreted metabolites of PGE_1 and PGE_2.



The pharmacological actions of the various prostaglandins are quite diverse. When administered intravaginally, PGE_2 will stimulate the endometrium of the gravid uterus to contract in a manner similar to uterine contractions observed during labor. Thus, PGE_2 is therapeutically available as dinoprostone (Prostin E2)

P.960

for use as an abortifacient at 12 to 20 weeks of gestation and for evacuation of uterine content in missed abortion or intrauterine fetal death up to 28 weeks of gestation. Additionally, PGE_2 is a potent stimulator of smooth muscle of the gastrointestinal (GI) tract and can elevate body temperature in addition to possessing potent vasodilating properties in most vascular tissue while possessing constrictor effects at certain sites. The PGEs in general cause pain when administered via the intradermal route. Many of these properties are shared by $PGF_{2\alpha}$ that also is therapeutically available as an abortifacient at 16 to 20 weeks of gestation and is available as dinoprost tromethamine (Prostin F2α). The synthetic 15-methyl derivative of $PGF_{2\alpha}$, carboprost, also is available as the tromethamine salt (Prostin 15/M) as an abortifacient at 13 to 20 of weeks gestation. However, $PGF_{2\alpha}$ differs from PGE_2 in that it does not significantly

alter blood pressure in humans. The PGD_2 causes both vasodilation and vasoconstriction. The PGEs produce a relaxation of bronchial and tracheal smooth muscle, but the PGFs and PGD_2 cause contraction. The PGE_1 is available as alprostadil (Prostin VR Pediatric) to maintain patency of the ductus arteriosus in neonates until surgery can be performed to correct congenital heart defects.

The effects of prostaglandins on the GI tract deserve special mention. The PGEs and PGI_2 inhibit gastric secretion that may be induced by gastrin or histamine. Prostaglandins appear to play a major cytoprotective role in maintaining the integrity of gastric mucosa. The PGE_1 exerts a protective effect on gastroduodenal mucosa by stimulating secretion of an alkaline mucus and bicarbonate ion and by maintaining or increasing mucosal blood flow. Thus, inhibition of prostaglandin formation in joints produces favorable results, as indicated by a reduction in fever, pain, and swelling. Inhibition of prostaglandin biosynthesis in the GI tract is unfavorable, however, because it may cause disruption of mucosal integrity, resulting in peptic ulcer disease that, as will be discussed later, is commonly associated with the use of NSAIDs and aspirin.

Alternatively, nonprostanoids also can be formed from PGH_2, as illustrated in Figure 36.4. Thromboxane synthetase acts on PGH_2 to produce thromboxane A_2 (TXA_2), whereas prostacyclin synthetase converts PGH_2 to prostacyclin (PGI_2), both of which possess short biological half-lives. A potent vasoconstrictor and inducer of platelet aggregation, TXA_2 has a biological half-life of approximately 30 seconds, being rapidly nonenzymatically converted to the more stable, but inactive, TXB_2. Prostacyclin, a potent hypotensive and inhibitor of platelet aggregation, has a half-life of approximately 3 minutes and is nonenzymatically converted to 6-keto-$PGF_{1\alpha}$. Platelets contain primarily thromboxane synthetase, whereas endothelial cells contain primarily prostacyclin synthetase. Considerable research efforts are being expended in the development of stable prostacyclin analogues and thromboxane antagonists as cardiovascular drugs. The pharmacological effects of some prostaglandins, TXA_2, and prostacyclin are summarized in Table 36.2.

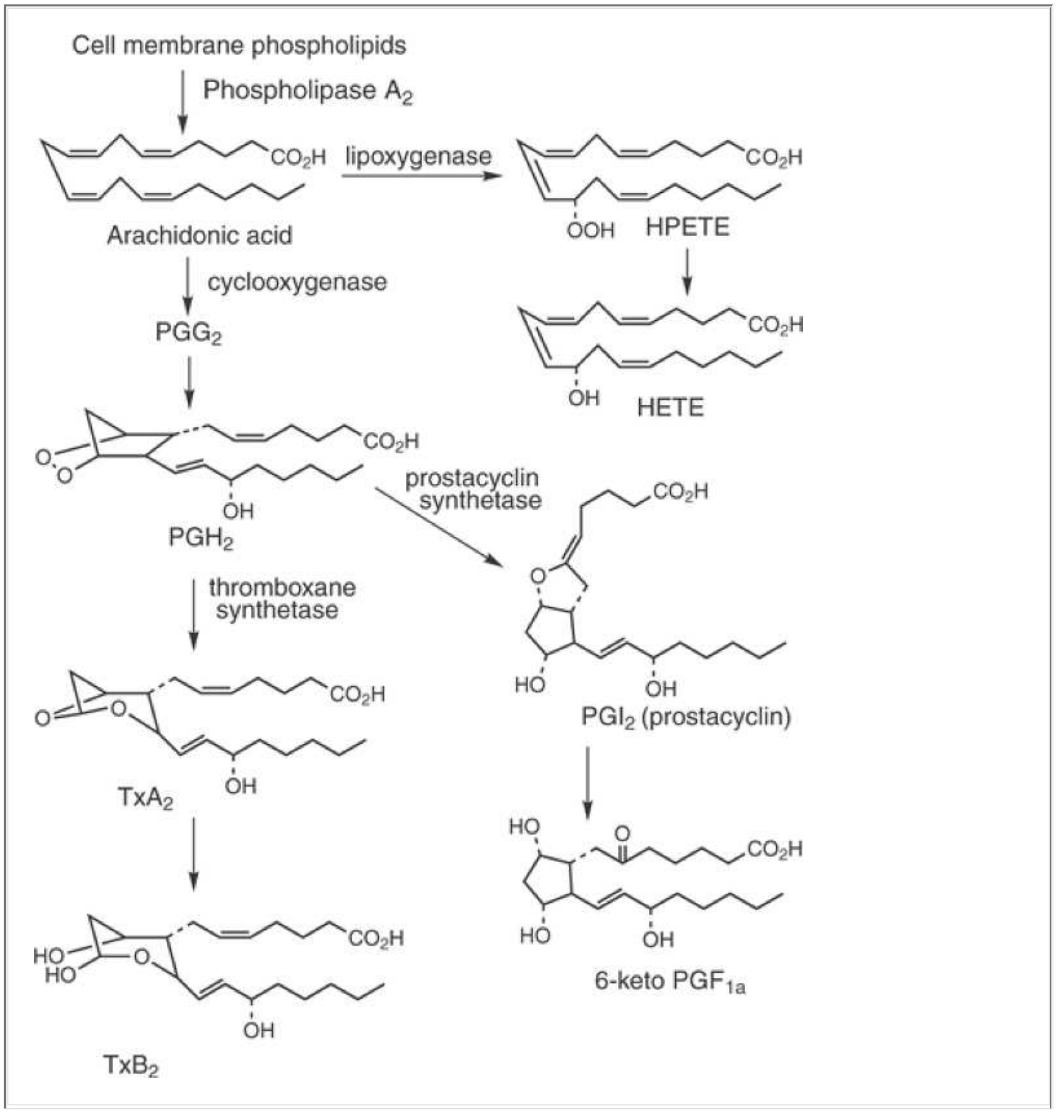


Fig. 36.4. Biosynthesis of thromboxanes, prostacyclin and leukotrienes.

The existence of distinct prostaglandin receptors may explain the broad spectrum of action displayed by the prostaglandins. The nomenclature of these receptors is based on the affinity displayed by natural prostaglandins, prostacyclin, or thromboxanes at each receptor type. Thus, EP receptors are those receptors for which the PGEs have high affinity, FP receptors are those for PGFs, DP receptors are those for PGDs, IP receptors are those for PGI_2, and TP receptors are those for TXA_2. These receptors are coupled through G proteins to effector mechanisms that include stimulation of adenylate cyclase and, hence, increased cyclic adenosine monophosphate levels and phospholipase C that results in increased levels of inositol 1,4,5-triphosphate. Three distinct receptors for leukotrienes have been identified as well.

Lipoxygenases are a group of enzymes that oxidize polyunsaturated fatty acids possessing two *cis* double bonds separated by a methylene group to produce lipid hydroperoxides (19). Arachidonic acid is thus metabolized to a number of hydroperoxy-eicosatetraenoic acid

P.961

derivatives (HPETEs). These enzymes differ in the position at which they peroxidize arachidonic acid and in their tissue specificity. For example, platelets possess only a 12-lipoxygenase, whereas leukocytes possess both a 12-lipoxygenase and a 5-lipoxygenase (28). The HPETE derivatives are not stable, being rapidly converted to a number of metabolites. Leukotrienes are products of the 5-lipoxygenase pathway and are divided into two major classes: hydroxylated eicosatetraenoic acids (LTs), represented by LTB_4, and peptidoleukotrienes (pLTs), such as LTC_4, LTD_4, and LTE_4. 5-Lipoxygenase will produce leukotrienes from 5-HPETE, as shown in Figure 36.5. LTA synthetase converts 5-HPETE to an unstable epoxide called LTA_4 that may be converted by LTA hydrolase to the leukotriene LTB_4 or by glutathione-S-transferase to LTC_4. Other cysteinyl leukotrienes (e.g., LTD_4, LTE_4, and LTF_4) can then be formed from LTC_4 by the removal of glutamic acid and glycine and then reconjugation with glutamic acid, respectively. Cysteinyl leukotrienes activate at least two receptors, designated as $CysLT_1$ and $CysLT_2$. A long-recognized mediator of inflammation, SRS-A (slow-reacting substance of anaphylaxis), is primarily a mixture of two leukotrienes, LTC_4 and LTD_4. The physiological roles of the various leukotrienes are becoming better understood. LTB_4 is a potent chemotactic agent for polymorphonuclear leukocytes, causes the accumulation of leukocytes at inflammation sites, and leads to the development of symptoms characteristic of inflammatory disorders. Both LTC_4 and LTD_4 are potent hypotensives and bronchoconstrictors. Because of the role played by LTs and pLTs in inflammatory conditions and asthma, it is not surprising that intensive research is being conducted in this area. The first cysteinyl leukotriene receptor antagonist, zafirlukast (Accolate) (Fig. 36.6), was approved in 1996 for the prophylaxis and chronic treatment of asthma and has been labeled “lukasts.” It is a selective and competitive receptor antagonist of the cysteinyl leukotriene, LTD_4 and LTE_4. The cysteinyl leukotrienes, originally described as slow-reacting substances of anaphylaxis, produce airway edema, smooth muscle constriction, and altered cellular activity associated with the inflammatory process, all of which are associated with the pathophysiology of asthma. In humans, pretreatment with single oral doses of zafirlukast inhibited bronchoconstriction caused by sulfur dioxide and cold air and reduced the both early and late-phase reaction in patients with asthma caused by inhalation of various

P.962

antigens, such as grass, cat dander, and ragweed. Zafirlukast reduced the increase in bronchial hyperresponsiveness to inhaled histamine that followed inhaled allergen challenge. It is rapidly absorbed and food reduces bioavailability to approximately 40%. It is extensively metabolized via hydroxylation reactions mediated primarily by CYP2C9, and to a minor extent CYP3A4, to essentially inactive metabolites. Excretion is 90% fecal and 10% via urine. Its elimination half-life is approximately 10 hours. A second leukotriene antagonist, montelukast (Singulair) (Fig. 36.6), was approved shortly thereafter for prophylaxis and chronic treatment of asthma as an antagonist of LTD_4 at the $CysLT_1$ receptor. Its oral bioavailability ranges from 60 to 75% depending on the dosage form used. On oral administration, the time to peak concentration ranges from 2 to 4 h. Food can reduce its bioavailability, prolonging time to maximum plasma concentration. Protein binding is more than 99%. Montelukast is also extensively metabolized via hydroxylation reactions mediated by CYP2C9 and CYP3A4 to essentially inactive metabolites. Montelukast is excreted primarily in feces (86%), with an elimination half-life of 3 to 6 hours. The first inhibitor of leukotriene biosynthesis, zileuton (Zyflo), was approved shortly after zafirlukast for prophylaxis and chronic treatment of asthma. Zileuton is a specific inhibitor of 5-lipoxygenase and, thus, inhibits the formation of LTB_4, LTC_4, LTD_4, and LTE_4. The *R*- (+)- and *S*-(–)- enantiomers equally inhibit 5-lipoxygenase, and the drug is marketed as the racemic mixture. Zileuton is metabolized primarily to two diasteromeric glucuronide conjugates and the N-dehydroxylated metabolite.

Table 36.2. Pharmacological Properties of Prostaglandins, Thromboxane, and Prostacyclin

	PGE_2	$PGF_{2\alpha}$	PGI_2	TxA_2
Uterus	Oxytocic	Oxytocic		
Bronchi	dilation	constriction		
Platelets			Inhibits aggregation	Aggregation
Blood vessels	Dilation	Constriction	Dilation	Constriction

Therapeutic Approach to Arthritic Disorders

The goal of drug treatment in early rheumatoid arthritis is to induce remission or at least eliminate evidence of disease activity. Rheumatoid arthritis was traditionally treated with a stepwise approach starting with NSAIDs and progressing through more potent drugs such as glucocorticoids, DMARDs, and biologic response modifiers. The DMARDs were avoided early in the disease because of their potentially serious side effects and were usually reserved for people who showed signs of joint damage. Over time, however, this strategy was recognized as being faulty, because people treated early with DMARDs have better long-term outcomes, with greater preservation of function and less work disability.

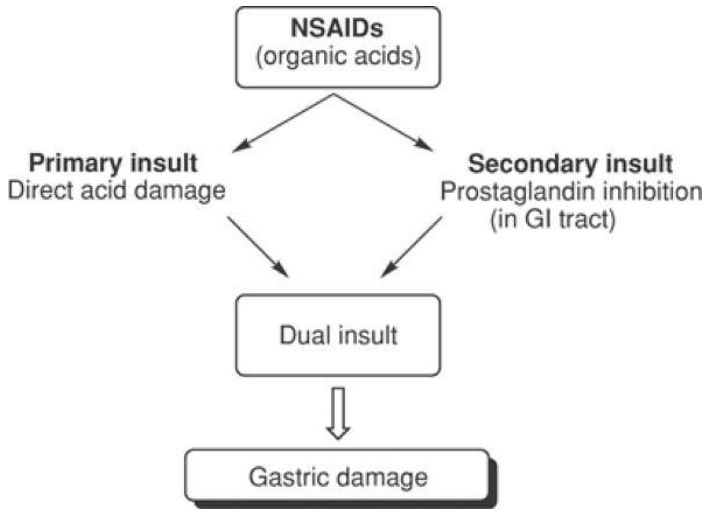

Fig. 36.7. NSAID-induced production of gastric damage by a dual-insult mechanism.

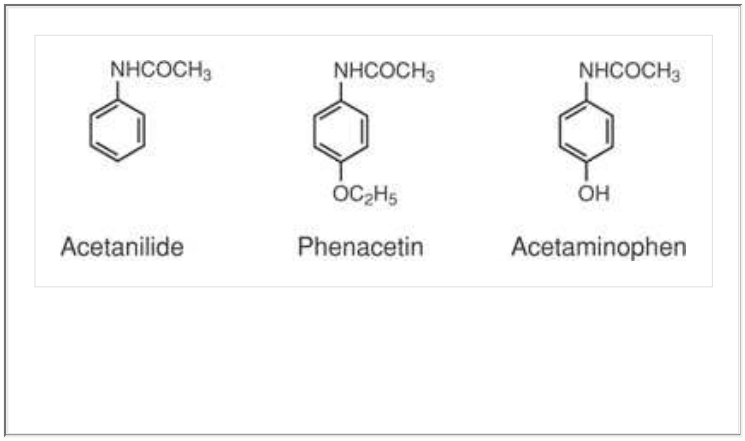
The current approach, therefore, is to treat rheumatoid arthritis aggressively with DMARDs and biologic response modifiers soon after diagnosis. Treating rheumatoid arthritis early with DMARDs, within 3–6 months after symptoms begin, controls inflammation better and is the best way to stop or slow progression of the disease and bring about remission and long term prevention of joint disease. Methotrexate is the cornerstone of DMARD therapy. Long-term treatment with methotrexate and biologic response modifiers may offer the best control of rheumatoid arthritis for the majority of people, which may eliminate the need for other NSAID medications.

A large number of NSAIDs are therapeutically available for the treatment of pain and inflammation associated with arthritic disorders, differing in efficacy but, perhaps more importantly, differing also in overall toxicity. As a group, NSAIDs can cause GI toxicity, such as dyspepsia, abdominal pain, heartburn, gastric erosion leading to wall perforation, peptic ulcer formation, bleeding, diarrhea, renal disorders (e.g., acute renal failure, tubular necrosis, and analgesic nephropathy), and other effects (e.g., tinnitus and headache). Gastric damage produced by NSAIDs generally involves a dual insult mechanism (Fig. 36.7). Most NSAIDs are acidic substances that produce a primary insult because of direct acid damage, an indirect contact effect, and a back diffusion of hydrogen ions. The secondary insult results from inhibition of prostaglandin biosynthesis in the GI tract, where prostaglandins exert a cytoprotective effect. The dual insult leads to gastric damage. A report from the Arthritis, Rheumatism, and Aging Medical Information System Post-Marketing Surveillance Program, before the introduction of COX-2–selective drugs, ranked the overall toxicity of NSAIDs in the following decreasing order: indomethacin > tolmetic > meclofenamate > ketoprofen > fenoprofen > salsalate > aspirin.

Therapeutic Classifications

Antipyretic Analgetics



Mechanism of Action

Drugs included in this class possess analgetic and antipyretic actions but lack anti-inflammatory effects. Antipyretics interfere with those processes by which pyrogenic factors produce fever, but they do not appear to lower body temperature in afebrile subjects. It had been historically accepted that the antipyretics exert their actions within the central nervous system (CNS), primarily at the hypothalamic thermoregulatory center, but more recent evidence suggests that peripheral actions also may contribute. Endogenous leukocytic pyrogens may be released from cells that have been activated by various stimuli, and antipyretics may act by inhibiting the activation of these cells by an exogenous pyrogen or by inhibiting the release of endogenous leukocytic pyrogens from the cells once they have been activated by the exogenous pyrogen. Substantial evidence exists suggesting a central antipyretic mechanism, an antagonism that may result from either a direct competition of a pyrogen and the antipyretic agent at CNS receptors, or an inhibition of prostaglandins in the CNS (29). Despite the extensive use of acetaminophen, the mechanism of action has not been fully elucidated. Acetaminophen may inhibit pain impulses by exerting a depressant effect on peripheral receptors; an antagonistic effect on the actions of bradykinin may play a role. The antipyretic effects may not result from inhibition of release of endogenous pyrogen from leukocytes but, rather, from inhibiting the action of released endogenous pyrogen on hypothalamic thermoregulatory centers. The fact that acetaminophen is an effective antipyretic/analgetic but an ineffective anti-inflammatory agent may result from its greater inhibition of prostaglandin biosynthesis via inhibition of the COX-3 isoform in the CNS compared with that in the periphery.

Table 36.3. Binding Constants (IC_{50} mM) of Selected NSAIDs for the COX enzymes

Drug	COX-1	COX-2	COX-3
Acetaminophen	>1,000	>1,000	460
Phenacetin	>1,000	>1,000	102
Aspirin	10	>1,000	3.1
Diclofenac	0.035	0.041	0.008
Ibuprofen	2.4	5.7	0.24
Indomethacin	0.010	0.66	0.016

Recent research in dogs has revealed a slice variant of COX-1 that was sensitive to inhibition by acetaminophen. This novel variant of the cyclooxygenase system was named COX-3, and it was hypothesized that inhibition of COX-3 could represent a primary CNS mechanism by which acetaminophen and phenacetin exerted their analgesic and antipyretic effects (30). The ability of selected analgesic/antipyretic drugs to inhibit COX-1, COX-2, and COX-3 is

shown in Table 36.3 (30).

Further studies revealed that similar cyclooxygenase variants were present in rodents and humans, but these did not appear to be inhibited by acetaminophen (31,32). These cyclooxygenase variants are proposed to be COX-active, however, and to have a role in the biochemistry of these species (33,34). There is substantial nonhomology between the human, canine, and rodent COX-3 proteins.

The mode of action of acetaminophen therefore is still in question. Certainly, the analgetic and antipyretic properties parallel the decrease in PGE_2 levels in the CNS caused by acetaminophen. The COX-1–deleted, but not the COX-2–deleted, mice showed a decrease in these actions (35). Those authors suggest that in this species, it is COX-1, or a variant of it, that is affected by acetaminophen. Unlike other NSAIDs, such as ibuprofen or aspirin, acetaminophen does not have significant anti-inflammatory, antiplatelet, or gastric ulcerogenic activity. Other authors claim that the mechanism of action of acetaminophen is thought to involve inhibition of COX-2, and this fits with the therapeutic profile of the recently discovered, powerful, and selective COX-2 inhibitors (36). Acetaminophen is only effective, however, when COX-2 activity is at a low level. This view partially explains the lack of anti-inflammatory action, because COX-2 activity will be high in this situation (37).

Graham and Scott (37) also have put forward the interesting hypothesis that acetaminophen acts by depletion of the stores of glutathione, which is a known cofactor for PGE synthase. This would explain the decrease in PGE production and the concomitant analgetic effect. The depletion of glutathione is the main cause of acetaminophen toxicity. The highly reactive benzoquinone-imine, formed by CYP2E1 isoform, must be conjugated with glutathione before it can react with other crucial cell components. In overdose, failure of this molecular mechanism results in serious liver damage. The depletion of

the body's supply of glutathione also should affect the biosynthesis of the inflammatory mediator leukotriene C4. At therapeutic acetaminophen levels, however, this does not seem to be significant.

A review paper discussing the dichotomies of the acetaminophen mechanism and COX-3 is available (38).

Historical Background

Acetanilide was introduced into therapy in 1886 under the name antifebrin as an antipyretic/analgetic agent but was subsequently found to be too toxic (methemoglobinemia and jaundice), particularly at high doses, to be useful. Phenacetin was introduced the following year and remained in use until the 1960s because of reports of nephrotoxicity. Phenacetin is longer acting than acetaminophen despite the fact that it is metabolized to acetaminophen but is a weaker antipyretic. Shortly thereafter, acetaminophen (paracetamol) was introduced in 1893 but remained unpopular for more than 50 years, until it was observed that it is a metabolite of both acetanilide and phenacetin. It remains the only useful agent of this group and is widely used as a nonprescription antipyretic/analgetic under a variety of trade names (Tylenol, Patrol, and Tempera). The analgetic activity of acetaminophen is comparable to that of aspirin, but acetaminophen lacks useful anti-inflammatory activity. Its advantages over aspirin as an analgetic, however, are that individuals who are hypersensitive to salicylates generally respond well to acetaminophen.

Structure–Activity Relationships

The structure–activity relationships of p-aminophenol derivatives have been widely studied. Based on the comparative toxicity of acetanilide and acetaminophen, aminophenols are less toxic than the corresponding aniline derivatives, although p-aminophenol itself is too toxic for therapeutic purposes. Etherification of the phenolic function with methyl or propyl groups produces derivatives with greater side effects than with ethyl groups. Substituents on the nitrogen atom that reduce basicity reduce activity unless that substituent is metabolically labile (e.g., acetyl). Amides derived from aromatic acids (e.g., N-phenylbenzamide) are less active or inactive.

Acetaminophen USP

Acetaminophen is weakly acidic (pK_a = 9.51) and synthesized by the acetylation of p-aminophenol. It is weakly bound to plasma proteins (18–25%). Acetaminophen is indicated for use as an antipyretic/analgetic, particularly in those individuals displaying an allergy or sensitivity to aspirin. It does not possess anti-inflammatory activity, but it will produce analgesia in a wide variety of arthritic and musculoskeletal disorders. It is available in various formulations, including suppositories, tablets, capsules, granules, and solutions. The usual adult dose is 325 to 650 mg every 4 to 6 hours. Doses of greater than 2.6 g/day are not recommended for long-term therapy because of potential hepatotoxicity issues. Acetaminophen, unlike aspirin, is stable in aqueous solution, making liquid formulations readily available, a particular advantage in pediatric cases.

Metabolism and Toxicity

The metabolism of acetanilide, acetaminophen, and phenacetin is illustrated in Figure 36.8 (39). As indicated earlier, both acetanilide and phenacetin are metabolized to acetaminophen. Additionally, both undergo hydrolysis to yield aniline derivatives that produce directly, or through their conversion to hydroxylamine derivatives, significant methemoglobinemia and hemolytic anemia, which resulted in their removal from the U.S. market. On the other hand, acetaminophen is undergoes rapid first-pass metabolism in the GI tract primarily by conjugation reactions, with the O-sulfate conjugate being the primary metabolite in children and the O-glucuronide being the primary metabolite in adults. A minor, but significant, product of both acetaminophen and phenacetin is the N-hydroxyamide produced by a CYP2E1 and CYP3A4. The CYP2E1 is the rate-limiting enzyme that initiates the cascade of events leading to acetaminophen hepatotoxicity; in the absence of this cytochrome P450 enzyme, toxicity will only be apparent at high concentrations. The N-hydroxyamide is then converted to a reactive toxic metabolite, an acetimidoquinone, which has been suggested (40) to produce the nephrotoxicity and hepatotoxicity associated with acetaminophen and phenacetin. Normally, this iminoquinone is detoxified by conjugation with hepatic glutathione. In cases of ingestion of large doses or overdoses of acetaminophen, however, hepatic stores of glutathione may be depleted by more than 70%, allowing the reactive quinone to interact with soft nucleophilic functional groups, primarily —SH groups, on hepatic proteins, resulting in the formation of covalent adducts that produce hepatic necrosis. Overdoses of acetaminophen can produce potentially fatal hepatic necrosis, renal tubular necrosis, and hypoglycemic coma. Various sulfhydryl-containing compounds were found to be useful as antidotes to acetaminophen overdoses. The most useful of these, N-acetylcysteine (Mucomyst, Acetadote), serves as a substitute for the depleted glutathione by enhancing hepatic glutathione stores and/or by enhancing disposition by nontoxic sulfate conjugation (41). N-Acetylcysteine also may inhibit the formation of the toxic iminoquinone metabolite (42). In cases of acetaminophen overdoses, N-acetylcysteine is administered as a 5% solution in water, soda, or juice or intravenously (IV) at 140 mg/kg followed by 17 maintenance doses of 70 mg/kg every 5 hours.

Drug Interactions

Hepatic necrosis develops at much lower doses of acetaminophen in some heavy drinkers than would be expected (39), perhaps because of the induction of the CYP2E1 system, depletion of glutathione stores, or aberrations in the primary sulfate and glucuronide conjugation pathways. At 4 g per day, acetaminophen has been reported to potentiate the response to oral anticoagulants, increasing prothrombin time (INR values) two to three times. Interactions with warfarin

(Coumadin), dicumarol, anisindione, and diphenadione have been suggested. The mechanism of these interactions has not been fully elucidated but may be associated with competition for plasma protein binding sites, because acetaminophen is a weak acid and is weakly bound, but may also interfere with the enzymes involved in vitamin K-dependent coagulation factor synthesis. The absorption of acetaminophen is enhanced by polysorbate and sorbitol and is reduced by anticholinergics and narcotic analgetics. Chemical incompatibilities also have been reported based on hydrolysis by strong acids or bases or by phenolic oxidation in the presence of oxidizing agents. Acetaminophen forms “sticky” mixtures with diphenhydramine HCl and discolors under humid conditions in the presence of caffeine or codeine phosphate.

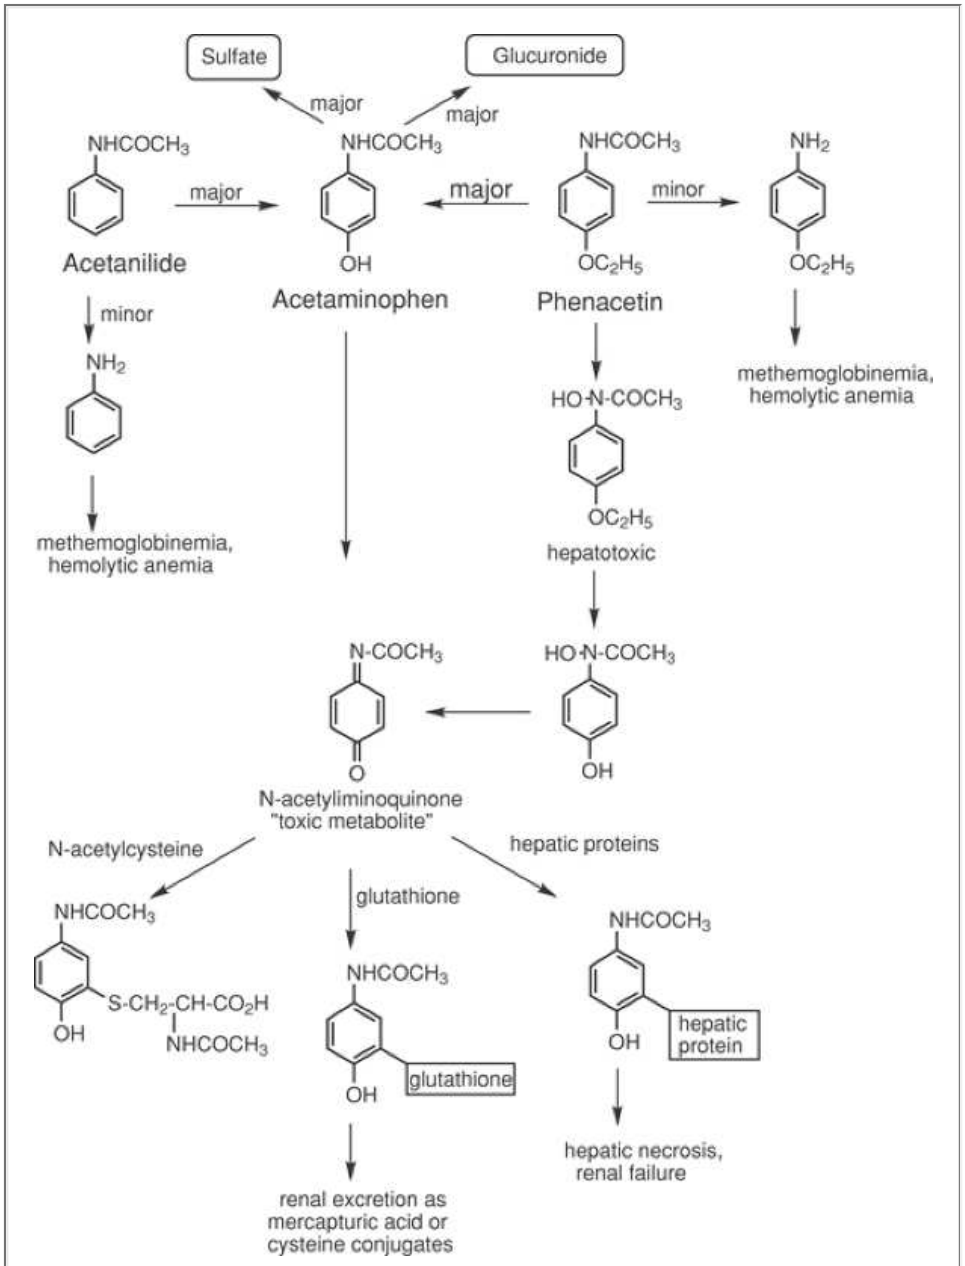


Fig. 36.8. Metabolism of acetaminophen.

Anti-Inflammatory Drugs

Salicylates

The use of salicylates dates back to the nineteenth century. Salicylic acid itself was first obtained in 1838 from salicin, a glycoside present in most willow and poplar bark. Interestingly, Hippocrates prescribed chewing willow bark for pain relief in the fifth century AD. In 1860, Kolbe synthesized salicylic acid from sodium phenoxide and carbon dioxide, a method that inexpensively produced large quantities. Derivatives of salicylic acid began to receive medical attention shortly thereafter. Sodium salicylate was employed as an antipyretic/antirheumatic agent in 1875, and the phenyl ester was used in 1886. Acetylsalicylic acid was prepared in 1853 but was not used medicinally until 1899. The term “aspirin” was given to acetylsalicylic acid by Dreser, the director of pharmacology at Frederich Bayer and Company in Germany, as a contraction of the letter “a” from acetyl and “spirin,” an older name given to salicylic acid (spiric acid) that was derived from a natural source in spirea plants. Since then, numerous derivatives of salicylic acid have been synthesized and evaluated pharmacologically, yet only a relatively few derivatives have achieved

therapeutic utility.

In addition to possessing antipyretic, analgetic, and anti-inflammatory properties, salicylates possess other

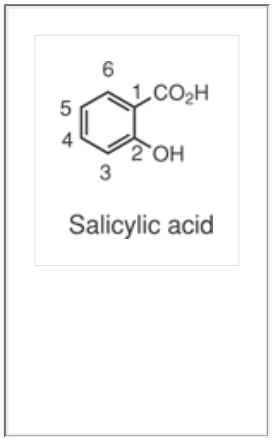
actions that have been proven to be therapeutically beneficial. Because salicylates promote the excretion of uric acid, they are useful in the treatment of gouty arthritis. More recent attention has been given to the ability of salicylates to inhibit platelet aggregation, which may contribute to heart attacks and stroke. Aspirin appears to inhibit prostaglandin cyclooxygenase in platelet membranes, thus blocking formation of the potent platelet-aggregating factor TXA_2 in a manner that is irreversible. The Physicians Health Study concluded that in a group of 22,071 participants, there was a 44% reduction in the risk of myocardial infarction in the group taking a single 325-mg aspirin tablet taken every other day versus the placebo group (43). The role of aspirin in reducing cardiac mortality has been reviewed (44). Also, aspirin and other NSAIDs might be protective against colon cancer (45). Thus, the therapeutic utility of aspirin continues to increase. Unfortunately, a number of side effects are associated with the use of salicylates, most notably GI disturbances such as dyspepsia, gastroduodenal bleeding, gastric ulcerations, and gastritis.

Mechanism of action

A number of possible mechanisms of action have been proposed for salicylates over the years. Among those that have been suggested are inhibition of the biosynthesis of histamine, antagonism of the actions of various kinins, inhibition of mucopolysaccharide biosynthesis, inhibition of lysosomal enzyme release, and inhibition of leukocyte accumulation. The most widely accepted mechanism of action currently is the ability of these drugs to inhibit the biosynthesis of prostaglandins at the cyclooxygenase stage discussed earlier. Aspirin is the only NSAID that covalently modifies cyclooxygenase by acetylating Ser-530 of COX-1 and Ser-516 of COX-2. Aspirin, however, is 10 to 100 times more potent against COX-1 than against COX-2 (46). Aspirin's actions on COX-1 prevent both endoperoxide and 15-peroxidation of arachidonic acid, but its action on COX-2 does not prevent formation of 15-OOH arachidonic acid (25).

Structure–activity relationships

Despite the vast effort that has been expended in the search to find a “better” aspirin—that is, one possessing fewer GI side effects but a greater potency and a longer duration of action yet is inexpensive and an antipyretic, analgetic, and anti-inflammatory agent that is overall superior to aspirin—none has yet to be discovered. The following structure–activity relationships have been established:



The active moiety appears to the salicylate anion. The side effects of aspirin, particularly the GI effects, appear to be associated with the carboxylic acid function. Reducing the acidity of this group (e.g., converting to an amide, salicylamide) maintains the analgetic actions of salicylic acid derivatives but eliminates the anti-inflammatory properties. Substitution on either the carboxyl or phenolic hydroxyl groups may affect potency and toxicity. Benzoic acid itself has only weak anti-inflammatory activity. Placing the phenolic hydroxyl group meta or para to the carboxyl group abolishes this activity. Substitution of halogen atoms on the aromatic ring enhances potency and toxicity. Substitution of aromatic rings at the 5-position of salicylic acid increases anti-inflammatory activity (e.g., diflunisal).

Absorption and metabolism

Most salicylates are rapidly and effectively absorbed on oral administration with the rate of absorption and bioavailability being dependent on a number of factors, including the dosage formulation, gastric pH, food contents in the stomach, gastric emptying time, the presence of buffering agents or antacids, and particle size. Because

salicylates are weak acids (acetylsalicylic acid pK_a = 3.5), absorption generally takes place primarily from the small intestine and, to a lesser extent, from the stomach by the process of passive diffusion of un-ionized molecules across the epithelial membranes of the GI tract. Thus, gastric pH is an important factor in the rate of absorption of salicylates. Any factor that increases gastric pH (e.g., buffering agents) will slow its rate of absorption, because more of the salicylate will be in the ionized form. The differences in the rates of absorption of aspirin, salicylate salts, and the numerous buffered preparations of salicylates actually are quite small, with absorption half-times in humans ranging from approximately 20 minutes for buffered preparations to 30 minutes for aspirin itself. The presence of food in the stomach also slows the rate of absorption. Formulation factors may contribute to the differences in absorption rates of the various brands of plain and buffered salicylate preparations. Tablet formulations consisting of small particles are absorbed faster than those of larger particle size. The bioavailability of salicylate from enteric-coated preparations may be inconsistent. Absorption of salicylate from rectal suppositories is slower and incomplete and is not recommended when high salicylate levels are required. Topical preparations of salicylic acid ester, e.g., methyl salicylate, are effective in that the rate of salicylate absorption from the skin is rapid. However, 3–5% solutions of salicylic acid are also applied topically as a keratolytic agent.

Salicylates are highly bound to plasma protein albumin, with binding being concentration dependent. At low therapeutic concentrations of 100 µg/mL, approximately 90% of aspirin is plasma protein bound, whereas at higher concentrations of approximately 400 µg/mL, only 76% binding is observed. Plasma protein binding is a major factor in the drug interactions observed for salicylates.

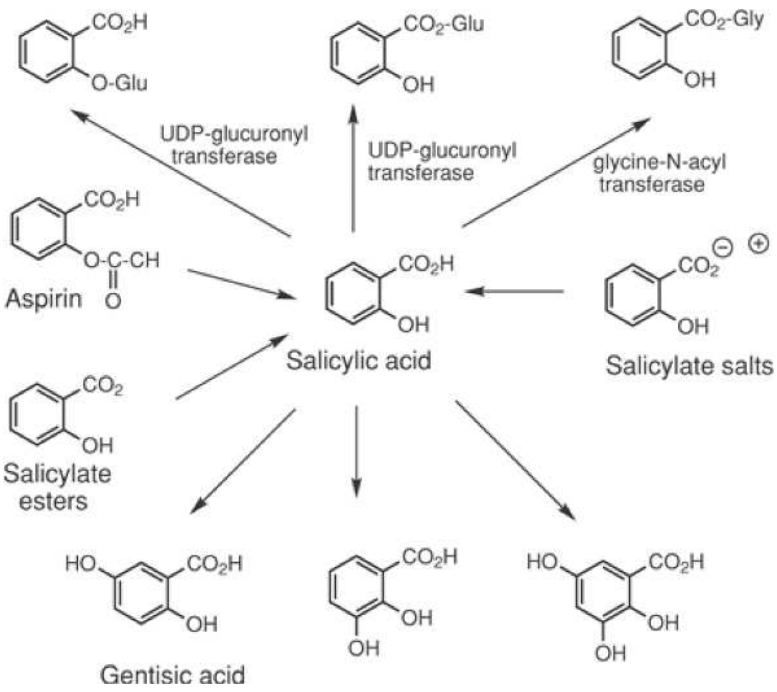


Fig. 36.9. Metabolism of salicylic acid derivatives. Glu, glucuronide conjugate; Gly, glycine conjugate.

The major metabolic routes of esters and salts of salicylic acid are illustrated in Figure 36.9. The initial route of metabolism of these derivatives is their conversion to salicylic acid, which may be excreted in the urine as the free acid (10%) or undergo conjugation with either glycine, to produce the major metabolite salicyluric acid (75%), or with glucuronic acid, to form the glucuronide ether and ester (15%). In addition, small amounts of metabolites resulting from microsomal aromatic hydroxylation are found. The major hydroxylation metabolite, gentisic acid, was once thought to be responsible for the anti-inflammatory actions of the salicylates, but its presence in trace quantities would rule out a major role for gentisic acid, or the other hydroxylation metabolites, in the pharmacological action of salicylates. The metabolism of pharmacokinetic properties of salicylates has been extensively reviewed (47).

Side effects

The most commonly observed side effects associated with the use of salicylates relate to disturbances of the GI

tract. Nausea, vomiting, epigastric discomfort, intensification of symptoms of peptic ulcer disease (e.g., dyspepsia and heartburn), gastric ulcerations, erosive gastritis, and GI hemorrhage occur in individuals on high doses of aspirin. The incidence of these side effects is more rare at low doses, but a single dose of aspirin can cause GI distress in 5% of individuals. Gastric bleeding induced by salicylates generally is painless but can lead to fecal blood loss and may cause a persistent iron deficiency anemia. At dosages that generally are useful in anti-inflammatory therapy, aspirin may lead to a loss of 3 to 8 mL/day of blood. The mechanism by which salicylates cause gastric mucosal cell damage may be caused by a number of factors, including gastric acidity, ability of salicylates to damage the normal mucosal barrier that protects against the back diffusion of hydrogen ions, ability of salicylates to inhibit the formation of prostaglandins (particularly those of the PGE series, which normally inhibit gastric acid secretion), and inhibition of platelet aggregation (leading to an increased tendency toward bleeding). Thus, salicylate use before surgery or tooth extraction is contraindicated.

Reye's syndrome is an acute condition that may follow influenza and chickenpox infections in children from infancy to their late teens, with the majority of cases occurring between the ages of 4 and 12 years. It is characterized by symptoms including sudden vomiting, violent headaches, and unusual behavior in children who appear to be recovering from an often mild viral illness. Although a rare condition (60–120 cases per year, or an incidence of 0.15 per 100,000 population of those ≤18 years), it can be fatal, with a death rate of between 20 and 30%. Fortunately, the number of cases is declining, partly because of the observations that more than 90% of children with Reye's syndrome were on salicylate therapy during a recent viral illness. Based on these observations, the U.S. Food and Drug Administration (FDA) has proposed that aspirin and other salicylates be labeled with a warning against their use in children younger than 16 years with influenza, chickenpox, or other flu-like illness. Acetaminophen would appear to be the drug of choice in children with these conditions.

Salicylates account for approximately 25% of all accidental poisonings in the United States.

Drug interactions

Because of the widespread use of salicylates, it is not surprising that interactions with many other drugs used in therapeutic combinations have been observed. Several of these interactions are clinically significant. More data are available for aspirin than for any other specific salicylate product. As mentioned previously, acetylsalicylic acid is a weak acid that is highly bound to plasma proteins (50–80%), and it will compete for these plasma protein binding sites with other drugs that are highly bound to these sites. The interaction that results from the combination of salicylates with oral anticoagulants represents one of the most widely documented clinically significant drug interactions reported to date. The plasma concentration of free anticoagulant increases in the presence of salicylates, necessitating a possible decrease in the dosage of anticoagulant required to produce a beneficial therapeutic effect. The ability of salicylates to produce GI ulcerations and bleeding, coupled with the inhibition of the clotting mechanism, results in a clinically significant drug interaction. In addition, salicylates may inhibit the synthesis of prothrombin by antagonizing the actions of vitamin K. Additionally, NSAIDs can produce these interactions. The competition for plasma protein binding sites also can lead to an increase in free methotrexate levels (thus enhancing the toxicity of methotrexate), enhanced toxicity of long-acting sulfonamides, and a hypoglycemic effect (resulting from displacement of oral hypoglycemic drugs). In large

doses, salicylates given concomitantly with uricosuric drugs, such as probenecid and sulfinpyrazone, may lead to a retention of uric acid and, thus, antagonize the uricosuric effect, despite the fact that salicylates when used alone increases urinary excretion of uric acid. The diuretic activity of aldosterone antagonists, such as spironolactone, may be antagonized by salicylates. Corticosteroids may decrease blood levels of salicylates because of their ability to increase the glomerular filtration rate. The incidence and severity of GI ulcerations may be increased if corticosteroids, salicylates, and NSAIDs are administered together. The GI bleeding induced by salicylates may be enhanced by the ingestion of ethanol. Numerous other interactions have been reported, but their clinical significance has not been fully established.

Salicylate hypersensitivity, particularly to aspirin, is relatively uncommon but must be recognized, because severe and potentially fatal reactions may occur. Signs of aspirin hypersensitivity appear soon after administration and include skin rashes, watery secretions, urticaria, vasomotor rhinitis, edema, bronchoconstriction, and anaphylaxis. Less than 1% of the U.S. population may experience aspirin hypersensitivity; this group consists primarily of middle-aged individuals. Females are more likely to experience aspirin intolerance or hypersensitivity. Aspirin-sensitive patients with asthma are especially at high risk. Mild salicylism may occur after repeated administration of large doses. Symptoms include dizziness, tinnitus, nausea, vomiting, diarrhea, and mental confusion. Doses of 10 to 30 g have been known to cause death in adults, but some individuals have ingested up to 130 g without fatality. More than 10,000 cases of serious salicylate toxicity occur in the United States each year.

Available preparations

The structures of the marketed preparations of salicylic acid are presented in Figure 36.10.

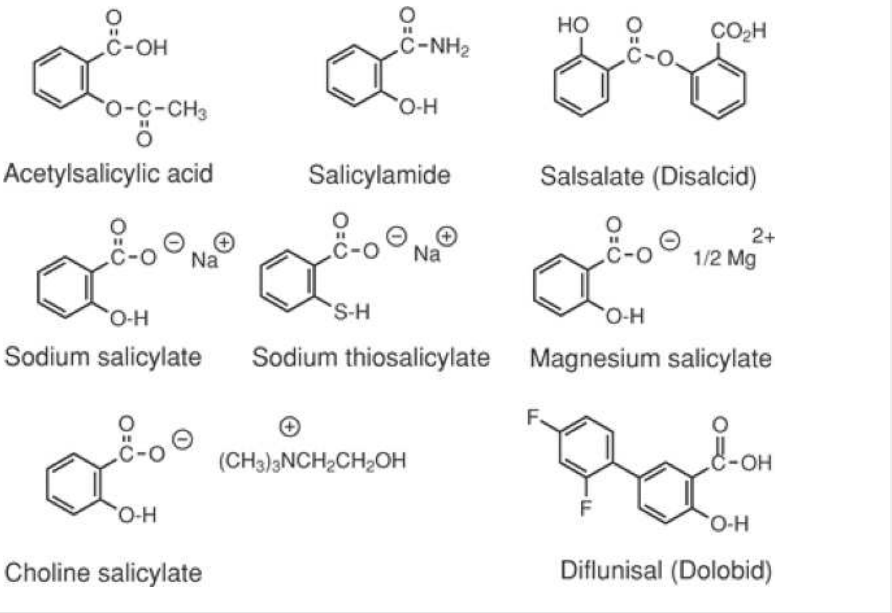

Fig. 36.10. Structures of marketed derivatives of salicylic acid.

Aspirin USP

Acetylsalicylic acid, or aspirin, is a white powder that is stable in a dry environment but that is hydrolyzed to salicylic acid and acetic acid under humid or moist conditions. Hydrolysis also can occur when aspirin is combined with alkaline salts or with salts containing water of hydration. Stable aqueous solutions of aspirin are thus unobtainable despite the addition of modifying drugs that tend to decrease hydrolysis. Aspirin is rapidly absorbed largely intact from the stomach and upper small intestine on oral administration but is rapidly hydrolyzed by plasma esterases. Peak plasma levels usually are achieved within 2 hours after administration. Increasing the pH of the stomach by the addition of buffering agents may affect absorption, because the degree of ionization will be increased.

Aspirin is indicated for the relief of minor aches and mild to moderate pain (325–650 mg every 4 hours), for arthritis and related arthritic conditions (3.2–6.0 g/day), to reduce the risk of transient ischemic attacks (1.3 g/day), for myocardial infarction prophylaxis (300–325 mg/day), and as a platelet aggregation inhibitor (80–325 mg per day). It is available in a large number of dosage forms and strengths as tablets, suppositories, capsules, enteric-coated tablets, and buffered tablets.

Salicylamide

Salicylamide is less acidic (pK_a 8.2) than other salicylic acid derivatives. Although poorly soluble in water, stable solutions can be formed at pH 9 through ionization of the phenolic group. It is absorbed from the GI tract on oral administration and is rapidly metabolized to inactive metabolites by intestinal mucosa, but not by hydrolysis. Activity appears to reside in the intact molecule. Salicylamide is approximately 40 to 55% plasma protein bound, and it competes with other salicylates and acetaminophen for glucuronide conjugation, decreasing the extent of conjugation of these other drugs. Excretion occurs rapidly, primarily in the urine. The major advantages of salicylamide are its general lack of gastric irritation relative to aspirin, and its use in individuals who are hypersensitive to aspirin. Salicylamide enters the CNS more rapidly than other salicylates and will cause sedation and drowsiness when administered in large doses. Whereas salicylamide is reported to be as effective as aspirin as an analgetic/antipyretic and is effective in relieving pain associated with arthritic conditions, it does not appear to possess useful anti-inflammatory activity (48). Thus, indications for the treatment of arthritic disease states are unwarranted, and its use is restricted to the relief of minor aches and pain at a dosage of 325 to 650 mg three or four times per day. Its effects in humans are not reliable, however, and its use is not widely recommended.

Salicylate Salts

Several salts of salicylic acid, sodium salicylate USP, choline salicylate USP, and magnesium salicylate USP, and

one salt of thiosalicylic acid, sodium thiosalicylate USP, are available. These salts are used primarily to decrease GI disturbances or because they form stable aqueous solutions. Sodium salicylate is half as potent, on a weight basis, as aspirin as an analgetic/

antipyretic, but it produces less GI irritation and equivalent blood levels and is useful in patients exhibiting hypersensitivity to aspirin. It generates salicylic acid in the GI tract, accounting for some GI irritation, and sodium bicarbonate sometimes is given concomitantly to reduce acidity. Sodium salicylate, unlike aspirin, does not affect platelet function, although prothrombin times are increased. It is available as tablets, enteric-coated tablets, and as a solution for injection.

Choline salicylate has a lower incidence of GI side effects compared with aspirin, and it has been shown to be particularly useful in treating juvenile rheumatoid arthritis, in which aspirin was ineffective. It is absorbed more rapidly than aspirin and produces higher salicylate plasma levels. It is available as a mint-flavored liquid.

Magnesium salicylate has a low incidence of GI side effects. Both sodium salicylate and magnesium salicylate should be used cautiously in individuals in whom excessive amounts of these electrolytes might be detrimental. The possibility of magnesium toxicity in individuals with renal insufficiency exists. It is available as tablets, but its safety in children under 12 years of age has not been fully determined.

Sodium thiosalicylate (Solate) is administered intramuscularly (IM) for the treatment of rheumatic fever, muscular pain, and acute gout.

Salsalate (Disalcid)

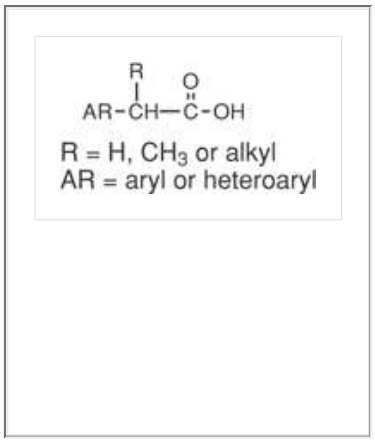
Salsalate, or salicylsalicylic acid, (pK_a 3.5 [COOH], 9.8 [AR-OH]) is a dimer of salicylic acid. It is insoluble in gastric juice but is soluble in the small intestine, where it is partially hydrolyzed to two molecules of salicylic acid and absorbed. On a molar basis, it produces 15% less salicylic acid than aspirin. It does not cause GI blood loss and can be given to aspirin-sensitive patients. Salsalate is available as capsules and tablets.

Diflunisal (Dolobid)

Diflunisal (pK_a 3.3) was introduced in the United States in 1982 and has gained considerable acceptance as an analgetic and as a treatment of rheumatoid arthritis and osteoarthritis. Diflunisal is metabolized primarily to ether and ester glucuronide conjugates. No metabolism involving changes in ring substituents has been reported. It is more potent than aspirin but produces fewer side effects and has a biological half-life three to four times greater than that of aspirin. It is rapidly and completely absorbed on oral administration, with peak plasma levels being achieved within 2 to 3 hours of administration. It is highly bound (99%) to plasma proteins after absorption. Its elimination half-life is 8 to 12 hours, and it is excreted into urine primarily as glucuronide conjugates. The most frequently reported side effects include disturbances of the GI system (e.g., nausea, dyspepsia, and diarrhea), dermatological reactions, and CNS effects (e.g., dizziness and headache).

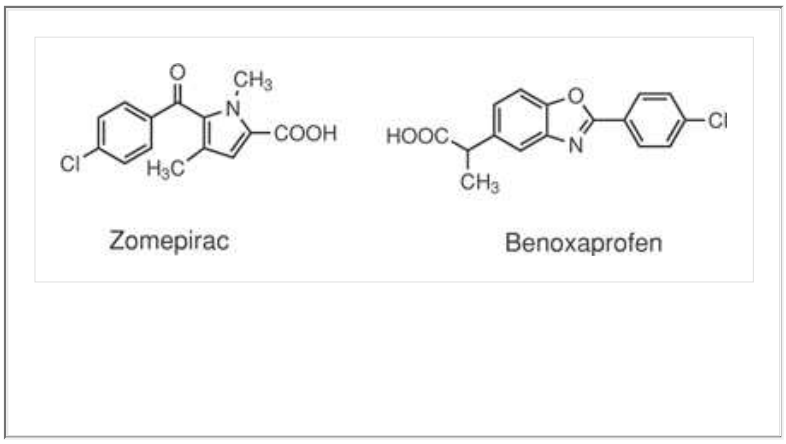
Diflunisal is a moderately potent inhibitor of prostaglandin biosynthesis, but it differs from the manner in which aspirin inhibits the cyclooxygenase system in that the inhibition is competitive and reversible in nature. Diflunisal does not have an appreciable effect on platelet aggregation, however, and does not significantly produce gastric or intestinal bleeding.

Arylalkanoic Acids



The largest group of NSAIDs is represented by the class of arylalkanoic acids as typified by the general chemical

structure, and several factors have caused this to be one of the most active areas of drug development in recent years. The impact that the introduction of phenylbutazone in the 1950s had on arthritis therapy was more than matched by the interest generated by the introduction of indomethacin in the mid-1960s. As a result of a study designed to investigate the anti-inflammatory activity of 350 indole acetic acid derivatives related structurally to serotonin and metabolites of serotonin, the Merck group led by Shen (49) reported the synthesis and antipyretic and anti-inflammatory activity of the most potent compound in the series, indomethacin. The observation that indomethacin possessed 1,085-fold the anti-inflammatory activity and 20-fold the antipyretic activity of phenylbutazone (and 10-fold the antipyretic activity of aminopyrine) generated considerable interest in the development of other aryl and heteroaryl acetic acid and propionic acid derivatives. The marketplace was ripe for new anti-inflammatory drugs and most pharmaceutical companies joined in the search for new arylalkanoic acids. The introduction of ibuprofen in the 1970s by Upjohn was quickly followed by the appearance of fenoprofen calcium, naproxen, and tolmetin. Sulindac, an analogue of indomethacin, was introduced in the late 1970s. The 1980s produced zomepirac, benoxaprofen, ketoprofen, flurbiprofen, suprofen, and diclofenac sodium. The 1990s produced ketorolac, etodolac, nabumetone, and most significantly, the development of selective COX-2 inhibitors, celecoxib, rofecoxib, and valicoxib, which reached the market during the period from 1997 to 2000. This rapid development has been accompanied by some setbacks, however. Zomepirac, introduced in 1980 as an analgetic, was withdrawn in 1983 because of severe anaphylactoid reactions, particularly in patients sensitive to aspirin. Benoxaprofen was withdrawn within 6 months of its introduction in 1982 because of several deaths caused by cholestatic jaundice in Europe and the United States. In addition, benoxaprofen produced photosensitivity reactions in patients when they were exposed to sunlight and onycholysis (loosening of the fingernails) in some patients. Suprofen, introduced as an analgetic in 1985, was removed from the market two years later because of flank pain and transient renal failure. In 1989, however, it was reintroduced for ophthalmic use. Numerous other arylalkanoic acids currently are being evaluated in various stages of clinical trials.



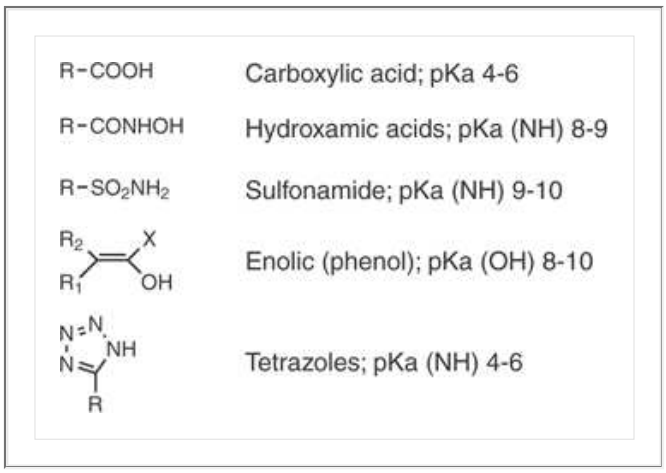
As discussed earlier, most NSAIDs possess a number of biochemical and pharmacological actions. As was the case for the salicylates, the arylalkanoic acids share, to various extents, the property of inhibition of prostaglandin biosynthesis by inhibiting COX-1 and COX-2 with varying degrees of selectivity (Table 36.3).

General structure–activity relationships

Drugs of this class share a number of common structural features. These general structure–activity relationships will be discussed here as they pertain to the proposed mechanism of action. Specific structure–activity relationships for each drug or drug class will be presented separately, where appropriate.

All nonselective COX inhibitors possess a center of acidity, which can be represented by a carboxylic acid function, an enolic function, a hydroxamic acid function, a sulfonamide, or a tetrazole ring. The relationship of this acid center to the carboxylic acid function of arachidonic acid is obvious. The activity of ester and amide derivatives of carboxylic acids generally is attributed to the metabolic hydrolysis products. One nonacidic drug, nabumetone, has been recently introduced in the United States, but as will be discussed later, its activity is attributed to its bioactivation to an active acid metabolite. The center of acidity generally is located one carbon atom adjacent to a flat surface represented by an aromatic or heteroaromatic ring. The distance between these centers is crucial, because increasing this distance to two or three carbons generally diminishes activity. Derivatives of aryl or heteroaryl acetic or propionic acids are most common. This aromatic system appears to correlate with the double bonds at the 5- and 8-positions of arachidonic acid. Substitution of a methyl group on the carbon atom separating the acid center from the aromatic ring tends to increase anti-inflammatory activity. The resulting α-methyl acetic acid, or 2-substituted propionic acid, analogues have been given the class name “profens” by the U.S. Adopted Name

Council. Groups larger than methyl decrease activity, but incorporation of this methyl group as part of an alicyclic ring system does not drastically affect activity. Introduction of a methyl group creates a center of chirality. Anti-inflammatory activity in those cases in which the enantiomers have been separated and evaluated, whether determined in vivo or in vitro by cyclooxygenase assays, is associated with the *S*-(+)-enantiomer. Interestingly, in those cases in which the propionic acid is administered as a racemic mixture, in vivo conversion of the *R*-enantiomer to the biologically active *S*-enantiomer is observed to varying degrees. A second area of lipophilicity that is noncoplanar with the aromatic or heteroaromatic ring generally enhances activity. This second lipophilic area may correspond to the area of the double bond in the 11-position of arachidonic acid. This lipophilic function may consist of an additional aromatic ring or alkyl groups either attached to or fused with the aromatic center.



General metabolism

Essentially all the arylalkanoic acid derivatives that are therapeutically available are extensively metabolized. Metabolism occurs primarily through hepatic microsomal enzyme systems and may lead to deactivation or bioactivation of the parent molecules. Metabolism of each drug will be treated separately.

Drug interactions

All the arylalkanoic acids are highly bound to plasma proteins and, thus, may displace other drugs from protein binding sites, resulting in an enhanced activity and toxicity of the displaced drugs. Interestingly, despite the high degree of plasma protein binding, indomethacin does not display this characteristic drug interaction. The most commonly observed interaction is that between the arylalkanoic acid and oral anticoagulants, particularly warfarin (Coumadin). Coadministration may prolong prothrombin time. Potential interactions with other acidic drugs, such as hydantoins, sulfonamides, and sulfonylureas, should be monitored. Concomitant administration of aspirin decreases plasma levels of arylalkanoic acids by as much as 20%. Probenecid, on the other hand, tends to increase these plasma levels. Interactions with drugs that may induce hepatic microsomal enzyme systems, such as phenobarbital, may enhance or diminish anti-inflammatory activity depending on whether the arylalkanoic acid is metabolically bioactivated or inactivated by this enzyme system. Certain diuretics, such as furosemide, inhibit the metabolism of prostaglandins by 15-hydroxy-prostaglandin dehydrogenase, and the resulting increase in PGE_2 levels induce plasma renin activity. Because the arylalkanoic acids block the biosynthesis of prostaglandins, the effects of furosemide can be antagonized, in part, offering a potentially significant drug interaction.

Aryl- and heteroarylacetic acids

The structures of the aryl- and heteroarylacetic acid derivatives and the aryl- and heteroarylpropionic acids ("profens") available are presented in Figure 36.11.

Indomethacin

Aqueous solutions of indomethacin are not stable because of the ease of hydrolysis of the p-chlorobenzoyl group. The original synthesis of indomethacin by Shen et al. (49) involved the formation of 2-methyl-5-methoxyindole acetic acid and subsequent

acylation after protection of the carboxyl group as the t-butyl ester. It was introduced in the United States in 1965. It is still one of the most potent NSAIDs in use. It also is a more potent antipyretic than either aspirin or acetaminophen, and it possesses approximately 10 times the analgetic potency of aspirin. The analgetic effect,

however, is widely overshadowed by concern over the frequency of side effects.

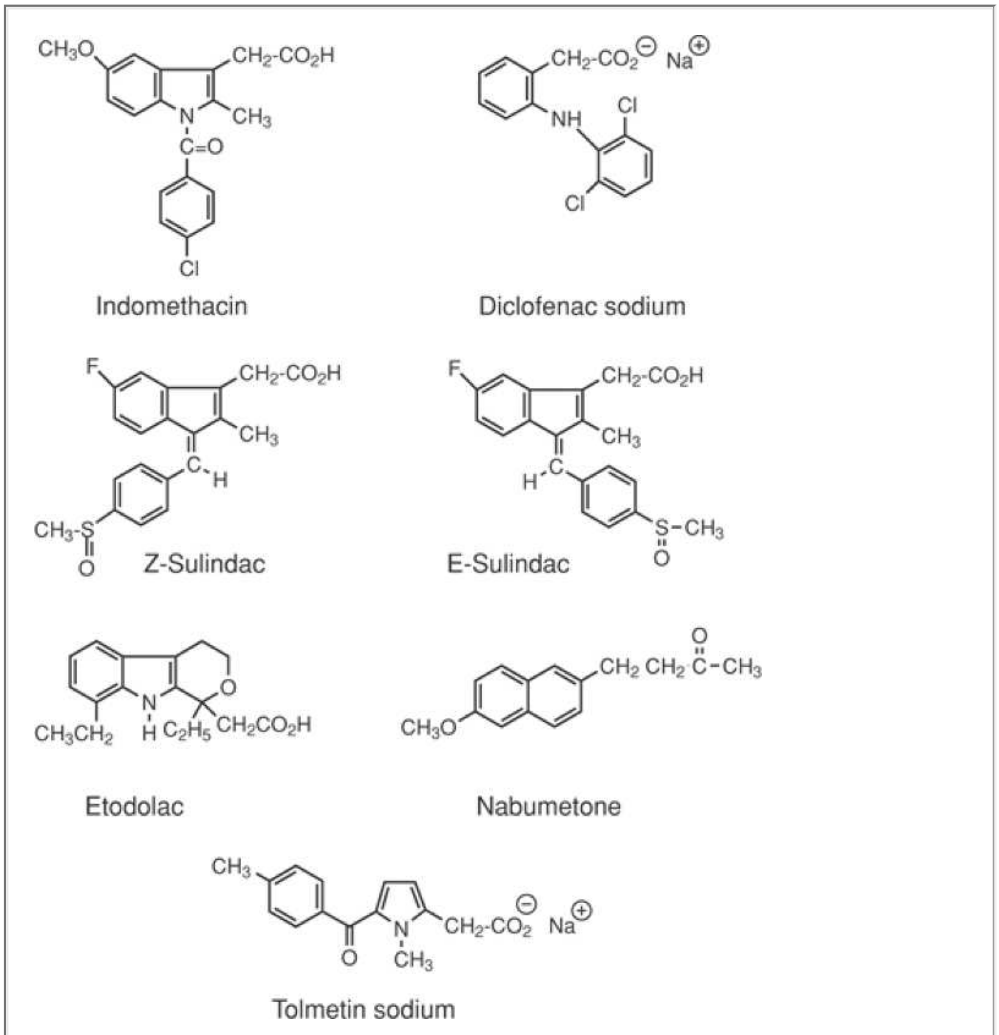


Fig. 36.11. Structures of aryl- and heteroarylacetic acid derivatives.

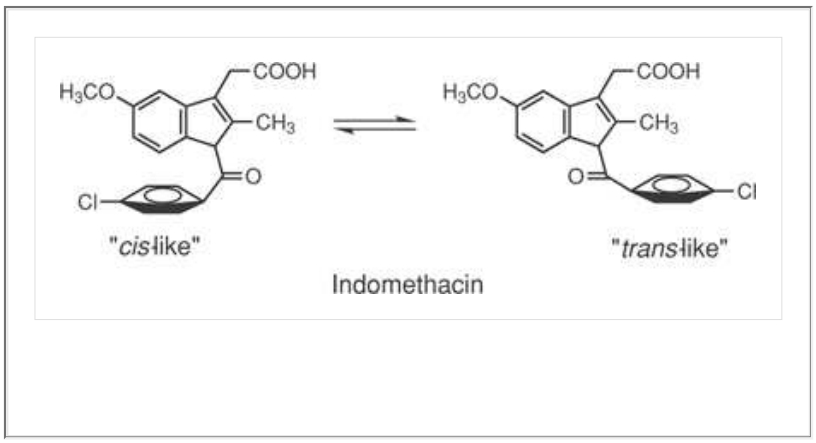
Structure–Activity Relationships

Replacement of the carboxyl group with other acidic functionalities decreases activity. Anti-inflammatory activity generally increases as the acidity of the carboxyl group increases and decreases as the acidity is decreased. Amide analogues are inactive. Acylation of the indole nitrogen with aliphatic carboxylic acids or aralkylcarboxylic acids results in amide derivatives that are less active than those derived from benzoic acid. N-Benzoyl derivatives substituted in the para-position with fluoro, chloro, trifluoromethyl, or thiomethyl groups are the most active. The 5-position of the indole ring is most flexible with regard to the nature of substituents that enhance activity. Substituents such as methoxy, fluoro, dimethylamino, methyl, allyloxy, and acetyl are more active than the unsubstituted indole ring. The presence of an indole ring nitrogen is not essential for activity, because the corresponding 1-benzylidenylindene analogues (e.g., sulindac) are active. Alkyl groups, especially methyl, at the α-position are more active than aryl substituents. Substitution of a methyl group at the α-position of the acetic acid side chain (to give the corresponding propionic acid derivative) leads to equiactive analogues. The resulting chirality introduced in the molecules is important. Anti-inflammatory activity is displayed only by the *S*-(+)-enantiomer. The conformation of indomethacin appears to play a crucial role in its anti-inflammatory actions. The acetic acid side chain is flexible and can assume a large number of different conformations. The preferred and lower-energy conformation of the N-*p*-chlorobenzoyl group is one in which the chlorophenyl ring is oriented away from the 2-methyl group (or *cis* to the methoxyphenyl ring of the indole nucleus) and is noncoplanar with the indole ring because of steric hindrance produced by the 2-methyl group and the hydrogen atom at the 7-position. These conformations are represented as follows:



Absorption and Metabolism

Absorption of indomethacin occurs rapidly on oral administration, and peak plasma levels are obtained within 2 to 3 hours. Being an acidic substance (pK_a = 4.5), it is highly bound to plasma proteins (97%). Indomethacin is converted to inactive metabolites, approximately 50% of a single dose is 5-O-demethylated by CYP2C9 and 10% conjugated with glucuronic acid. Nonhepatic enzyme systems hydrolyze indomethacin to N-deacylated metabolites. The metabolism of indomethacin is illustrated in Figure 36.12.

The ability of indomethacin to potently inhibit prostaglandin biosynthesis may account for its anti-inflammatory, antipyretic, and analgetic actions. Pronounced side effects are frequently observed at antirheumatic doses. A large number of individuals taking indomethacin, especially those over the age of 70, experience undesirable effects of the GI tract (e.g., nausea, dyspepsia, diarrhea, and erosion of the stomach walls), the CNS (e.g., headache, dizziness, and vertigo), and the ears (tinnitus), and many patients must discontinue its use. As with other arylalkanoic acids, administration of indomethacin with food or milk decreases GI side effects.

Indomethacin is available for the short-term treatment of acute gouty arthritis, acute pain of ankylosing spondylitis, and osteoarthritis. An injectable form to be reconstituted also is available as the sodium trihydrate salt for IV use in premature infants with patent ductus arteriosus. Because of its ability to suppress uterine activity by inhibiting prostaglandin biosynthesis, indomethacin also has an unlabeled use to prevent premature labor.

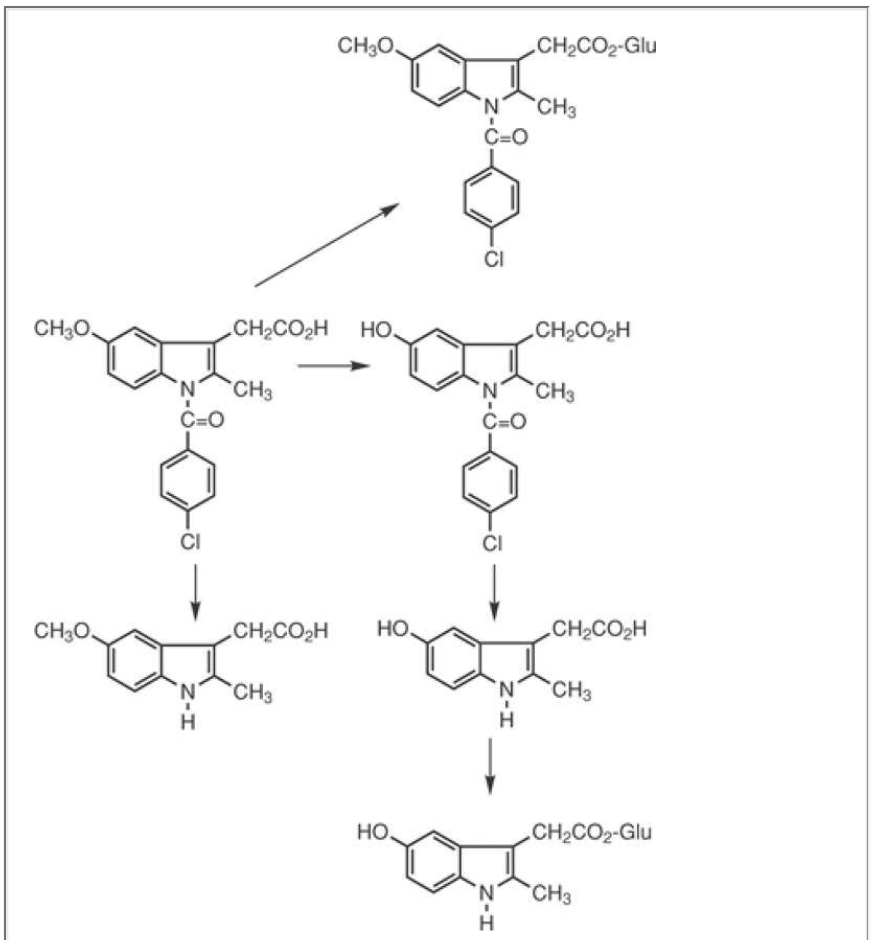


Fig. 36.12. Metabolism of indomethacin. Glu, glucuronide.

Sulindac

Sulindac was introduced in the United States in 1978 by Merck as a result of chemical studies designed to produce an analogue without the side effects commonly associated with the use of indomethacin, particularly GI irritation. It achieved wide popularity, and it remains one of the more widely used NSAIDs. Its synthesis also was reported by Shen et al. (50). Sulindac is a pro-drug and is converted to a metabolite that appears to inhibit the cyclooxygenase system approximately eight-fold as effectively as aspirin. In anti-inflammatory and antipyretic assays, it is only about half as potent as indomethacin but is equipotent in analgetic assays.

Structure–Activity Relationships

The use of classical bio-isosteric changes in medicinal chemistry drug design was invoked in the design of sulindac. The isosteric replacement of the indole ring with the indene ring system resulted in a derivative with therapeutically useful anti-inflammatory activity and fewer CNS and GI side effects but with other undesirable effects, particularly poor water solubility and resultant crystalluria. The replacement of the N-p-chlorobenzoyl substituent with a benzylidiene function resulted in active derivatives. However, when the 5-methoxy group of the indene isostere was replaced with a fluorine atom, enhanced analgetic effects were observed. The decreased water solubility of the indene isostere was alleviated by replacing the chlorine atom of the phenyl substituent with a sulfinyl group. The importance of stereochemical features in the action of sulindac, introduced by the benzylidene double bond, is evidenced by the observation that the (Z)-isomer is a much more potent anti-inflammatory agent than the corresponding (E)-isomer (Fig. 36.10). This *cis*-relationship of the phenyl substituent to the aromatic ring bearing the fluoro substituent is similar to the proposed conformation of indomethacin, suggesting that both indomethacin and sulindac assume similar conformations at the active site of arachidonic acid cyclooxygenase.

Absorption and Metabolism

Sulindac is well absorbed on oral administration (90%), reaches peak plasma levels within 2 to 4 hours, and being acidic (pK_a = 4.5), is highly bound to serum proteins (93%). The metabolism of sulindac plays a major role in its actions, because all of the pharmacological activity is associated with its major metabolite. Sulindac is, in fact, a pro-drug, the sulfoxide function being reduced to the active sulfide metabolite. Sulindac is absorbed as the sulfoxide, which is not an inhibitor of prostaglandin biosynthesis in the GI tract. As discussed earlier, prostaglandins exert a protective effect in the GI tract, and inhibition of their synthesis here leads to many of the GI side effects noted for most NSAIDs. Once sulindac enters the circulatory system, it is reduced to the sulfide, which is an inhibitor of prostaglandin biosynthesis in the joints. Thus, sulindac produces less GI side effects, such as bleeding, ulcerations, and so on, than indomethacin and many other NSAIDs. In addition, the active metabolite has a plasma half-life approximately twice that of the parent compound (~16 hours versus 8 hours), which favorably affects the dosing schedule. In addition to the sulfide metabolite, sulindac is oxidized to the corresponding sulfone, which is inactive. A minor product results from hydroxylation of the benzylidene function and the methyl group at the 2-position. Glucuronides of several metabolites also are found. Sulindac as well as the sulfide and the sulfone metabolites are all highly protein-bound. Despite the fact that the sulfide metabolite is a major activation product and is found in high concentration in human plasma, it is not found in human urine, perhaps because of its high degree of protein binding. The major excretion product is the sulfone metabolite and its glucuronide conjugate. The complete metabolism of sulindac is illustrated in Figure 36.13.

Whereas the toxicity of sulindac is lower than that observed for indomethacin and other NSAIDs, the spectrum of adverse reactions is very similar. The most frequent side effects reported are associated with irritation of the GI tract (e.g., nausea, dyspepsia, and diarrhea), although these effects generally are mild. Effects on the CNS (e.g., dizziness and headache) are less common. Dermatological effects are less frequently encountered.

Sulindac is indicated for long-term use in the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, and acute gouty arthritis. The usual maximum dosage is 400 mg/day, with starting doses recommended at 150 mg twice a day. It is recommended that sulindac be administered with food.

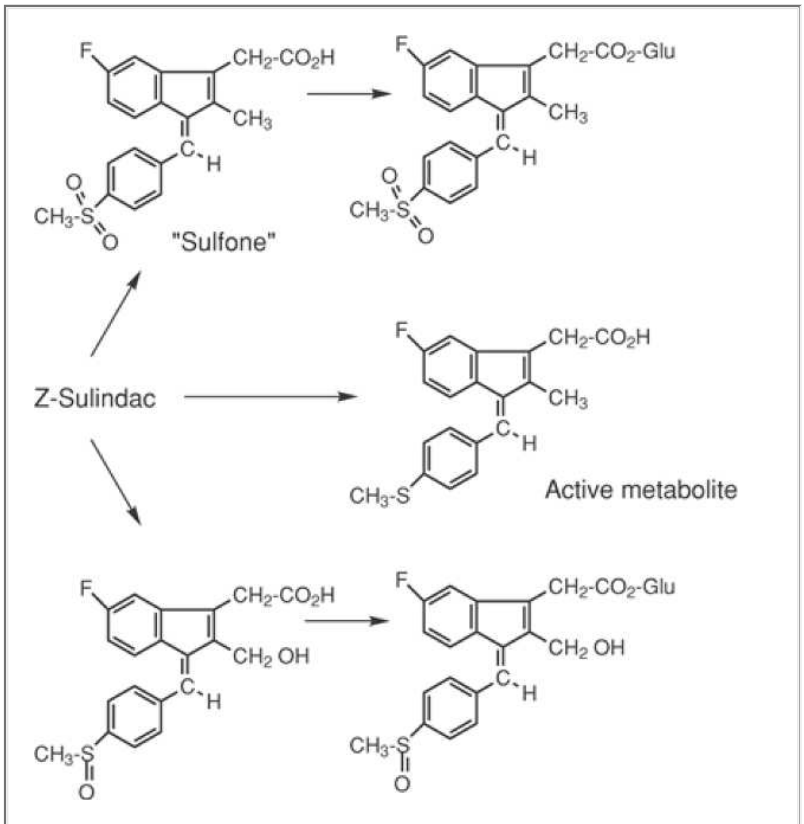

Fig. 36.13. Metabolism of sulindac. Glu, glucuronide.

Tolmetin Sodium

Tolmetin is synthesized straightforwardly from 1-methylpyrrole (51). It was introduced in the United States in 1976,

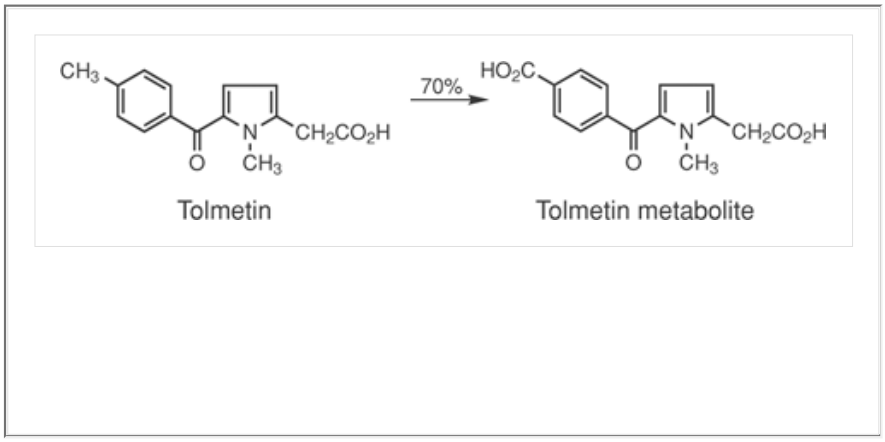
and like other NSAIDs, inhibits prostaglandin biosynthesis. Tolmetin, however, also inhibits polymorph migration and decreases capillary permeability. Its anti-inflammatory activity, as measured in the carrageenan-induced rat paw edema and cotton pellet granuloma assays, is intermediate between those of phenylbutazone and indomethacin.

Structure–Activity Relationships

The relationship of tolmetin to indomethacin is clear, with each containing a noncoplanar *p*-chlorobenzoyl group and an acetic acid function. Tolmetin possesses a pyrrole ring instead of the indole ring in indomethacin. Replacement of the 5-*p*-toluoyl group with a *p*-chlorobenzoyl moiety produced little effect on activity, whereas introduction of a methyl group in the 4-position of the pyrrole ring produced interesting results. The 4-methyl-5-*p*-chlorobenzoyl analogue is approximately four times as potent as tolmetin. Substitution of the *p*-methyl group of tolmetin with a *p*-chloro group blocked oxidative metabolism, increasing duration of action to approximately 24 hours. McNeil marketed this compound in 1980 as zomepirac, an analgetic that was removed from the market in 1983 because of severe anaphylactic reactions, particularly in patients sensitive to aspirin. Unlike the previous structure–activity relationships discussed for arylalkanoic acids, the propionic acid analogue is slightly less potent than tolmetin.

Absorption and Metabolism

Tolmetin sodium is rapidly and almost completely absorbed on oral administration, with peak plasma levels being attained within the first hour of administration. It has a relatively short plasma half-life of approximately 1 hour because of extensive first-pass metabolism, involving hydroxylation of the *p*-methyl group to the primary alcohol, which is subsequently oxidized to the dicarboxylic acid shown below. This metabolite is inactive in standard in vivo anti-inflammatory assays. The free acid (pK_a = 3.5) is highly bound to plasma proteins (99%), and excretion of tolmetin and its metabolites occurs primarily in the urine.



Approximately 15 to 20% of an administered dose is excreted unchanged and 10% as the glucuronide conjugate of the parent drug. Conjugates of the dicarboxylic acid metabolite account for the majority of the remaining administered drug.

The most frequently adverse reactions are those involving the GI tract (e.g., abdominal pain, discomfort, and nausea) but appear to be less than those observed with aspirin. The CNS effects (e.g., dizziness and drowsiness) also are observed. Few cases of overdosage have been reported, but in such cases, recommended treatment includes elimination of the drug from the GI tract by emesis or gastric lavage and elimination of the acidic drug from the circulatory system by enhancing alkalinization of the urine with sodium bicarbonate.

Tolmetin sodium is indicated for the treatment of rheumatoid arthritis, juvenile rheumatoid arthritis, and osteoarthritis.

Diclofenac Sodium

Diclofenac is synthesized from N-phenyl-2,6-dichloroaniline (52). It is available in 120 different countries and, perhaps, is the most widely used NSAID in the world. It was introduced in the United States in 1989 but was first marketed in Japan in 1974. It ranks among the top prescription drugs in the United States. Diclofenac possesses structural characteristics of both arylalkanoic acid and the anthranilic acid classes of anti-inflammatory drugs, and it displays anti-inflammatory, analgetic, and antipyretic properties. In the carrageenan-induced rat paw edema assay, it is twice as potent as indomethacin and 450 times as potent as aspirin. As an analgetic, it is six times more potent than indomethacin and 40 times as potent as aspirin in the phenyl benzoquinone–induced writhing assay in mice. As an antipyretic, it is twice as potent as indomethacin and more than 350 times as potent as aspirin in the yeast-

induced fever assay in rats. Diclofenac is unique among the NSAIDs in that it possesses three possible mechanisms of action: 1) inhibition of the arachidonic acid cyclooxygenase system (3 to 1,000 times more potent than other NSAIDs on a molar basis), resulting in a decreased production of prostaglandins and thromboxanes; 2)

inhibition of the lipoxygenase pathway, resulting in decreased production of leukotrienes, particularly the pro-inflammatory LKB_4; and 3) inhibition of arachidonic acid release and stimulation of its reuptake, resulting in a reduction of arachidonic acid availability.

Structure–Activity Relationships

Structure–activity relationships in this series have not been extensively studied. It does appear that the function of the two *o*-chloro groups is to force the anilino-phenyl ring out of the plane of the phenylacetic acid portion, this twisting effect being important in the binding of NSAIDs to the active site of the COX, as previously discussed.

Absorption and Metabolism

Diclofenac is rapidly and completely (~100%) absorbed on oral administration, with peak plasma levels being reached within 1.5 to 2.5 hours. The free acid (pK_a = 4.0) is highly bound to serum proteins (99.5%), primarily albumin. Only 50 to 60% of an oral dose is bioavailable because of extensive hepatic metabolism. Four major metabolites resulting from aromatic hydroxylation have been identified. The major metabolite via CYP3A4 is the 4′-hydroxy derivative and accounts for 20 to 30% of the dose excreted, whereas the 5-hydroxy, 3′-hydroxy, and 4′,5-dihydroxy metabolites via CYP2C9 account for 10 to 20% of the excreted dose. The remaining drug is excreted in the form of sulfate conjugates. Although the major metabolite is much less active than the parent compound, it may exhibit significant biological activity, because it accounts for 30 to 40% of all of the metabolic products. The metabolism of diclofenac is illustrated in Figure 36.14.

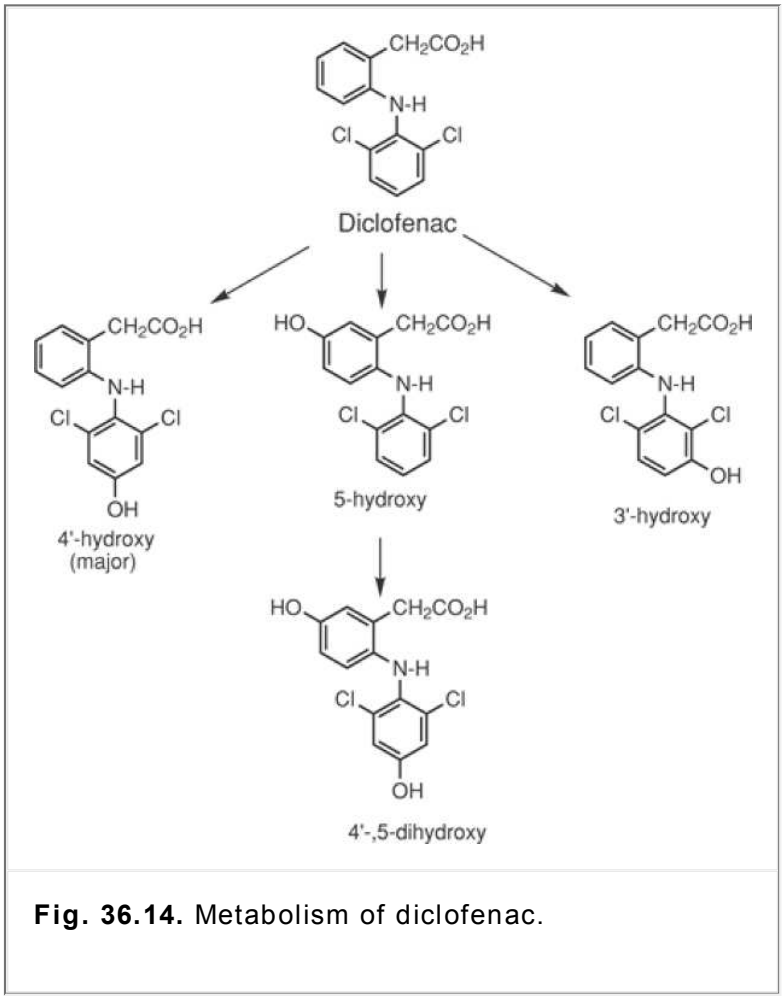


Fig. 36.14. Metabolism of diclofenac.

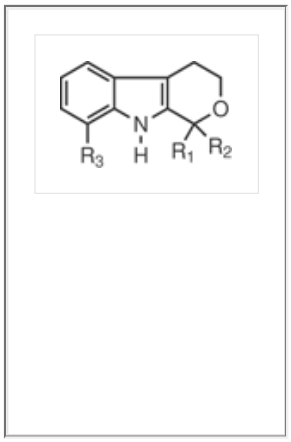
Diclofenac sodium is indicated for the treatment of rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis.

Etodolac

Etodolac is promoted as the first of a new chemical class of anti-inflammatory drugs, the pyranocarboxylic acids. Although not strictly an arylacetic acid derivative (because there is a two-carbon atom separation between the carboxylic acid function and the hetero-aromatic ring) (Fig. 36.10), it still possesses structural characteristics similar to those of the heteroarylacetic acids and is classified here. It was introduced in the United States in 1991 for acute and long-term use in the management of osteoarthritis and as an analgetic. It also possesses antipyretic activity. Etodolac is marketed as a racemic mixture, although only the *S*-(+)-enantiomer possesses anti-inflammatory activity in animal models. Etodolac also displays a high degree of enantioselectivity in its inhibitory effects on the arachidonic acid cyclooxygenase system. With regard to its anti-inflammatory actions, etodolac was approximately 50 times more active than aspirin, three times more potent than sulindac, and one-third as active as indomethacin. The ratio of the anti-inflammatory activity to the median effective dose (ED50) for gastric ulceration or erosion was more favorable for etodolac (median inhibitory dose [ID50]/ED50 = 10) than for aspirin, naproxen, sulindac, or indomethacin (ID50/ED50 = 4). At 2.5 to 3.5 times the effective anti-inflammatory dose, etodolac was reported to produce less GI bleeding than indomethacin, ibuprofen, or naproxen. The primary mechanism of action appears to be inhibition of the biosynthesis of prostaglandins at the cyclooxygenase step, with no inhibition of the lipoxygenase system. Etodolac, however, possesses a more favorable ratio of inhibition of prostaglandin biosynthesis in human rheumatoid synoviocytes and chondrocytes than by cultured human gastric mucosal cells compared to ibuprofen, indomethacin, naproxen, diclofenac, and piroxicam. Thus, although etodolac is no more potent an NSAID than many others, the lower incidence of GI side effects represents a potential therapeutic advantage.

Structure–Activity Relationships

During a search for newer, more effective antiarthritic drugs in the 1970s, the Ayerst group led by Humber investigated a series of pyranocarboxylic acids of the general structure shown below (53,54).



Structure–activity relationship studies indicated that alkyl groups at R_1 and an acetic acid function at R_2 enhanced anti-inflammatory activity. Lengthening the acid chain, or ester or amide derivatives, gave inactive compounds. The corresponding α-methylacetic acid derivatives also were inactive. Increasing the chain length of the R_1 substituent

to ethyl or n-propyl gave derivatives that were 20 times more potent than methyl. A number of aromatic substituents in the aromatic ring were evaluated, and substituents at the 8-position were most beneficial. Among the most active were the 8-ethyl, 8-n-propyl, and 7-fluoro-8-methyl derivatives. Etodolac was found to possess the most favorable anti-inflammatory to gastric distress properties among these analogues.

Absorption and Metabolism

Etodolac is rapidly absorbed following oral administration, with maximum serum levels being achieved within 1 to 2 hours, and it is highly bound to plasma proteins (99%) with pK_a 4.7. The penetration of etodolac into synovial fluid is greater than or equal to that of tolmetin, piroxicam, or ibuprofen. Only diclofenac appears to provide greater penetration. Etodolac is metabolized to three hydroxylated metabolites and to glucuronide conjugates, none of which possesses important pharmacological activity. Metabolism appears to be the same in the elderly as in the general population, so no dosage adjustment appears necessary.

Etodolac is indicated for the management of the signs and symptoms of osteoarthritis and for the management of pain.

Nabumetone

Nabumetone is unique among the NSAIDs in that it represents a new class of nonacidic pro-drugs, being rapidly

metabolized after absorption to form a major active metabolite, 6-methoxynaphthaleneacetic acid. It was introduced in the United States in 1992 and is synthesized from 2-acetyl-6-methoxynaphthalene (55). Nabumetone, being nonacidic, does not produce a significant primary insult and is an ineffectual inhibitor of prostaglandin cyclooxygenase in gastric mucosa, thus producing minimum secondary insult. The result is that gastric side effects of nabumetone appear to be minimized. Once the parent drug enters the circulatory system, however, it is metabolized to an active metabolite, 6-methoxynaphthalene-2-acetic acid (6MNA), which is an effective inhibitor of cyclooxygenase in joints. Nabumetone thus represents a classic example of the prodrug approach in drug design.

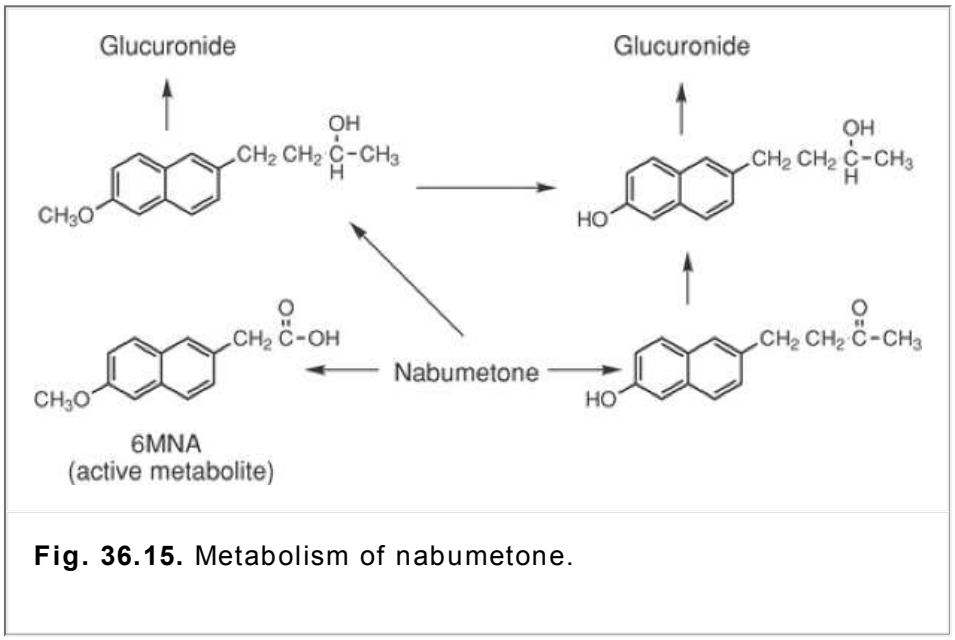


Fig. 36.15. Metabolism of nabumetone.

In the carrageenan-induced rat paw assay, nabumetone is approximately 13 times more potent than aspirin, one-third as active as indomethacin, and half as active as diclofenac. It is only half as active as aspirin as an analgetic, as measured by the phenylquinone-induced writhing assay in mice. Despite its lower potency, the advantages of nabumetone may reside in its favorable gastric irritancy profile. The ratio of gastric irritancy dose in rats to anti-inflammatory activity in rats (ED50) for nabumetone is 21.25, whereas this ratio is 0.41 for aspirin, 0.55 for indomethacin, 0.72 for diclofenac, 3.00 for tolmetin, and 7.85 for zomepirac.

Structure–Activity Relationships

Introduction of methyl or ethyl groups on the butanone side chain greatly reduced anti-inflammatory activity. The ketone function can be converted to a dioxolane with retention of activity, whereas converting the ketone to an oxime reduced activity. Removal of the methoxy group at the 6-position reduced activity, but replacement of the methoxy with a methyl or chloro group gave active compounds. Replacement of the methoxy with hydroxyl, acetoxy, or N-methylcarbamoyl groups, or positional isomers of the methoxy group at the 2- or 4-positions, greatly reduced activity. The active metabolite, 6-MNA, is closely related structurally to naproxen, differing only by the lack of an α-methyl group. The ketone precursor, [4-(6-methoxy-2-naphthyl)pentan-2-one], that would be expected to produce naproxen as a metabolite was inactive in chronic models of inflammation.

Absorption and Metabolism

Nabumetone is absorbed primarily from the duodenum. Milk and food increase the rate of absorption and the bioavailability of the active metabolite. Plasma concentrations of unchanged drug are too low to be detected in most subjects after oral administration, so most pharmacokinetic studies have involved the disposition of the active metabolite. Pharmacokinetic properties are altered in elderly patients, with higher plasma levels of the active metabolite being noted. Nabumetone undergoes rapid and extensive metabolism in the liver, with a mean absolute bioavailability of the active metabolite of 38%. The metabolism of nabumetone is illustrated in Figure 36.15. The major,

most active metabolite is 6MNA, but the initial alcohol metabolite, a minor product, and its esters also possess significant anti-inflammatory properties.

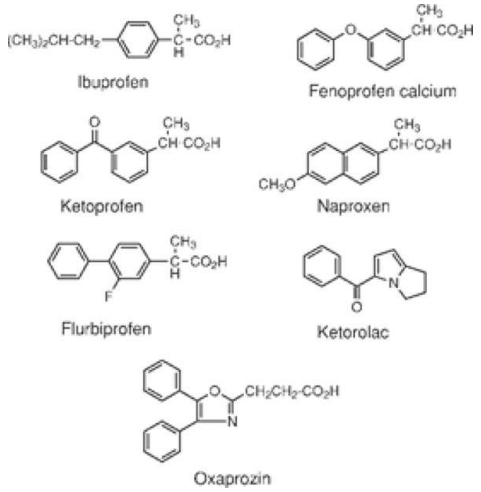

Fig. 36.16. Structures of aryl- and heteroarylpropionic acid derivatives.

Nabumetone is indicated for the acute and chronic treatment of the signs and symptoms of osteoarthritis and rheumatoid arthritis. The recommended starting dosage is 1,000 mg as a single dose with or without food. More symptomatic relief of severe or persistent symp-toms may be obtained at doses of 1,500 or 2,000 mg/day.

Aryl- and heteroarylpropionic acids

Structures of aryl- and heteroarylpropionic acid derivatives are shown in Figure 36.16.

±-Ibuprofen

The synthesis of ibuprofen was originally reported in 1964 from p-isobutylacetophenone (56), but the drug was not marketed in the United States until 1974, despite the fact that it had been available for several years in Europe. It was the first NSAID approved since indomethacin, and was immediately accepted into therapy. Its success precipitated the introduction of many new drugs in the 1970s. This chemical class currently comprises the largest group of NSAIDs. Ibuprofen became the first prescription NSAID to become available as an OTC analgetic in almost 30 years and is available under a number of brand names. It is marketed as the racemic mixture, although biological activity resides almost exclusively in the *S*-(+)-isomer. Ibuprofen is more potent than aspirin but less potent than indomethacin in anti-inflammatory and prostaglandin biosynthesis inhibition assays, and it produces moderate degrees of gastric irritation.

Structure–Activity Relationships

The substitution of an α-methyl group on the alkanoic acid portion of acetic acid derivatives enhances anti-inflammatory actions and reduces many side effects. For example, the acetic acid analogue of ibuprofen, ibufenac (*p*-isobutylphenylacetic acid), is less potent and more hepatotoxic than ibuprofen. The stereochemistry associated with the chiral center in the arylpropionic acids, but lacking in the acetic acid derivatives, plays an important role in both the in vivo and in vitro activities of these drugs. As indicated earlier, although marketed as a racemic mixture, the (+)-enantiomer of ibuprofen possess greater activity in vitro than the (–)-isomer. The eudismic (*S*/*R*) ratio for the inhibition of bovine prostaglandin synthesis is approximately 160, but in vivo, the two enantiomers are equiactive (see next section on absorption and metabolism). The (+)-enantiomer of ibuprofen—and of most of the arylpropionic acids under investigation—has been shown to possess the (*S*)-absolute configuration.

Absorption and Metabolism

Ibuprofen is rapidly absorbed on oral administration, with peak plasma levels being generally attained within 2 hours and a duration of action of less than 6 hours. As with most of these acidic NSAIDs, ibuprofen (pK_a = 4.4) is extensively bound to plasma proteins (99%) and will interact with other acidic drugs that are protein bound. Metabolism occurs rapidly, and the drug is nearly completely excreted in the urine as unchanged drug and oxidative metabolites within 24 hours following administration (Fig. 36.17). Metabolism by CYP2C9 (90%) and CYP2C19 (10%) involves primarily ω-, and ω_1-, and ω_2-oxidation of the p-isobutyl side chain, followed by alcohol oxidation of the

primary alcohol resulting from ω–oxidation to the corresponding carboxylic acid. All metabolites are inactive. When

ibuprofen is administered as the individual enantiomers, the major metabolite isolated is the *S*-(+)-enantiomer whatever the configuration of the starting enantiomer. Interestingly, the *R*-(–)-enantiomer is inverted to the *S*-(+)-enantiomer in vivo via an acetyl–coenzyme A intermediate, accounting for the observation that the two enantiomers are bioequivalent in vivo. This is a metabolic phenomenon that also has been observed for other arylpropionic acids, such as ketoprofen, benoxaprofen, fenoprofen, and naproxen (57).

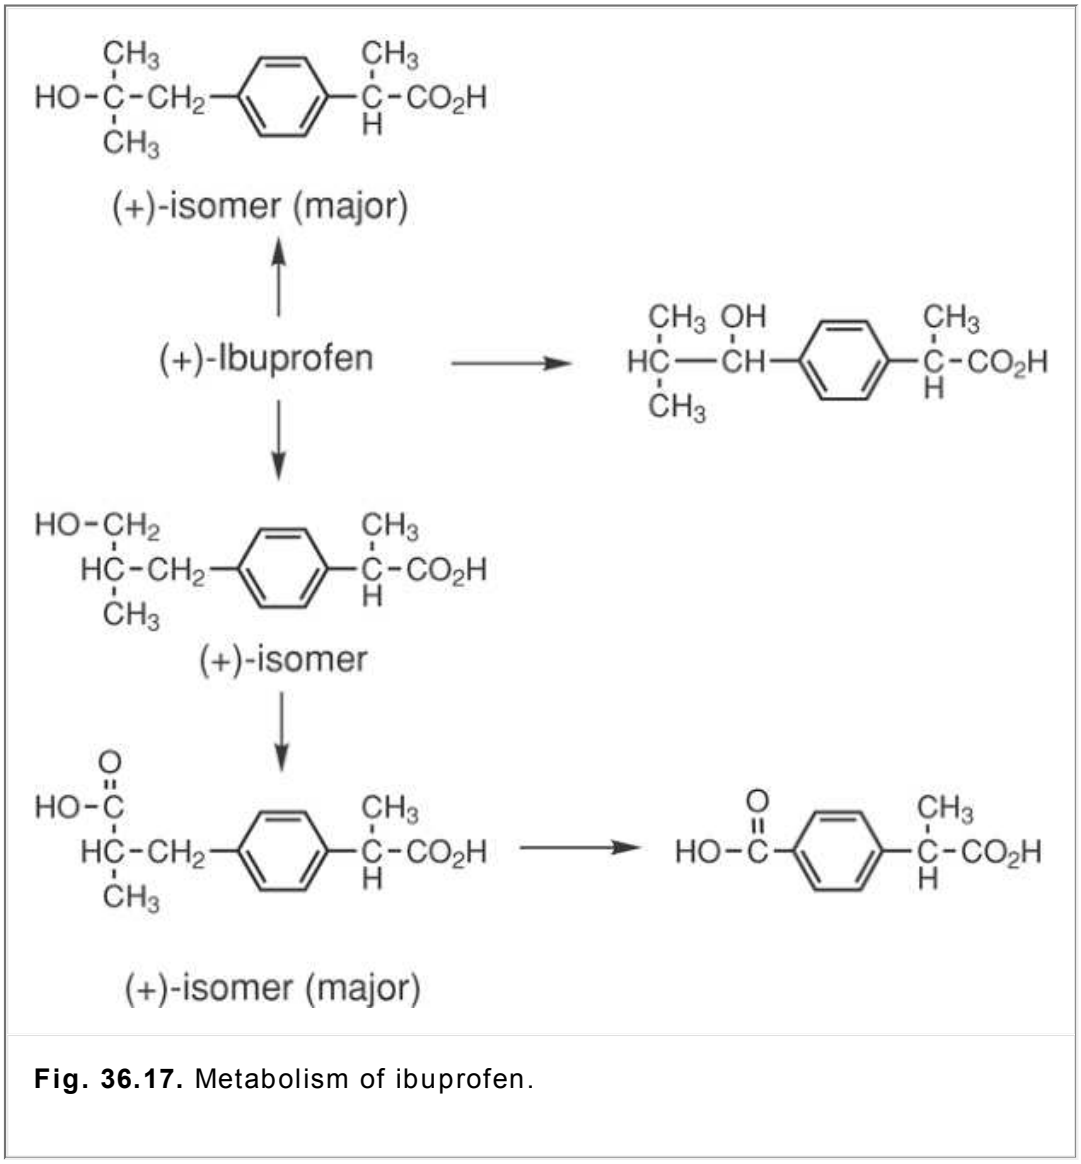

Fig. 36.17. Metabolism of ibuprofen.

Ibuprofen is indicated for the relief of the signs and symptoms of rheumatoid arthritis and osteoarthritis, the relief of mild to moderate pain, the reduction of fever, and the treatment of dysmenorrhea.

±-Fenoprofen Calcium

The calcium and sodium salts of fenoprofen possess similar bioavailability, distribution, and elimination characteristics. It is the calcium salt that is marketed, however, because it has the advantage of being less hygroscopic. Its original synthesis was reported in 1970 (58), and it was marketed in the United States in 1976. Fenoprofen is less potent in anti-inflammatory assays than ibuprofen, indomethacin, ketoprofen, or naproxen. As an inhibitor of prostaglandin biosynthesis, it is much less potent than indomethacin, more potent than aspirin, and about equipotent with ibuprofen. It also possesses analgetic and antipyretic activity. It possesses other pharmacological properties, such as inhibition of phagocytic and complement functions and stabilization of lysosomal membranes. Fenoprofen is marketed as a racemic mixture, because no differences have been observed in the in vivo anti-inflammatory or analgetic properties of the individual enantiomers. The ability of *R*-(–)-arylpropionic acids to undergo inversion to the *S*-(+)-enantiomers, however, may be involved. Like other NSAIDs, in vitro prostaglandin

synthesis assays indicate that the *S*-(+)-enantiomer is more potent than the *R*-(–)-isomer.

Structure–Activity Relationships

Placing the phenoxy group in the ortho- or para-position of the arylpropionic acid ring markedly decreases activity. Replacement of the oxygen bridge between the two aromatic rings with a carbonyl group yields an analogue (ketoprofen) that also is marketed.

Absorption and Metabolism

Fenoprofen is readily absorbed (85%) on oral administration and is highly bound (99%) to plasma proteins. Peak plasma levels are attained within 2 hours of administration. The free acid has a pK_a of 4.5, which is within the range of the other arylalkanoic acids. Fenoprofen is rather extensively metabolized, primarily through glucuronide conjugation with the parent drug and the CYP2C9 4′-hydroxy metabolite.

Fenoprofen calcium is indicated for treatment of rheumatoid arthritis and osteoarthritis and for the relief of mild to moderate pain.

±-Ketoprofen

Ketoprofen (Fig. 36.10) was introduced in 1986 and was synthesized from 2-(p-amino- phenyl)propionic acid via a thiaxanthone intermediate (59). Ketoprofen, unlike many NSAIDs, inhibits the synthesis of leukotrienes and leukocyte migration into inflamed joints in addition to inhibiting the biosynthesis of prostaglandins. It stabilizes the lysosomal membrane during inflammation, resulting in decreased tissue destruction. Antibradykinin activity also has been observed. Bradykinin is released during inflammation and can activate peripheral pain receptors. In addition to anti-inflammatory activity, ketoprofen also possesses antipyretic and analgetic properties. Although it is less potent than indomethacin as an anti-inflammatory agent and an analgetic, its ability to produce gastric lesions is about the same (60).

Absorption and Metabolism

Ketoprofen is rapidly and nearly completely absorbed on oral administration, reaching peak plasma levels within 0.5 to 2 hours. It is highly plasma protein bound (99%) despite a lower acidity (pK_a = 5.9) than some other NSAIDs. Wide variation in plasma half-lives has been reported. It is metabolized by glucuronidation of the carboxylic acid, CYP3A4 and CYP2C9 hydroxylation of the benzoyl ring, and reduction of the keto function.

Ketoprofen is indicated for the long-term management of rheumatoid arthritis and osteoarthritis, for mild to moderate pain, and for primary dysmenorrhea.

Naproxen

Naproxen is synthesized from 2-methoxynaphthalene and the (+)-isomer obtained by resolution with cinchonidine (61). It was introduced in the United States in 1976 and, as a generic drug, has consistently been among the more popular NSAIDs. It is marketed as the *S*-(+)-enantiomer, but interestingly, the sodium salt of the (–)-isomer also is on the market as Anaprox. As an inhibitor of prostaglandin biosynthesis, it is 12 times more potent than aspirin, 10 times more potent than phenylbutazone, three to four times more potent than ibuprofen, and four times times more potent than fenoprofen, but it is approximately 300 times less potent than indomethacin. In vivo anti-inflammatory assays are consistent with this relative order of potency. In the carrageenan-induced rat paw edema assay, it is 11 times more potent than phenylbutazone and 55 times as potent as aspirin, but only 0.7 times as potent as indomethacin. In the phenylquinone writhing assay for analgesia, it is nine times as potent as phenylbutazone and seven times as potent as aspirin, but only 10% as potent as indomethacin. In the yeast-induced pyrexia assay for antipyretic activity, it is seven times as potent as phenylbutazone, 22 times as potent as aspirin, and 1.2 times as potent as indomethacin. The order of gastric ulcerogenic activity is sulindac < naproxen < aspirin, indomethacin, ketoprofen, and tolmetin.

Structure–Activity Relationships

In a series of substituted 2-naphthylacetic acids, substitution in the 6-position led

to maximum anti-inflammatory activity. Small lipophilic groups, such as Cl, CH_3S, and CHF_2O, were active analogues, with CH_3O being the most potent. Larger groups were found to be less active. Derivatives of 2-naphthylpropionic acids are more potent than the corresponding acetic acid analogues. Replacing the carboxyl group with functional groups capable of being metabolized to the carboxyl function (e.g., —CO_2CH_3, —CHO, or —CH_2OH) led to a retention of activity. The S-(+)-isomer is the more potent enantiomer. Naproxen is the only arylalkanoic acid NSAID currently marketed as optically active isomers.

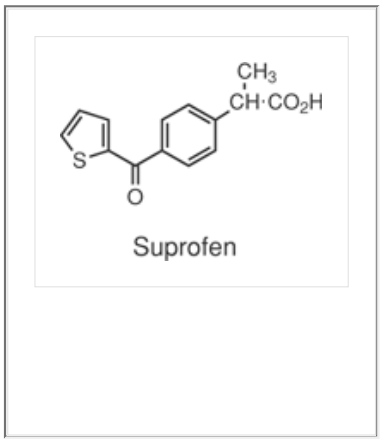
Absorption and Metabolism

Naproxen is almost completely absorbed following oral administration. Peak plasma levels are achieved within 2 to 4 hours following administration. Like most of the acidic NSAIDs (pK_a = 4.2), it is highly bound (99.6%) to plasma proteins. Approximately 70% of an administered dose is eliminated as either unchanged drug (60%) or as conjugates of unchanged drug (10%). The remainder is converted to the 6-O-desmethyl metabolite by both CYP3A4 and CYP1A2 and, further, to the glucuronide conjugate of the demethylated metabolite. The 6-O-desmethyl metabolite lacks anti-inflammatory activity. Like most of the arylalkanoic acids, the most common side effect associated with the use of naproxen is irritation to the GI tract. The most common other adverse reactions are associated with CNS disturbances (e.g., nausea and dizziness).

Naproxen is indicated for the treatment of rheumatoid arthritis, osteoarthritis, juvenile arthritis, ankylosing spondylitis, tendinitis, bursitis, acute gout, and primary dysmenorrhea and for the relief of mild to moderate pain.

±-Suprofen

Suprofen is a white, microcrystalline powder that is slightly soluble in water. It was originally synthesized from thiophene in 1974 (62) and was introduced in the United States in 1985 for the treatment of dysmenorrhea and as an analgetic for mild to moderate pain. Reports of severe flank pain and transient renal failure appeared, however, with the syndrome being noted abruptly within several hours after one or two doses of the drug; therefore, suprofen was removed from the U.S. market in 1987. Obviously, clinical trials are not always sufficient to determine a drug's safety, and postmarketing surveillance becomes most important. Suprofen was reintroduced in the United States in 1990 as a 1% ophthalmic solution for the prevention of surgically induced miosis during cataract extraction. Miosis complicates the removal of lens material and implantation of a posterior chamber intraocular lens that thus increases the risk of ocular trauma. The mechanism of action also involves inhibition of prostaglandin synthesis, because prostaglandins constrict the iris sphincter independent of a cholinergic mechanism. Additionally, prostaglandins also break down the blood-aqueous barrier, allowing the influx of plasma proteins into aqueous humor, resulting in an increase in intraocular pressure.



±-Flurbiprofen

Flurbiprofen (Fig. 36.10) synthesis was originally reported in 1974 (63). During a study of the pharmacological properties of a large number of substituted phenylalkanoic acids, including ibuprofen and ibufenac, the most potent were found to be substituted 2-(4-biphenyl)propionic acids. Further toxicological and pharmacological studies indicated that flurbiprofen possessed the most favorable therapeutic profile, so it was selected for further clinical development. It was not marketed until 1987, when it was introduced as the sodium salt as Ocufen, the first topical NSAID indicated for ophthalmic use in the United States. The indication for Ocufen is the same as that for Profenal—that is, to inhibit intraoperative miosis induced by prostaglandins in cataract surgery. Thus, flurbiprofen is an inhibitor of prostaglandin synthesis. The oral form was introduced in 1988 as Ansaid (another non-steroidal anti-inflammatory drug) and gained immediate acceptance. In acute inflammation assays in adrenalectomized rats, flurbiprofen was found to be 536-fold more potent than aspirin and 100-fold more potent than phenylbutazone. Orally, it was half as potent as methylprednisolone. As an antipyretic, it was 403 times as potent as aspirin in the yeast-induced fever assay in rats and was 26 times more potent than ibuprofen as an antinociceptive.

Absorption and Metabolism

Flurbiprofen is well absorbed after oral administration, with peak plasma levels being attained within 1.5 hours. Food alters the rate of absorption but not the extent of its bioavailability. It is extensively bound to plasma proteins (99%)

and has a plasma half-life of 2 to 4 hours. Metabolism is extensive, with 60 to 70% of flurbiprofen and its metabolites being excreted as sulfate and glucuronide conjugates. Flurbiprofen shows some interesting metabolic patterns, with 40 to 47% as the 4′-hydroxy metabolite, 5% as the 3′,4′-dihydroxy metabolite, 20 to 30% as the 3′-hydroxy-4′-methoxy metabolite, and the remaining 20 to 25% of the drug being excreted unchanged. None of these metabolites demonstrates significant anti-inflammatory activity. The metabolism of flurbiprofen is presented in Figure 36.18.

Flurbiprofen is indicated as an oral formulation for the acute or long-term treatment of rheumatoid arthritis and osteoarthritis and as an ophthalmic solution for the inhibition of intraoperative miosis.

Ketorolac Tromethamine

Ketorolac (Fig. 36.10) represents a cyclized, heteroarylpropionic acid derivative, with the α-methyl group being fused to the pyrrole ring. It was introduced in 1990 and is indicated as a peripheral analgetic for

short-term use and for the relief of ocular itching caused by seasonal allergic conjunctivitis, although it exhibits anti-inflammatory and antipyretic activity as well. It was initially introduced only in an injectable form, but recently, an oral formulation has been made available. Its analgetic activity resembles that of the centrally acting analgetics, with 15 to 30 mg of ketorolac producing analgesia equivalent to a 12-mg dose of morphine, and it has become a widely accepted alternative to narcotic analgesia. Ketorolac inhibits prostaglandin synthesis. Although the analgetic effect is achieved within 10 minutes of injection, peak analgesia lags behind peak plasma levels by 45 to 90 minutes. The free acid has a pK_a of 3.5, and it is not surprising that it is highly plasma protein bound (>99%). Ketorolac is metabolized by CYP2C9 to its *p*-hydroxy derivative and to conjugates that are excreted primarily in the urine.

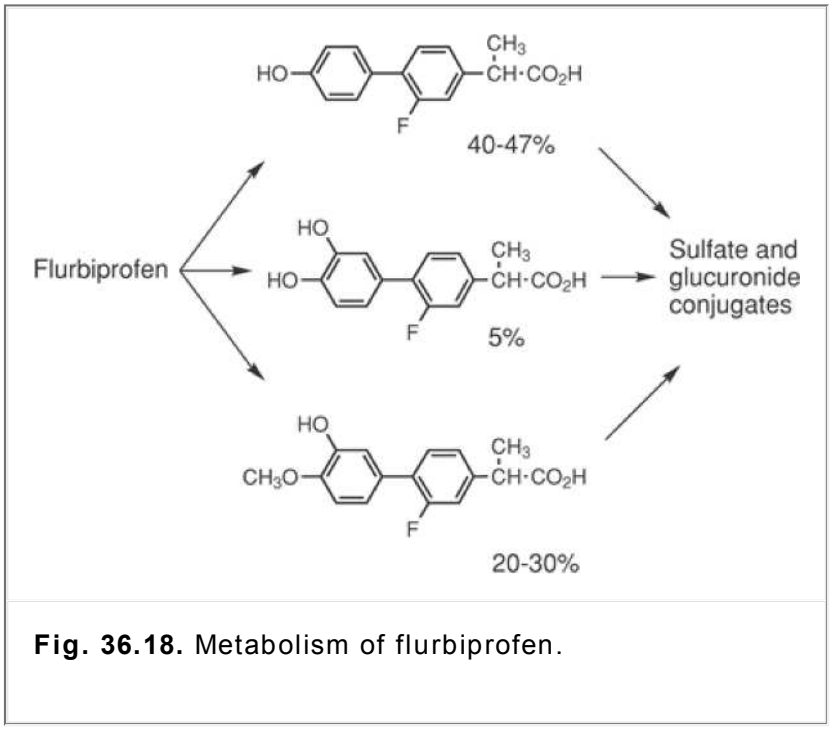


Fig. 36.18. Metabolism of flurbiprofen.

Oxaprozin

Oxaprozin (Fig. 36.10) was marketed in 1993 for acute and long-term use in the management of signs and symptoms of osteoarthritis and rheumatoid arthritis. Oxaprozin is synthesized by condensing benzoin with succinic anhydride and cyclizing the resulting benzoin hemisuccinate with ammonium acetate. Although not formally a propionic acid of the α-methylacetic acid type, it appears to be similar to the other propionic acid derivatives considered here. Oxaprozin is well absorbed (100%) following oral administration, but maximum plasma concentrations are not reached until 3 to 5 hours following ingestion. Oxaprozin is an anti-inflammatory agent possessing a rapid onset of action and a prolonged duration of action. In both the carrageenan raw paw edema assay and analgetic tests, it was equipotent with aspirin. Oxaprozin has been associated with the appearance of rash and/or mild photosensitivity. Some patients experience an increased incidence of rash on sun-exposed skin during clinical testing. Oxaprozin, aspirin, ibuprofen, indomethacin, naproxen, and sulindac have comparable efficacy in the treatment of rheumatoid arthritis, whereas oxaprozin, aspirin, naproxen, and piroxicam have comparable efficacy in osteoarthritis. It is highly bound to plasma proteins (99%), is highly lipophilic, and undergoes little first-pass metabolism. Metabolism is via hepatic microsomal

oxidation and glucuronidation. Active phenolic metabolites are produced (<5%) but do not appear to contribute significantly to the overall pharmacological activity of oxaprozin.

Oxaprozin possesses a relatively long elimination half-life of 59 hours (range, 26–92 hours), enabling once-daily dosing. Administration with food appears to delay absorption but not bioavailability.

Several properties of the NSAIDs are summarized in Table 36.4.

N-Arylanthranilic Acids (Fenamic Acids)

The anthranilic acid class of NSAIDs is the result of the application of classical medicinal chemistry bio-isosteric drug design concepts, because these derivatives are nitrogen isosteres of salicylic acid. In the early 1960s, the Parke-Davis research group reported the development of a series of N-substituted anthranilic acids that have since been given the chemical class name of fenamic acids. The fact that this class of compounds possesses little advantage over the salicylates with respect to their anti-inflammatory and analgetic properties has diminished interest in their large-scale development relative to the arylalkanoic acids. Mefenamic acid was introduced in the United States in 1967 as an analgetic, and this remains the primary indication despite the fact that it possesses modest anti-inflammatory activity. Flufenamic acid has been available in Europe as an antirheumatic agent, but there are no apparent plans to introduce this drug in the United States. With regard to anti-inflammatory activity, mefenamic acid is approximately 1.5 times as potent as phenylbutazone and half as potent as flufenamic acid. Meclofenamic acid was introduced in the United States as its sodium salt in 1980, primarily as an antirheumatic agent and analgetic. The structures of these fenamic acids are shown in Figure 36.19.

The fenamic acids share a number of pharmacological properties with the other NSAIDs. Because these drugs are potent inhibitors of prostaglandin biosynthesis, it is tempting to speculate that this represents their primary mechanism of action. Scherrer, like Shen, had proposed a hypothetical receptor for NSAIDs and later modified (64) the receptor to represent the active site of arachidonic acid cyclooxygenase. Structurally, the fenamic acids fit the proposed active site of arachidonic acid cyclooxygenase proposed by Shen (12) (Fig. 36.1), because they possess an acidic function connected to an aromatic ring along with an additional lipophilic binding site—in this case, the N-aryl substituent. The greater anti-inflammatory activity of meclofenamic acid compared to that of mefenamic acid correlates well with its ability to inhibit prostaglandin synthesis. Scherrer (65) compared the in vivo anti-inflammatory activities, clinical

anti-inflammatory doses in humans, and the in vitro inhibition of prostaglandin synthesis activities of mefenamic acid, meclofenamic acid, phenylbutazone, indomethacin, and aspirin and suggested an important role of prostaglandin synthesis inhibition in the production of therapeutic effects of the fenamic acids.

Table 36.4. Some Properties of the NSAIDs

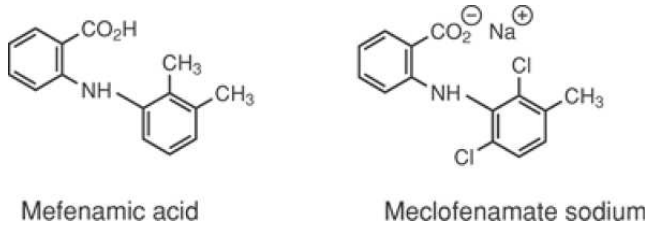
Drug	Year Introduced	Anti-inflammatory Dose (mg)	Onset (Duration) of Action	Peak Plasma Levels (h)	Protein binding (%)	Biotransformati
Aspirin	1899	3200–6000	ND	2	90	Plasma hydrolysis and hepatic
Diclofenac (Voltaren)	1989	100–200	30 min (~8 h)	1.5–2.5	99	Hepatic; first-pass metabolism: 3A4
Diflunisal (Dolobid)	1982	500–1000	1 h (8–12 h)	2–3	99	Hepatic
Etodolac (Lodine)	1991	800–1200	30 min (4–6 h)	1–2	99	Hepatic : 2C9

Fenoprofen Ca (Nalfon)	1976	1200–2400	NR	2	99	Hepatic :2C9
Flurbiprofen (Ansaid)	1988	200–300	NR	1.5	99	Hepatic : 2C9
Ibuprofen (Motrin, Advil)	1974	1200–3200	30 min (4–6h)	2	99	Hepatic; first-pass
Indomethacin (Indocin)	1965	75–150	2–4 h (2–3 d)	2–3	97	Hepatic : 2C9
Ketoprofen (Orudis)	1986	150–300	NR	0.5–2	99	Hepatic :2c9, 3A4
Meclofenamate Na (Meclomen)	1980	200–400	1h (4–6h)	4.0	99	Hepatic :2C9
Mefenamic acid (Ponstel)	1967	1000	NR	2–4	79	Hepatic: 2C9
Meloxicam (Mobic)	2000	7.5–15	NR	4–5	99	Hepatic 2C9
Nabumetone* (Relafen)	1992	1500–2000	NR	2.5 (1–8) 6-MNA	99**	Hepatic; first-pass metabolism to 6-MNA
Naproxen (Naprosyn, Anaprox)	1976	500–1000	NR	2–4	99	Hepatic: 3A4, 1A2
Oxaprozin (Daypro)	1993	1200	NR	3–5	99	Hepatic: 2C9
Piroxicam (Feldene)	1982	20	2–4 h (24 h)	2	99	Hepatic: 2C9
Sulindac* (Clinoril)	1978	400	NR	2–4	93	Hepatic; sulfide metabolite active

Tolmetin (Tolectin)	1976	1200	NR	<1	99	Hepatic

H= hours; m= min; NR=not reported.
* Pro-drug

Side effects are those primarily associated with GI disturbances (e.g., dyspepsia, discomfort, and especially, diarrhea), some CNS effects (e.g., dizziness, headache, and drowsiness), skin rashes, and transient hepatic and renal abnormalities. Isolated cases of hemolytic anemia have been reported.

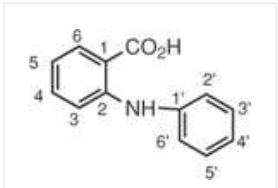


Mefenamic acid Meclofenamate sodium

Fig. 36.19. Structures of N-arylanthranilic acids (fenamic acids).

General structure–activity relationships

Substitution on the anthranilic acid ring generally reduces activity, whereas substitution of the N-aryl ring can lead to conflicting results. In the ultraviolet erythema assay for anti-inflammatory activity, the order of activity generally 3′ > 2′ ≫ 4′ for monosubstitution, with the 3′-CF_3 derivative (flufenamic acid) being particularly potent.



The opposite order of activity was observed, however, in the rat paw edema assay, with the 2′-Cl derivative being

more potent than the 3′-Cl analogue. In disubstituted derivatives, in which the nature of the two substituents is the same, 2′,3′-disubstitution appears to be the most effective. A plausible explanation may be found in an examination of the proposed topography of the active sites of arachidonic acid cyclooxygenase using either the Shen or Sherrer models. Proposed binding sites include a hydrophobic trough to which a lipophilic group, noncoplanar with the ring bearing the carboxylic acid function, binds. Substituents on the N-aryl ring that force this ring to be noncoplanar with the anthranilic acid ring should enhance binding at this site and, thus, activity. This may account for the enhanced

anti-inflammatory activity of meclofenamic acid, which has two ortho-substituents forcing this ring out of the plane of the anthranilic acid ring, over flufenamic acid (no ortho-substituents) and mefenamic acid (one ortho-substituent). Meclofenamic acid possesses 25 times greater anti-inflammatory activity than mefenamic acid. The NH-moiety of anthranilic acid appears to be essential for activity, because replacement of the NH function with O, CH_2, S, SO_2, N-CH_3, or N-$COCH_3$ functionalities significantly reduces activity. Finally, the position, rather than the nature, of the acidic function is critical for activity. Anthranilic acid derivatives are active, whereas the *m*- and *p*-aminobenzoic acid analogues are not. Replacement of the carboxylic acid function with the isosteric tetrazole moiety has little effect on activity.

Drug interactions

The pK_a values of the N-arylanthranilic acids (4.0–4.2) resemble those of the arylalkanoic acids; thus, it is not surprising that they are strongly bound to plasma proteins and that interactions with other highly protein bound drugs are very probable. The most common interactions reported are those of mefenamic acid and meclofenamic acid with oral anticoagulants. Concurrent administration of aspirin results in a reduction of plasma levels of meclofenamic acid.

Specific drugs

Mefenamic Acid

Mefenamic acid is synthesized from o-chlorobenzoic acid and 2,3-dimethylaniline under catalytic conditions (66). Mefenamic acid is the only fenamic acid derivative that produces analgesia centrally and peripherally. Mefenamic acid is indicated for the short-term relief of moderate pain and for primary dysmenorrhea.

Mefenamic acid is absorbed rapidly following oral administration, with peak plasma levels being attained within 2 to 4 hours. It is highly bound to plasma proteins (78.5%) and has a plasma half-life of 2 to 4 hours. Metabolism occurs through regioselective oxidation of the 3′-methyl group and glucuronidation of mefenamic acid and its metabolites. Urinary excretion accounts for approximately 50 to 55% of an administered dose, with unchanged drug accounting for 6%, the 3′-hydroxymethyl metabolite (primarily as the glucuronide) accounting for 25%, and the remaining 20% as the dicarboxylic acid (of which 30% is the glucuronide conjugate) (Fig. 36.20). These metabolites are essentially inactive.

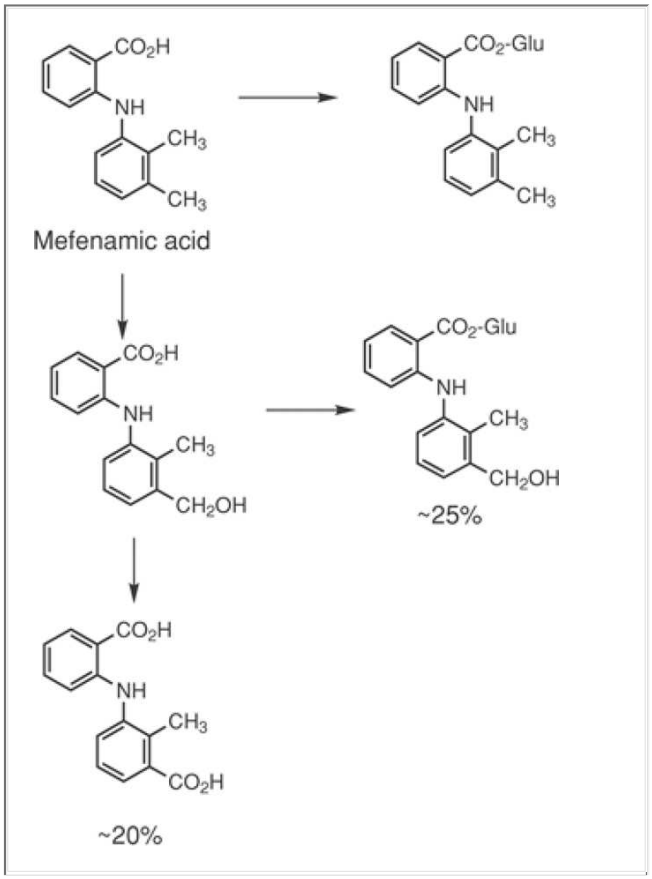


Fig. 36.20. Metabolism of mefenamic acid.

Meclofenamate Sodium

Meclofenamate sodium is rapidly and almost completely absorbed following oral administration, reaching peak plasma levels within 2 hours. It is highly bound to plasma proteins (99%) and has a plasma half-life of 2 to 4 hours. Metabolism involves oxidation of the methyl group, aromatic hydroxylation, monodehalogenation, and conjugation. Urinary excretion accounts for approximately 75% of the administered dose. The major metabolite is the product of 3′-methyl oxidation and has been shown to possess anti-inflammatory activity (Fig. 36.21).

Meclofenamate sodium is indicated for the relief of mild to moderate pain, the acute and chronic treatment of rheumatoid arthritis and osteoarthritis, the treatment of primary dysmenorrhea, and the treatment of idiopathic, heavy menstrual blood loss.

Oxicams

The enolic acid class of NSAIDs has been termed “oxicams” by the U.S. Adopted Name Council to describe the

series of 4-hydroxy-1,2-benzothiazine carboxamides that possess anti-inflammatory and analgetic properties. These structurally distinct substances resulted from extensive studies by the Pfizer group in an effort to produce noncarboxylic acid, potent, and well-tolerated anti-inflammatory drugs. Several series were prepared, including 2-aryl-1,3-indanediones, 2-arylbenzothiophen-3-(2H)-one 1,1-dioxides, dioxoquinoline-4-carboxamides, and 3-oxa-2H-1,2-benzothiazine-4-carboxamide 1,1-dioxides, and evaluated. These results, combined with the previously known activity of 1,3-dicarbonyl derivatives, such as phenylbutazone, led to the development of the oxicams. The first member of this class, piroxicam, was introduced in the United States in 1982 as Feldene and gained immediate acceptance.

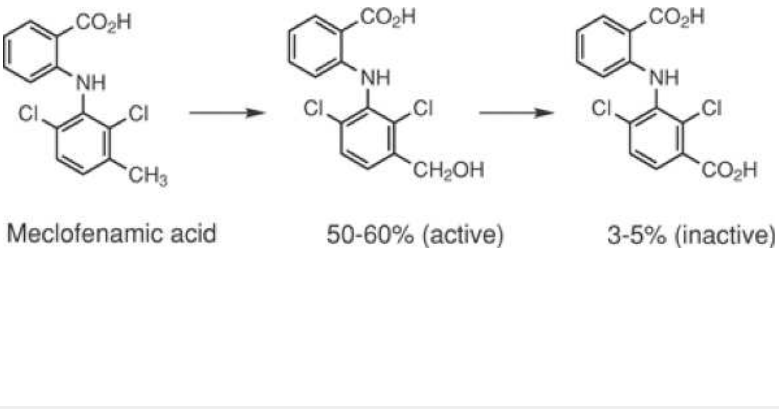

Fig. 36.21. Metabolism of meclofenamic acid.

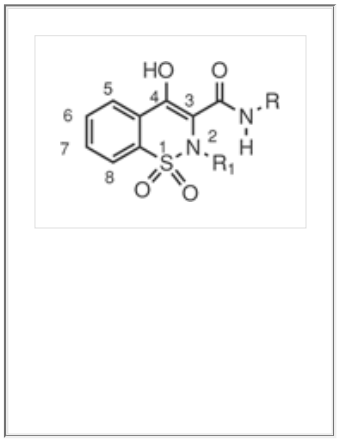
Piroxicam is potent in standard in vivo assays, being 200 times more potent than aspirin and at least 10 times as potent as any other standard agent in the ultraviolet erythema assay, as potent as indomethacin and more potent than phenylbutazone or naproxen in the carrageenan-induced rat paw edema assay, and equipotent with indomethacin and 15 times more potent than phenylbutazone in the rat adjuvant arthritis assay. It is less potent than indomethacin, equipotent with aspirin, and more potent than fenoprofen, ibuprofen, naproxen, and phenylbutazone as an analgetic in the phenylquinone writhing assay. Piroxicam inhibits the migration of polymorphonuclear cells into inflammatory sites and inhibits the release of lysosomal enzymes from these cells. It also inhibits collagen-induced platelet aggregation. It is an effective inhibitor of arachidonic acid cyclooxygenase, being almost equipotent with indomethacin and more potent than ibuprofen, tolmetin, naproxen, fenoprofen, phenylbutazone, and aspirin in the inhibition of prostaglandin biosynthesis by methylcholanthrene-transformed mouse fibroblasts (MC-5) assay. A template for designing anti-inflammatory compounds based on CPK space-filling models of the peroxy radical precursor of PGG and inhibitors of cyclooxygenase was proposed (67), and the ability of oxicams, particularly piroxicam, to inhibit this enzyme was subsequently rationalized on the ability of oxicams to assume a conformation resembling that of the peroxy radical precursor (68).

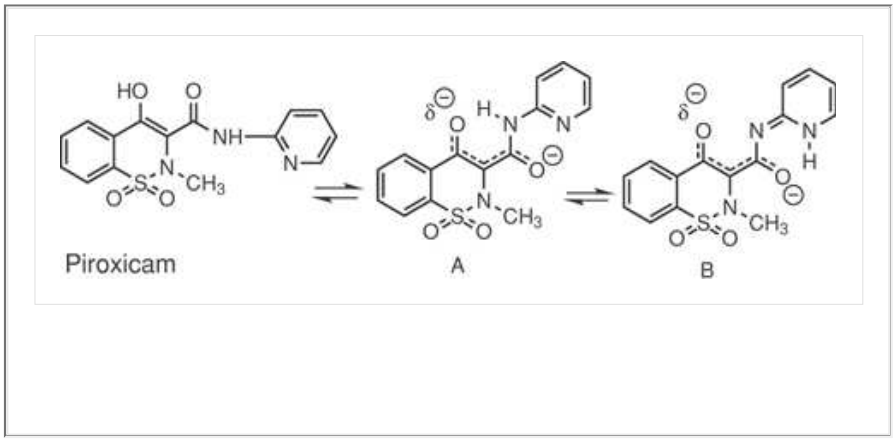
Approximately 20% of individuals on piroxicam report adverse reactions. Not unexpectedly, the greatest incidence of side effects result from GI disturbances. The reported incidence of peptic ulcers, however, is less than 1%.

As will be discussed later, a new oxicam derivative, meloxicam, has been approved as a selective COX-2 inhibitor for the treatment of osteoarthritis.

General structure–activity relationships

Within the series of 4-hydroxy-1,2-benzothiazine carboxamides represented by the general structure shown below, optimum activity was observed when R_1 was a methyl substituent. The carboxamide substituent, R, generally is an aryl or heteroaryl substituent, because alkyl substituents are less active. Oxicams are acidic compounds, with pK_a values in the range of four to six. N-heterocyclic carboxamides generally are more acidic than the corresponding N-aryl carboxamides, and this enhanced acidity was attributed (69) to stabilization of the enolate anion by the pyridine nitrogen atom, as illustrated in tautomer A and additional stabilization by tautomer B:





This explains the observation that primary carboxamides are more potent than the corresponding secondary derivatives, because no N-H bond would be available to enhance the stabilization of the enolate anion. When the aryl group is *o*-substituted, variable results were obtained, whereas *m*-substituted derivatives generally are more potent than the corresponding *p*-isomers. In the aryl series, maximum activity is observed with a *m*-Cl substituent. No direct correlations were observed between acidity and activity, partition coefficient, and electronic or spatial properties in this series. Two major differences, however, are observed when R = heteroaryl rather than aryl: The pK_a values generally are two to four units lower, and anti-inflammatory activity increased as much as sevenfold. The greatest activity is associated with the 2-pyridyl (as in piroxicam), 2-thiazolyl, or 3-(5-methyl) isoxazolyl ring systems, with the latter derivative (isoxicam) having been withdrawn from the European market in 1985 following several reports of severe skin reactions. In addition to possessing activity equal to or greater than indomethacin in the carrageenan-induced rat paw edema assay, the heteroaryl carboxamides also possess longer plasma half-lives, providing an improvement in dosing scheduling regimens.

General metabolism

Although the metabolism of piroxicam varies quantitatively from species to species, qualitative similarities are found in the metabolic pathways of humans, rats, dogs, and rhesus monkeys. It is extensively metabolized in humans, with

less than 5% of an administered dose being excreted unchanged. The major metabolites in humans result from CYP2C9 hydroxylation of the pyridine ring and subsequent glucuronidation; other metabolites are of lesser importance

(Fig. 36.22). Aromatic hydroxylation at several positions of the aromatic benzothiazine ring also occurs; two hydroxylated metabolites have been extracted from rat urine. On the basis of NMR deuterium-exchange studies, hydroxylation at the 8-position was ruled out, indicating that hydroxylation occurs at two of the remaining positions. Other novel metabolic reactions occur. Cyclodehydration gave a tetracyclic metabolite (the major metabolite in dogs), whereas ring contraction following amide hydrolysis and decarboxylation eventually yields saccharin. All the known metabolites of piroxicam lack anti-inflammatory activity. For example, the major human metabolite is 1,000-fold less effective as an inhibitor of prostaglandin biosynthesis than piroxicam itself. Related oxicams undergo different routes of metabolism. For example, sudoxicam (the N-2-thiazolyl analogue) undergoes primarily hydroxylation of the thiazole ring, followed by ring-opening, whereas isoxicam undergoes primarily cleavage reactions of the benzothiazine ring.

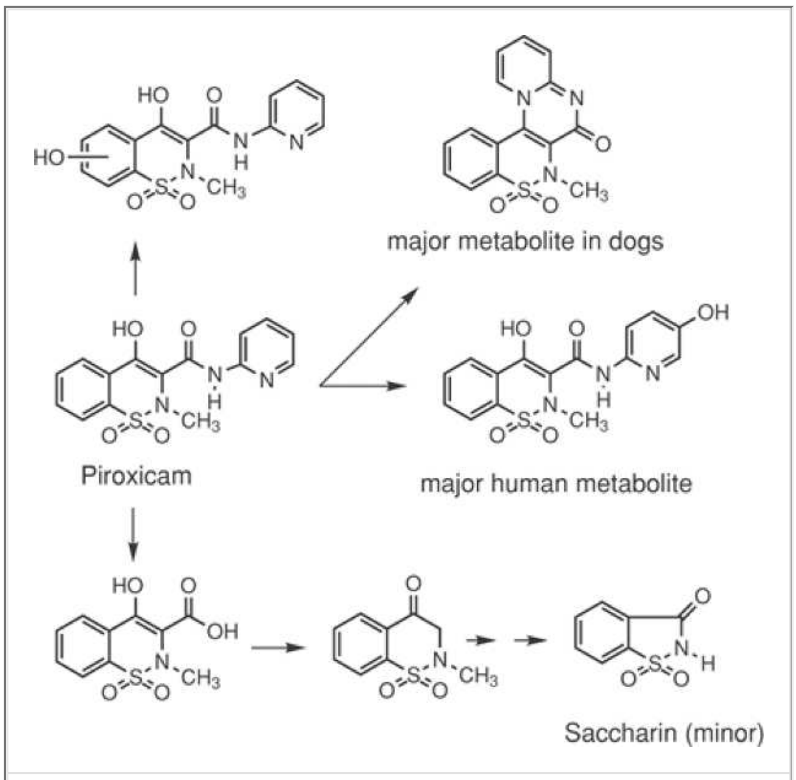


Fig. 36.22. Metabolism of piroxicam.

Drug interactions

Few reports of therapeutically significant interactions of oxicams with other drugs have appeared. Concurrent administration of aspirin has been shown to reduce piroxicam plasma levels by approximately 20%, whereas the anticoagulant effect of acenocoumarin is potentiated, presumably as a result of plasma protein displacement.

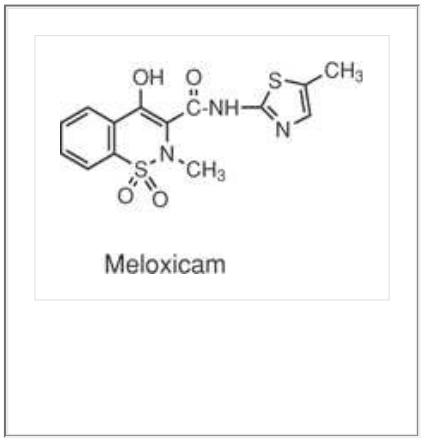
Specific Drugs Piroxicam

Prixoicam is synthesized by ring-expansion reactions of saccharin derivatives (70). Piroxicam is readily absorbed on oral administration, reaching peak plasma levels in approximately 2 hours. Peak plasma levels appear to be lower when given with food at low doses (30 mg), with no differences appearing with a 60-mg dose, but in general, food does not markedly affect bioavailability. Being acidic (pK_a = 6.3), it is highly bound to plasma proteins (99%). Piroxicam possesses an extended plasma half-life (38 hours), making single daily dosing possible. Piroxicam is indicated for long-term use in rheumatoid arthritis and osteoarthritis.

Meloxicam

In April 2000, the U.S. FDA approved meloxicam for the treatment of osteoarthritis. When meloxicam was initially

introduced in the United Kingdom, it was promoted as a selective COX-2 inhibitor. Meloxicam, however, is less selective than celecoxib and much less selective than rofecoxib in in vitro studies (see Selective COX-2 Inhibitors). Meloxicam is readily absorbed when administered orally and is highly bound to plasma proteins. Meloxicam is extensively metabolized in the liver, primarily by CYP2C9 and, to a lesser extent, by CYP3A4. The advantages of meloxicam over celecoxib and rofecoxib in the treatment of osteoarthritis (or rheumatoid arthritis) are not readily apparent.



Meloxicam

Gastroenteropathy Induced By Nonselective COX NSAIDs

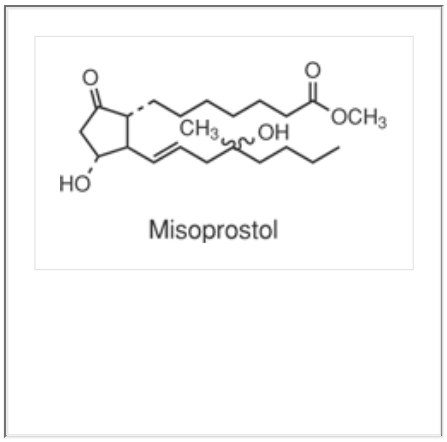
The effectiveness and popularity of the NSAIDs in the United States and Europe make this class one of the most commonly used classes of therapeutic entities. More than 75 million prescriptions are written annually for the NSAIDs, including aspirin. Unfortunately, until the introduction of the selective COX-2 inhibitors, almost all of the current drugs, which are nonselective COX-1 and COX-2 inhibitors, share the undesirable property of producing damaging effects to gastric and intestinal mucosa, resulting in erosion, ulcers, and GI bleeding, and these represent the major adverse reactions to the use of NSAIDs. As many as 20,000 deaths and 100,000 hospitalizations per year have been associated with GI complications resulting from the use of NSAIDs. Approximately 30 to 40% of patients taking NSAIDs report some type of gastric injury, and approximately 10% discontinue therapy because of these effects. These acute and chronic injuries to gastric mucosa result in a variety of lesions referred to as NSAID gastropathy, which differs from peptic ulcer disease by their localization more frequently in the stomach rather than in the duodenum. Additionally, NSAID-induced lesions occur more frequently in the elderly than typical peptic ulcers do. Normally, the stomach protects itself from the harmful effects of hydrochloric acid and pepsin by a number of protective mechanisms referred to as the gastric mucosal barrier, which consists of epithelial cells, the

mucous and bicarbonate layer, and mucosal blood flow. Gastric mucosa actually is a gel consisting of polymers of glycoprotein, which limit the diffusion of hydrogen ions. These polymers reduce the rate at which hydrogen ions (produced in the lumen) and bicarbonate ion (secreted by the mucosa) mix; thus, a pH gradient is created across the mucus layer. Normally, gastric mucosal cells are rapidly repaired when they are damaged by factors such as food, ethanol, or acute ingestion of NSAIDs. Among the cytoprotective mechanisms is the ability of prostaglandins of the PGE series, particularly PGE_1, to increase the secretion of bicarbonate ion and mucus and to maintain mucosal blood flow. The prostaglandins also decrease acid secretion, permitting the gastric mucosal barrier to remain intact.

As mentioned earlier, Figure 36.7 illustrates the ability of aspirin and NSAIDs to induce gastric damage by a dual-insult mechanism. Aspirin and the NSAIDs are acidic substances that can damage the GI tract, even in the absence of hydrochloric acid, by changing the permeability of cell membranes, allowing a back diffusion of hydrogen ions. These weak acids remain un-ionized in the stomach, but the resulting lipophilic nature of these substances allows accumulation or concentration in gastric mucosal cells. Once inside these cells, however, the higher pH of the intracellular environment causes the acids to dissociate and become “trapped” within the cells. The permeability of the mucosal cell membrane is thus altered, and the accumulation of hydrogen ions causes mucosal cell damage. This gastric damage is a result, therefore, of the primary insult of acidic substances. As detailed earlier in this chapter, the primary mechanism of action of the NSAIDs is to inhibit the biosynthesis of prostaglandins at the cyclooxygenase step. The resulting nonselective inhibition of prostaglandin biosynthesis in the GI tract prevents the prostaglandins from exerting their protective mechanism on gastric mucosa; thus, the NSAIDs induce gastric damage through this secondary insult mechanism.

The use of PGE_1 to reduce NSAID-induced gastric damage is limited by the fact that it is ineffective orally and degrades rapidly on parenteral administration, primarily by oxidation of the 15-hydroxy group. To overcome these limitations, misoprostol was synthesized as a prostaglandin pro-drug analogue in which oral activity was achieved by

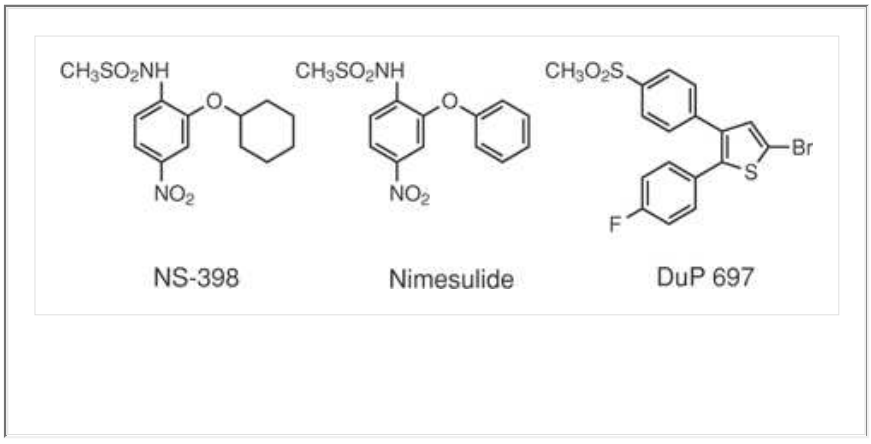
administering the drug as the methyl ester, allowing the bioactive acid to be liberated after absorption. Oxidation of the 15-hydroxy group was overcome by moving the hydroxy group to the 16-position, thus "fooling" the enzyme prostaglandin 15-OH dehydrogenase. Oxidation was further limited by the introduction of a methyl group at the 16-position, producing a tertiary alcohol that is more difficult to oxidize than the secondary alcohol group of the prostaglandins. Misoprostol was introduced in 1989 as a mixture of stereoisomers at the 16-position as Cytotec for the prevention of NSAID-induced gastric ulcers (but not duodenal ulcers) in patients at high risk of complications from a gastric ulcer, particularly the elderly and patients with concomitant debilitating disease and in individuals with a history of gastric ulcers.



Misoprostol

Selective COX-2 Inhibitors

As previously discussed, the most notable achievement in the development of NSAIDs has been in the area of selective COX-2 inhibitors (coxibs). Classical NSAIDs share similar side effect profiles, particularly on the GI tract, many of which have been attributed to the inhibition of cyclooxygenase, the rate-limiting step in prostaglandin biosynthesis. With the discovery of two isoforms of cyclooxygenase, COX-1 and COX-2, and the realization that COX-1 is beneficial in maintaining normal processes in the GI tract by producing cytoprotective prostaglandins, stimulating bicarbonate secretion and mucus and producing an overall reduction in acid secretion, the search for drugs that selectively inhibit the COX-2 isoform has received much attention. The traditional NSAIDs inhibit COX-1, COX-2, and thromboxane synthetase to varying degrees of selectivity. Decreased gastric mucosal protection (resulting in an enhanced risk of ulceration) and stress-induced decreased renal perfusion result from nonselective inhibition of COX, whereas inhibition of thromboxane synthesis results in increased prostaglandin synthesis and a reduction in platelet aggregation and, thus, an increased bleeding tendency. Those NSAIDs with a greater selectivity for COX-1 generally cause greater GI bleeding and renal toxicity than those with greater selectivity for COX-2.



NS-398 Nimesulide DuP 697

These early studies led to extensive efforts by many laboratories to develop selective inhibitors of the COX-2 isoform with the goal of developing an "ideal" NSAID—that is, one that selectively inhibits COX-2, thus reducing the inflammatory response but not interfering with the GI-protective functions of COX-1. Two early lead compounds were developed, NS-398 and DuP 697, which have served as the basis of the development of two widely explored chemical classes. NS-398 and nimesulide are the prototypes of compounds known as "sulides,"

whereas DuP 697 is the prototype of a class of COX-2 inhibitors termed "coxibs." These efforts led to the introduction of three selective COX-2 inhibitors in the U.S. market (celecoxib, rofecoxib, and valdecoxib), whereas

other selective inhibitors under investigation may have been halted (Fig. 36.23). An excellent review of the various chemical classes of selective COX-2 inhibitors has been published (71). Selective COX-2 inhibitors were designed to take advantage of the much larger NSAID binding site on COX-2 compared to the NSAID binding site on COX-1, resulting from the substitution of the smaller amino acid valine in COX-2 for isoleucine at position 523 in COX-2 (see earlier discussion). In COX-1, the larger isoleucine residue near the active site restricts access by larger, relatively rigid side-chain substituents, such as sulfamoyl or sulfonyl side chains usually seen in the selective COX-2 inhibitors.

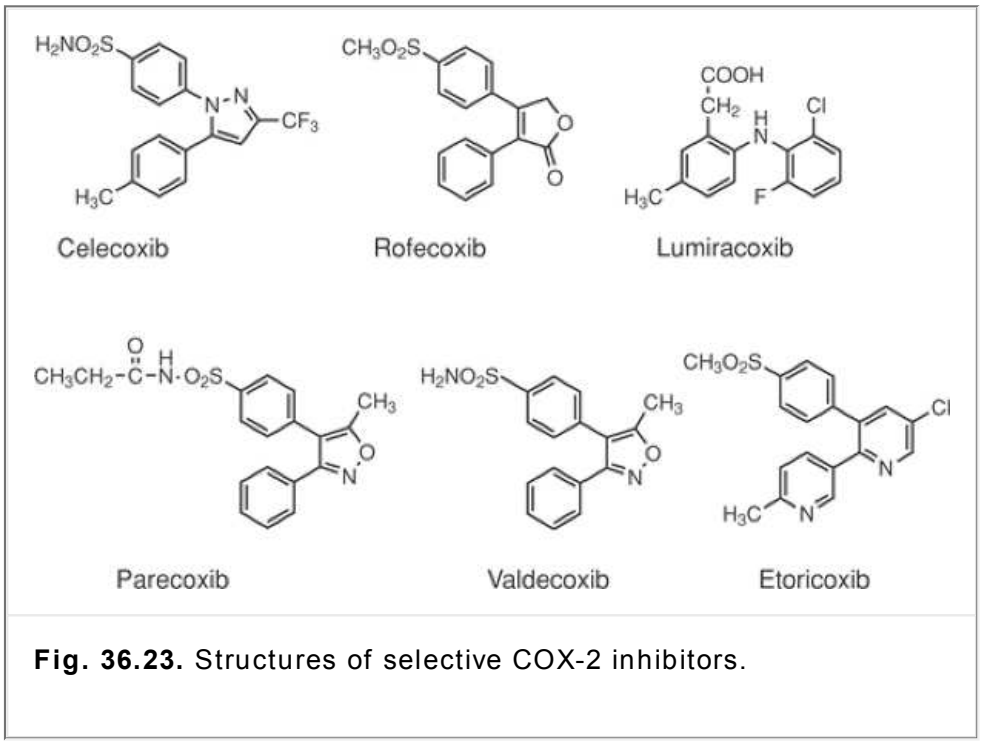


Fig. 36.23. Structures of selective COX-2 inhibitors.

A comparison of the selectivity of several NSAIDs and selective COX-2 inhibitors was recently presented (Fig. 36.24) (72). In another study regarding the pharmacological and biochemical profile of a new investigational selective COX-2 inhibitor, etoricoxib, the following comparison of COX-1/COX-2 selectivity for several selective and nonselective inhibitors in human whole blood assays was reported (Table 36.5) (73).

The U.S. FDA classifies only celecoxib, rofecoxib, and valdecoxib as selective COX-2 inhibitors. It classifies all other NSAIDs as nonselective.

Perhaps as interesting as the role that COX-2 selective inhibitors play in reducing the incidence of GI side effects among NSAIDs are the reports of other potential therapeutic uses for this new class of drugs, including potential use in the treatment of Alzheimer's disease and carcinomas of various types. The COX-2 appears to be induced in inflammatory plaques that are evident in the CNS in Alzheimer's disease. Several reports have appeared indicating that patients taking NSAIDs have a lower incidence and a decreased rate of progression of Alzheimer's disease. Epidemiological studies suggest a significant reduction in the risk for colon cancer in patients regularly taking aspirin. Additionally, NSAIDs have been reported to reduce the growth rate of polyps in the colon in humans as well as the incidence of tumors of the colon in animals. The expression of COX-2 appears to be significantly up-regulated in carcinoma of the colon. The effectiveness of NSAIDs in the prevention and treatment of other cancers, such as prostate cancer and mammary carcinoma, has been reported as well.

This effectiveness is more noticeable among COX-2 selective drugs.

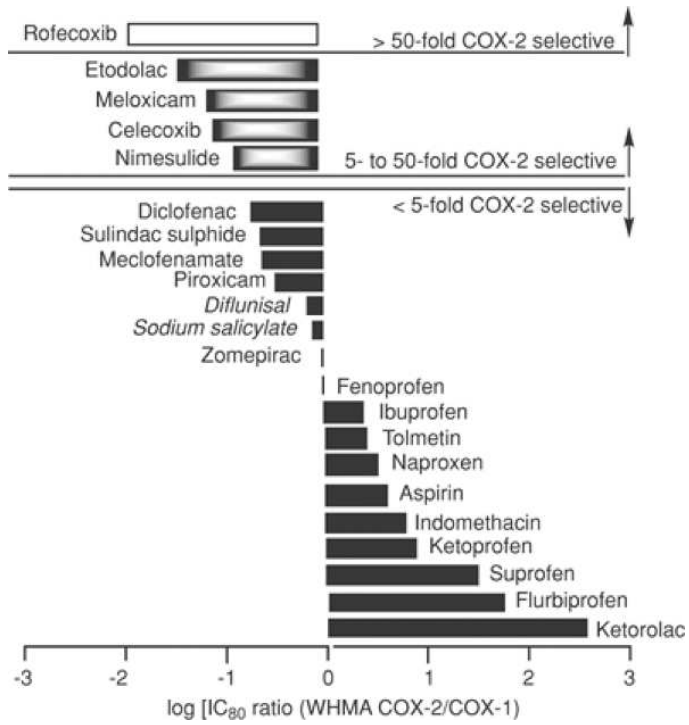

Fig. 36.24. Selectivity of COX-2 inhibitors and NSAIDs given as log inhibitory concentration (IC80) ratio. The "0" line indicates equipotency. (Adapted from Warner TD, Giuliano F, Vojnovic I, et al. Nonsteroid drug selectivities for cyclooxygenase-1 rather than cyclooxygenase-2 are associated with human gastrointestinal toxic-ity: a full in vitro analysis. Proc Natl Acad Sci U S A 1999;96:7563–7568; with permission.)

Table 36.5. A Comparison of IC50 (μM) Binding Constants for Selective Versus Nonselective COX Inhibitors

Drug	COX-1	COX-2	COX-1/COX-2 Ratio
Etoricoxib	116	1.1	106
Rofecoxib	18.8	0.53	35
Valdecoxib	26.1	0.87	30
Celecoxib	6.7	0.87	7.6
Nimesulide	4.1	0.56	7.3
Diclofenac	0.15	0.05	3.0
Etodolac	9.0	3.7	2.4

Meloxicam	1.4	0.70	2.0
Indomethacin	0.19	0.44	0.4
Ibuprofen	4.8	24.3	0.2
6MNA	28.9	154	0.2
Piroxicam	0.76	9.0	0.08

6MNA, 6-methoxynaphthalene-2-acetic acid.

Despite the promise of therapeutic effectiveness of the selective COX-2 inhibitors, the potential for severe cardiovascular effects prompted a critical review of these drugs. This concern was initiated through the revelation of long-term clinical trials of rofecoxib that indicated an increased risk of heart attack. One study completed in 2000, named VIGOR (74), showed an increased risk of myocardial infarction. A later retrospective analysis (75) of 1.4 million patients showed that daily rofecoxib doses of greater than 25 mg increased the risk of heart problems by 3.6-fold as compared with older NSAIDs. The coxibs were found (76) to suppress the formation of PGI_2, which may result in elevated blood pressure and accelerated atherogenesis as well as predisposing patients on coxib therapy to a heightened thrombotic response on the rupture of an atherosclerotic plaque (77). These effects may be related to the different consequences of inhibition of COX-1 and COX-2. Whereas COX-1 mediates the production of prostaglandins and the platelet aggregate stimulator TXA_2, COX-2 may mediate the production of the platelet aggregate inhibitor, prostacyclin. In an excellent review of the adverse cardiovascular effects of selective COX-2 inhibitors, it was suggested that the apparent consequence of selective inhibition of COX-2 is a significant reduction in the production of prostacyclins, whereas the production of TXA_2 by COX-1 is unaffected (78). Of practical interest is a report that resveratrol, an *m*-hydroxyquinone present in red wine that has been suggested to be one agent responsible for the cardioprotective effects observed with the consumption of red wine (i.e., the “French Paradox”), inhibits COX-1 with no apparent effect on COX-2 (79). Thus, the design of highly selective inhibitors of COX-2 would not be as desirable therapeutically as drugs that preferentially inhibit COX-2 but also inhibit COX-1 to a lesser extent.

In one of the most publicized drug withdrawals, Merck voluntarily withdrew rofecoxib from the U.S. market in September 2004, followed by Pfizer's withdrawal of valdecoxib in April 2005. Thus, the future of selective COX-2 inhibitors in the treatment of inflammatory disorders is very clouded.

Specific drugs

Celecoxib (Celebrex)

Celecoxib is synthesized by condensing 4-methyl-acetophenone and ethyltrifluoroacetate with sodium methoxide and the resulting butanedione derivative cyclized with 4-hydrazinophenylsulfonamide (80). It was the first NSAID to be marketed as a selective COX-2 inhibitor. Celecoxib is well absorbed from the GI tract, with peak plasma concentrations generally being attained within 3 hours of administration. Peak plasma levels in geriatric patients may be increased, but dosage adjustments in elderly patients generally are not required unless the patient weighs less than 50 kg. Celecoxib is excreted in the urine and feces primarily as inactive metabolites, with less than 3% of an administered dose being excreted as unchanged drug. Metabolism occurs primarily in the liver by CYP2C9 and involves hydroxylation of the 4-methyl group to the primary alcohol, which is subsequently oxidized

to its corresponding carboxylic acid, the major metabolite (73% of the administered dose) (Fig. 36.25). The carboxylic acid is conjugated, to a slight extent, with glucuronic acid to form the corresponding glucuronide. None of the isolated metabolites have been shown to exhibit pharmacological activity as inhibitors of either COX-1 or COX-2. Celecoxib also inhibits CYP2D6; thus, the potential of celecoxib to alter the pharmacokinetic profiles of other drugs inhibited by this isoenzyme exists. Celecoxib, however, does not appear to inhibit other CYP isoforms, such as CYP2C19 or CYP3A4. Other drug interactions related to the metabolic profile of celecoxib have been noted, particularly with other drugs that inhibit CYP2C. For example, coadministration of celecoxib with fluconazole can

significantly increase plasma concentration of celecoxib, because fluconazole inhibits CYP2C9.

Celecoxib may cause an increased risk of serious cardiovascular thrombotic events, myocardial infarction, and stroke, which can be fatal. All NSAIDs may have a similar risk. This risk may increase with duration of use. Patients with cardiovascular disease or risk factors for cardiovascular disease may be at greater risk. The NSAIDs, including celecoxib, cause an increased risk of serious GI adverse events, including bleeding, ulceration, and perforation of the stomach or intestines, which can be fatal. These events can occur at any time during use and without warning symptoms. Elderly patients are at greater risk for serious GI events.

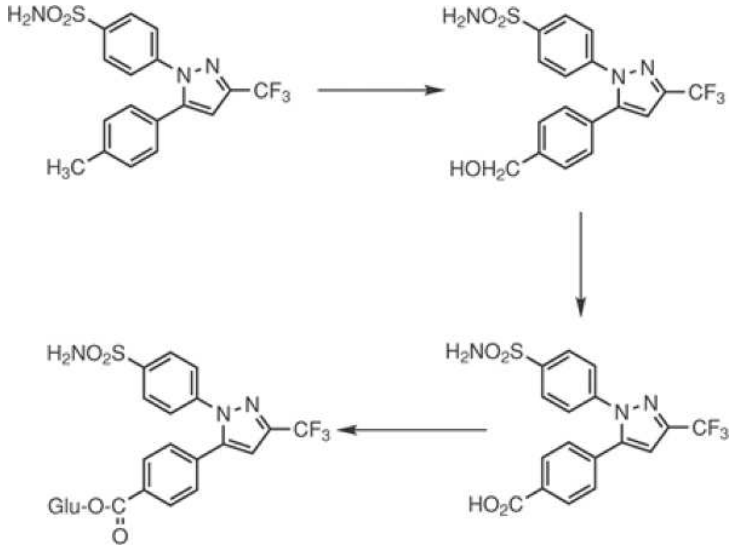

Fig. 36.25. Metabolism of celecoxib.

Celecoxib is currently indicated for the relief of signs and symptoms of osteoarthritis and rheumatoid arthritis and to reduce the number of adenomatous colorectal polyps in familial adenomatous polyposis as an adjunct to usual care. Celecoxib is at least as effective as naproxen in the symptomatic management of osteoarthritis and at least as effective as naproxen and diclofenac in the symptomatic treatment of rheumatoid arthritis, and it is less likely to cause adverse GI effects. Celecoxib appears to be effective in the management of pain associated with both of these arthritic conditions, but effectiveness in acute or chronic pain has not been fully demonstrated. Unlike aspirin, celecoxib does not exhibit antiplatelet activity. Concomitant administration of aspirin and celecoxib may increase the incidence of GI side effects. Another notable potential drug interaction with celecoxib is its ability, like other NSAIDs, to reduce the blood pressure response to angiotensin-converting enzyme inhibitors. A more detailed discussion of the chemical, pharmacological, pharmacokinetic, and clinical aspects of celecoxib is available (81).

Rofecoxib (Vioxx)

Rofecoxib has been synthesized by a number of synthetic routes that have been summarized elsewhere (82). It was the second selective COX-2 inhibitor to be marketed. Rofecoxib is well absorbed from the GI tract on oral administration, with peak plasma levels generally being attained within 2 to 3 hours of dosing. Bioavailability averages 93% following administration of a single dose. The area under the plasma concentration–time curve is increased in patients older than 65 years compared to younger adults and is increased slightly in black and Hispanic patients compared with white patients, but the difference is not considered to be clinically significant.

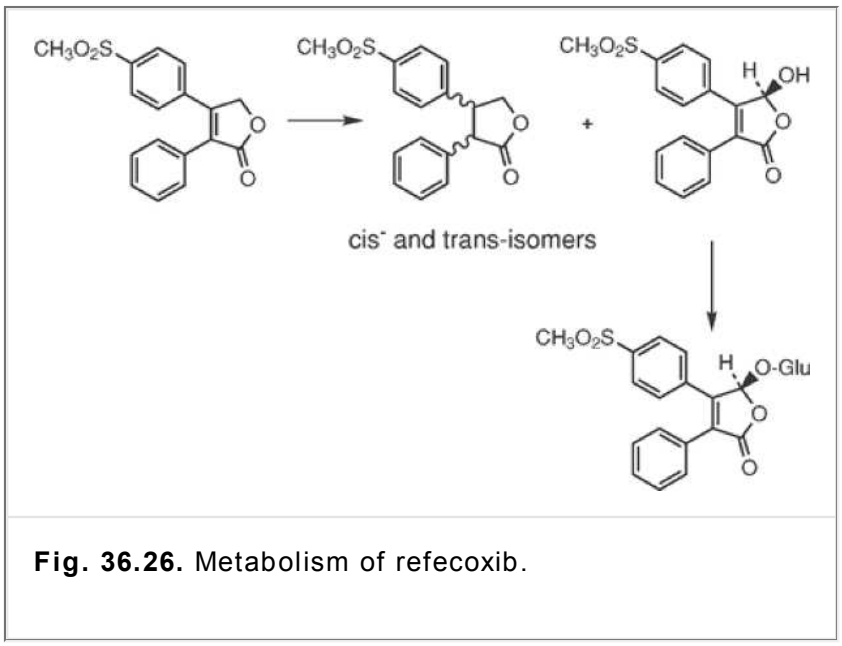

Fig. 36.26. Metabolism of refecoxib.

Rofecoxib is excreted primarily in the urine (72%) as metabolites. Less than 1% is excreted in the urine as unchanged drug, whereas approximately 14% is excreted in the feces as unchanged drug. Although the metabolism of rofecoxib has not been fully determined, the microsomal cytochrome P450 system appears to play only a minor role—a major difference in the metabolic routes of rofecoxib and celecoxib. The major metabolic route appears to form reduction of the dihydrofuranone ring system by cystolic enzymes to the to *cis*- and *trans*- dihydro derivatives. Also isolated is the glucuronide of a hydroxy derivative that results from CYP2C9 oxidative metabolism. None of the isolated metabolites of rofecoxib possess pharmacological activity as COX-1 or COX-2 inhibitors. The metabolism of rofecoxib is presented in Figure 36.26.

Rofecoxib (Vioxx) was voluntarily withdrawn from the United States and the worldwide market on September 30, 2004, because of safety concerns regarding an increased risk for cardiovascular events, including heart attack and stroke, in patients taking rofecoxib.

Rofecoxib was indicated for the relief of the signs and symptoms of osteoarthritis, for the management of acute pain in adults, and for the treatment of primary

dysmenorrhea. Rofecoxib, diclofenac, and ibuprofen possess comparable efficacy in the treatment of osteoarthritis, but serious adverse effects on the GI tract are not observed with rofecoxib. In the treatment of pain, a single 50-mg dose of rofecoxib, a single 550-mg dose of naproxen sodium, and a single 400-mg dose of ibuprofen possess similar onsets of action. Rofecoxib, naproxen sodium, and ibuprofen displayed similar effectiveness in the treatment of postoperative dental pain. A 50-mg dose of rofecoxib was as effective as a 550-mg dose of naproxen sodium in the relief of primary dysmenorrhea in adults. Like celecoxib, rofecoxib does not affect platelet aggregation or bleeding and should not be used as a substitute for aspirin in the prevention of cardiovascular events. A more detailed discussion of the chemical, pharmacological, pharmacokinetic, and clinical aspects of rofecoxib is available (83).

Rofecoxib is approved for the relief of the signs and symptoms of osteoarthritis and the treatment of primary dysmenorrheal.

Valdecoxib (Bextra)

Valdecoxib is freely soluble in alkaline aqueous solutions. At recommended doses, the mean oral bioavailability for valdecoxib is 83%, and the time to peak concentration is approximately 3 hours. Time to peak plasma concentration was delayed by 1 to 2 hours when administered with a high-fat meal. Protein binding is very high at 98%. Valdecoxib exhibits linear pharmacokinetics over the usual clinical dose range. Valdecoxib is extensively metabolized in humans. The primary metabolite for valdecoxib involved CYP2C9 hydroxylation of the 5-Me group, which was further metabolized to the inactive carboxylate, and N-hydroxylation at the sulfonamide moiety. Oxidative breakdown of the N-hydroxy sulfonamide function group led to the formation of the corresponding sulfinic acid and sulfonic acid metabolites. The O-and N-glucuronides were the major urinary metabolites. Only 3% of the administered dose was recovered in urine as unchanged valdecoxib. Its elimination half-life is 8 to 11 hours. Approximately 70% of a valdecoxib dose is eliminated in the urine as metabolites, and less than 5% is excreted in the feces and urine

unchanged.

> Valdecoxib (Bextra) was voluntarily withdrawn from the U.S. market on April 7, 2005, because of safety concerns regarding increased risk of cardiovascular events and reports of serious and potentially life-threatening skin reactions, including deaths, in patients taking valdecoxib.

Valdecoxib is approved for the relief of the signs and symptoms of osteoarthritis and adult rheumatoid arthritis and for the treatment of primary dysmenorrhea. Valdecoxib is contraindicated for the treatment of postoperative pain immediately following coronary artery bypass graft surgery.

Precautions to consider for valdecoxib are that it may cause bronchoconstriction or anaphylaxis in aspirin-sensitive patients with asthma, who have experienced severe bronchospasm after taking aspirin or other NSAIDs.

Parecoxib (Parecoxib Sodium, Dynstat)

As shown in Figure 36.23, parecoxib is a pro-drug of valdecoxib administered IM or IV for perioperative analgesic and anti-inflammatory use. As a pro-drug, it undergoes rapid in vivo hydrolysis to valdecoxib. It is the only parenterally administered coxib. Parecoxib at greater than 20 mg has analgesic activity superior to that of placebo and similar to that of parenteral 30 or 60 mg of ketorolac in patients with postoperative dental pain. A significant adverse effect is drug hypersensitivity. Parecoxib is currently marketed worldwide but has not been approved for use in the United States.

Etoricoxib (Arcoxia)

Etoricoxib (Fig. 36.23) is a selective COX-2 inhibitor being developed for postsurgical treatment of dental pain (120 mg) and osteoarthritis. It has a methylsulfonyl group common to the other coxib inhibitors. Etoricoxib is rapidly absorbed, with an oral bioavailability of 80 to 100%, and reaches maximum plasma concentrations in 1 to 2 hours after dosing. Food decreases the rate of absorption but has no effect on the extent of absorption. It exhibits a long elimination half-life of approximately 22 hours, demonstrating linear plasma pharmacokinetics with no accumulation during multiple dosing. Etoricoxib is metabolized involving oxidation of its 6′-methyl group primarily by CYP3A4 but is not an inhibitor of CYP3A4. Other metabolites include 1′-N-oxide and glucuronides. Etoricoxib is primarily excreted as metabolites into the urine.

Lumiracoxib (Prexige)

Lumiracoxib (Fig. 36.23) is a selective COX-2 inhibitor developed for the treatment of osteoarthritis, rheumatoid arthritis, and acute pain. It structurally differs from the other selective COX-2 inhibitors in being a phenylacetic acid with a carboxylic acid group (pK_a = 4.7). Lumiracoxib is rapidly absorbed, with an oral bioavailability of 74%, and reaches a maximum plasma concentration 2 hour after dosing. It is highly plasma protein bound and has a short elimination half-life of approximately 4 hours, demonstrating linear plasma pharmacokinetics with no accumulation during multiple dosing. Lumiracoxib is extensively metabolized involving oxidation of its 5-Me group and 4′-hydroxylation of the dihalogenated aromatic ring. The major in vitro oxidative pathways is catalyzed primarily by CYP2C9. Lumiracoxib and its metabolites are excreted via renal and fecal routes in approximately equal amounts. The COX-2 selectivity was confirmed by a lack of inhibition of arachidonic acid and collagen-induced platelet aggregation. As with other selective coxibs, lumiracoxib exhibits a reduced incidence of gastroduodenal erosions compared with that of naproxen. It was approved for use in the United Kingdom and the United States in 2007.

Disease-Modifying Antirheumatic Drugs

The drugs previously discussed as NSAIDs, both the nonselective COX and selective COX-2 inhibitors, have proven to be beneficial in the symptomatic treatment of arthritic disorders and to be a popular therapeutic regimen. Despite their effectiveness and popularity, however, it should be remembered that none of these drugs are effective in preventing or inhibiting the underlying pathogenic, chronic inflammatory processes. Recent interest has been generated by drugs that are effective in the treatment of arthritic disorders yet fail to demonstrate significant activity in the standard screening assays for antiarthritic drugs. Disease-modifying antirheumatic drugs (DMARDs) differ from the previously discussed drugs in that they are drugs that retard or halt the underlying progression, limiting the amount of joint damage that occurs in rheumatoid arthritis while lacking the anti-inflammatory and analgetic effects observed with NSAIDs. Although both NSAIDs and DMARDs improve symptoms of active rheumatoid arthritis, only DMARDs have been shown to alter the disease course and to improve radiographic outcomes. The DMARDs have an effect on rheumatoid arthritis that is different and more delayed in onset than either NSAIDs or corticosteroids. Once persistent disease activity (chronic synovitis) is established, a DMARD should be considered. The development of

erosions or joint space narrowing on radiographs of the involved joints is a clear indication for DMARD therapy; however, one should not wait for radio-graphic changes to occur. They are much slower acting, taking as long as 3 months for measurable clinical benefits to be observed. Although these drugs also possess potentially dangerous adverse side effects, which in many cases limit their long-term use, DMARDs are effective in reducing joint destruction and the progression of early rheumatoid arthritis.

A 2004 study reported that taking DMARDs at early stages in the development of rheumatoid arthritis is especially important to slow the disease and to save the joints and other tissues from permanent damage. Typically, DMARDs are used with an NSAID or a cortico-steroid. The NSAID or corticosteroid handles your immediate symptoms and limits inflammation, and the DMARD goes to work on the disease itself.

The DMARDS can be divided into two general categories: synthetic DMARDS, which can be taken orally, and biological DMARDS, which are given by IV infusion or subcutaneously, that target and inactivate cell proteins (cytokines) and T lymphocytes (T cells) from causing joint inflammation. The DMARD methotrexate, in combination with the biological DMARDs, may offer the best control of rheumatoid arthritis for the majority of people, eliminating the need for NSAID medications.

Synthetic Disease-Modifying Antirheumatic Drugs

The synthetic DMARDs include gold salts, hydroxychloroquine, and sulfasalazine. Less common synthetic DMARDs are penicillamine and minocycline. Synthetic immunosuppressants used for the treatment of inflammatory diseases include the antimetabolites methotrexate, leflunomide, and azathioprine.

Gold compounds

Historical Background

At the end of the 19th century, the chemotherapeutic applications of heavy metal derivatives were receiving considerable interest. Among those metals gaining the greatest attention were gold compounds (or gold salts). The first of these, gold cyanide, was effective in vitro against *Mycobacterium tuberculosis*. This discovery prompted others to extend the use of gold compounds in other disease states that are thought to be tubercular in origin. Early clinical observations had suggested similarities in the symptoms of tuberculosis and rheumatoid arthritis, and some thought rheumatoid arthritis to be an atypical form of tuberculosis. In 1927, aurothioglucose was found to relieve joint pain when used to treat bacterial endocarditis. The area of chrysotherapy had begun. Subsequent investigations led to an extensive study of gold compounds in Great Britain by the Empire Rheumatism Council, which reported in 1961 that sodium aurothiomalate was effective in slowing the development of progressive joint diseases. Both aurothioglucose and sodium aurothiomalate are orally ineffective and are administered by IM injection. In 1985, the first orally effective gold compound for arthritis, auranofin, was introduced in the United States. Several other gold compounds have been evaluated clinically but do not appear to offer advantages in terms of efficacy or toxicity.

Mechanism of Action

The biochemical and pharmacological properties shared by gold compounds are quite diverse. The mechanism by which they produce their antirheumatic actions has not been totally determined. The earlier observations that gold compounds were effective in preventing arthritis induced by hemolytic streptococci and by pleuropneumonia-like organisms led to the postulation that they acted through an antimicrobial mechanism. The inability of gold compounds to consistently inhibit mycoplasmal growth in vitro while inhibiting the arthritic process independent of microbial origins, however, suggested that they did not directly produce their effects by this mechanism. The involvement of immunological processes in the pathogenesis of arthritis suggested that a direct suppression of the immunologic response by gold compounds was involved. Available evidence, however, suggests that whereas enzymatic mediators released as a result of the immune response may be inhibited, no direct effect on either immediate or delayed cellular responses is evident to suggest any immunosuppressive mechanism. Suggestions have been made that protein denaturation and macroglobulin formation cause the proteins to become antigenic, thus initiating the immune response and producing biochemical changes in connective tissue, which ultimately leads to rheumatoid arthritis. The possibility that gold compounds inhibit the

aggregation of macroglobulins and, in turn, inhibit the formation of immune complexes may account for their ability to slow connective tissue degradation. Interaction with collagen fibrils and, thus, reduction of collagen reactivity that alters the course of the arthritic process also have been postulated. Perhaps the most widely accepted mechanism of action is related to the ability of gold compounds to inhibit lysosomal enzymes, the release of which promotes the inflammatory response. The lysosomal enzymes glucuronidase, acid phosphatase, collagenase, and acid hydrolases are inhibited, presumably through a reversible interaction of gold with sulfhydryl groups on the enzymes. Gold thiomalate inhibits glucosamine-6-phosphate synthetase, a rate-limiting step in mucopolysaccharide biosynthesis and

a property shared, to a lesser extent, by several NSAIDs. Gold sodium thiosulfate is a potent uncoupler of oxidative phosphorylation. Gold sodium thiomalate also is a fairly effective inhibitor of prostaglandin biosynthesis in vitro, but the relationship of this effect to the antiarthritic actions of gold compounds has not been clarified.

Side Effects

Toxic side effects have been associated with the use of gold compounds, with the incidence of reported adverse reactions in patients on chrysotherapy being as high as 55%. Serious toxicity occurs in 5 to 10% of reported cases. The most common adverse reactions include dermatitis (e.g., erythema, papular, vesicular, and exfoliative dermatitis), mouth lesions (e.g., stomatitis preceded by a metallic taste and gingivitis), pulmonary disorders (e.g., interstitial pneumonitis), nephritis (e.g., albuminuria and glomerulitis), and hematologic disorders (e.g., thrombocytopenic purpura, hypoplastic and/or aplastic anemia, and eosinophilia; blood dyscrasias are rare in incidence but can be severe). Less commonly reported reactions are GI disturbances (e.g., nausea, anorexia, and diarrhea), ocular toxicity (e.g., keratitis with inflammation and ulceration of the cornea and subepithelial deposition of gold in the cornea), and hepatitis. In those cases in which severe toxicity occurs, excretion of gold can be markedly enhanced by the administration of chelating agents, the two most common of which are dimercaprol (British Anti-Lewisite [BAL]) and penicillamine. Corticoids also suppress the symptoms of gold toxicity and the concomitant administration of dimercaprol, and corticosteroids have been recommended in cases of severe gold intoxication.

General Structure–Activity Relationships

Structure–activity relationships of gold compounds have not received a great amount of attention. Two important relationships, however, have been established: 1) Monovalent gold (aurous ion [Au^{+}]) is more effective than trivalent gold (auric ion [Au^{3+}]) or colloidal gold, and 2) only those compounds in which aurous ion is attached to a sulfur-containing ligand are active (Fig. 36.27). The nature of the ligands affects tissue distribution and excretion properties and, usually, are highly polar, water-soluble functions. Aurous ion has only a brief existence in solution and is rapidly converted to metallic gold or auric ion. Aqueous solutions decompose on standing at room temperature, posing a stability problem for the two injectable gold compounds therapeutically available (aurothioglucose and gold sodium thiomalate). Complexation of Au^{+} with phosphine ligands stabilizes the reduced valence state and results in both nonionic complexes that are soluble in organic solvents and an enhancement of oral bioavailability. Other changes also occur. In the phosphine-Au-S compounds, gold has a coordination number of 2, and the molecules are nonconducting monomers in solution. The injectable gold compounds are monocoordinated. Whereas nongold phosphine compounds are ineffective in arthritic assays, the nature of the phosphine ligand in the gold coordination complexes appears to play a greater role in antiarthritic activity than the other groups bound to gold. Within a homologous series, the triethylphosphine gold derivatives provide greatest activity.

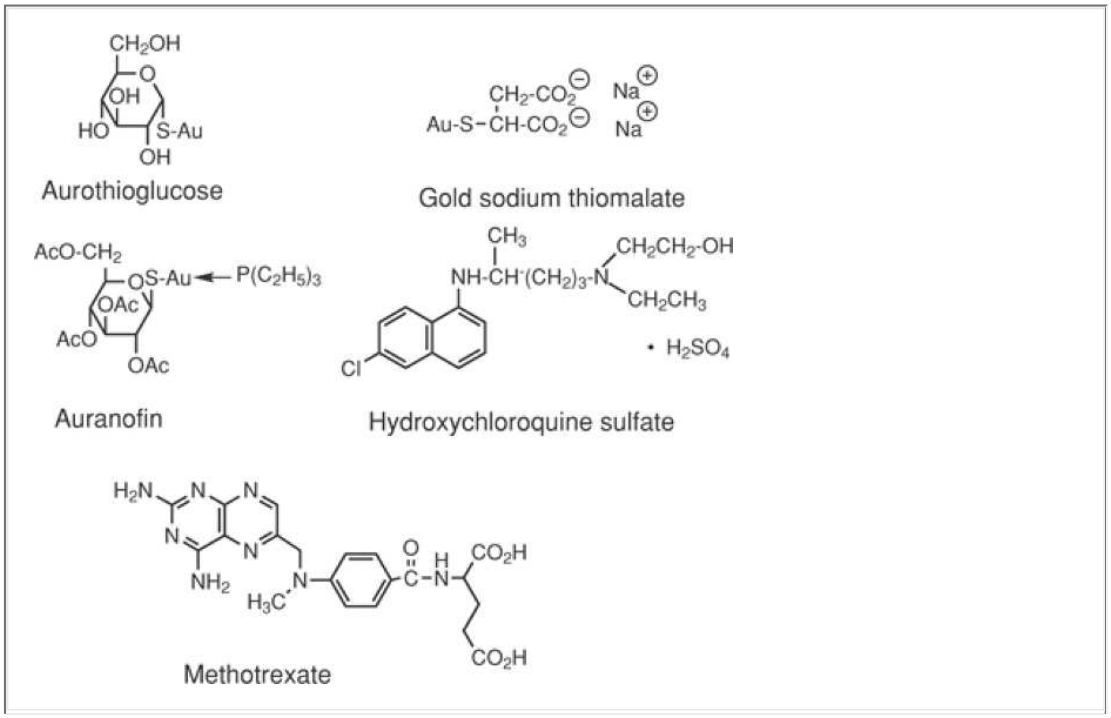

Fig. 36.27. Structures of disease-modifying antirheumatic drugs (DMARDs).

The structures of the three therapeutically available gold compounds in the United States are shown in Figure 36.27.

Absorption and Metabolism

Gold compounds generally are rapidly absorbed following IM injection, and the gold is widely distributed in body tissues, with the highest concentrations found in the reticuloendothelial system and in adrenal and renal cortices. Binding of gold from orally administered gold to red blood cells is higher than that of injectable gold. Gold accumulates in inflamed joints, where high levels persist for at least 20 days following injection. Although gold is excreted primarily in the urine, the bulk of injected gold is retained. Gold can be found in the urine months later.

Drug Interactions

The only significant drug interactions reported are the concurrent administration of drugs that

also produce blood dyscrasias (most notably phenylbutazone and the antimalarial and immunosuppressive drugs).

Specific Drugs Gold Sodium Thiomalate

Gold sodium thiomalate (actually a mixture of mono- and disodium salts of gold thiomalic acid) is very water soluble. It is available as a light-sensitive, aqueous solution of pH 5.8 to 6.5. The gold content is approximately 50%. It is administered IM, because it is not absorbed on oral administration and is highly bound (95%) to plasma proteins.

Gold sodium thiomalate is indicated in the treatment of active adult and juvenile rheumatoid arthritis as one part of a complete therapy program. It is recommended that injections be given to patients only when they are in a supine position. They must remain so for 10 minutes following injection.

Aurothioglucose

Aurothioglucose is highly water soluble, and its aqueous solutions decompose on long standing. It therefore is available as a suspension in sesame oil. Gold content is approximately 50%. Following IM injection, it is highly protein bound (95%), and peak plasma levels are achieved within 2 to 6 hours. Following a single 50-mg dose, the biological half-life ranges from 3 to 27 days, but following successive weekly doses, the half-life increases to 14 to 40 days after the third dose. The therapeutic effect does not correlate with serum plasma gold levels but appears to depend on total accumulated gold. Aurothioglucose is indicated for the adjunctive treatment of adult and juvenile rheumatoid arthritis.

Auranofin

Auranofin contains approximately 29% gold. The carbohydrate portion assumes a chair conformation, with all substituents occupying the equatorial position. It is the first orally effective gold compound used to treat rheumatoid arthritis. On a mg gold/kg basis, it is reported to be as effective in the rat adjuvant arthritis assay as the parenterally effective drugs. Daily oral doses produce a rapid increase in kidney and blood gold levels for the first 3 days of treatment, with a more gradual increase on subsequent administration. Plasma gold levels are lower than those attained with parenteral gold compounds. The major route of excretion is via the urine. Auranofin may produce fewer adverse reactions than parenteral gold compounds, but its therapeutic efficacy also may be less.

Auranofin is indicated in adults with active rheumatoid arthritis who have not responded sufficiently to one or more NSAIDs.

Aminoquinolines

Background

The 4-aminoquinoline class of antimalarial drugs has been known to possess pharmacological actions that are beneficial in the treatment of rheumatoid arthritis. Two of these drugs, chloroquine and hydroxychloroquine (Fig. 36.27), have been used as antirheumatics since the early 1950s. The corneal and renal toxicity of chloroquine, however, has resulted in its discontinuance for this purpose, although it is still indicated as an antimalarial agent and an amebicide. Whereas hydroxychloroquine is less toxic, it also is less effective than chloroquine as an antirheumatic. The mechanism of action of these drugs as an antirheumatic remains unresolved. Interestingly, most

of the data available relates to chloroquine rather than hydroxychloroquine but is assumed to be applicable to the latter. The spectrum of action of the 4-aminoquinolines differs from the NSAIDs in that chloroquine appears to be an antagonist of certain preformed prostaglandins. This effect, however, would indicate an acute, rather than a chronic, antirheumatic effect, whereas chloroquine has been shown to be similar to gold compounds in that it possesses a slow onset of action. Beneficial effects are noted only after 1 to 2 months of administration. Chloroquine inhibits chemotaxis of polymorphonuclear leukocytes in vitro but not in vivo. Its effects on collagen metabolism in connective tissue also are unclear. The most widely accepted mechanism of action of chloroquine and, presumably, of hydroxychloroquine is related to its ability to accumulate in lysosomes. Although evidence indicating stabilization of lysosomal membranes is not convincing, it may inhibit the activity of certain lysosomal enzymes, such as cartilage chondromucoprotease and cartilage cathepsin B. There does not appear to be a correlation of the antirheumatic effects of the 4-aminoquinolines with their antimalarial activity.

Hydroxychloroquine sulfate

Hydroxychloroquine sulfate is highly water soluble and exists in two different forms of different melting points. It is readily absorbed on oral administration, reaching peak plasma levels within 1 to 3 hours. It concentrates in organs such as the liver, spleen, kidneys, heart, lung, and brain, thereby prolonging elimination. Hydroxychloroquine is metabolized by N-dealkylation of the tertiary amines, followed by oxidative deamination of the resulting primary amine to the carboxylic acid derivative. In addition to possessing corneal and renal toxicity, hydroxychloroquine also may cause CNS, neuromuscular, GI, and hematological side effects. Hydroxychloroquine sulfate is indicated for the treatment of rheumatoid arthritis, lupus erythematosus, and malaria.

Immunosuppressants

The discovery of drugs that modify the immune response, whether as immunoregulatory, immunostimulatory, or immunosuppressive agents, has been the focus of much recent research activity. Several substances that suppress the immune system have been explored as antirheumatic drugs, because the etiology of rheumatoid arthritis may involve a destructive immune response (3,4). Thus, unlike drugs previously discussed, immunosuppressive drugs may act at the steps involved in the pathogenesis of the inflammatory disorders. As a group, however, these drugs are cytotoxic, as evidenced

by the initial development of these drugs as anticancer agents. Among the more widely employed immunosuppressants are azathioprine, methotrexate, leflunomide, and cyclophosphamide. All of these drugs are quite toxic and, generally, are indicated for rheumatoid arthritis only in those patients with severe, active disease who have not responded to full-dose NSAID therapy and at least one DMARD and a corticosteroid. Interestingly, although aspirin and NSAIDs are effective in only one-third of children with juvenile arthritis, methotrexate, when given only once a week at low doses (<20 mg) to minimize side effects, is effective. Cyclosporine (Sandimmune) has been investigated in rheumatoid arthritis and appears to offer short-term benefits, although its toxic effects also limit its long-term use. Cyclosporine appears to inhibit the proliferation of T-helper/inducer lymphocytes, blocking the signaling pathway involved in the etiology of rheumatoid arthritis. The immunosupressants can have potentially serious side effects, such as increased susceptibility to infection.

Specific Drugs Leflunomide

Leflunomide is a DMARD with anti-inflammatory and immunosuppressive activity used for the management of rheumatoid arthritis. It retards structural damage associated with arthritis in adults who have moderate to severe active rheumatoid arthritis. Leflunomide also is being investigated for use in patients with solid tumors and organ transplant recipients.

Leflunomide is a pro-drug that is rapidly and almost completely metabolized (half-life, <60 minutes) following oral administration to teriflunomide, the pharmacologically active α-cyanoenol metabolite (Fig. 36.28). The C_3-H of the isoxazole ring is essential for the ring opening to its active metabolite. The reaction is similar to CYP1A2-catalyzed dehydration of aldoximes. The exact mechanism of action of leflunomide in the management of rheumatoid arthritis has not been fully elucidated but appears to principally involve inhibition of B-lymphocyte (B-cell) proliferation, reducing antibody formation. Activated lymphocytes must proliferate and synthesize large quantities of cytokines, requiring increased de novo synthesis of uridine monophosphate (UMP) and other pyrimidine nucleotides for its cell life cycle. Therefore, any substance that reduces the intracellular concentration of pyrimidine nucleotides will affect the growth of these activated cells.

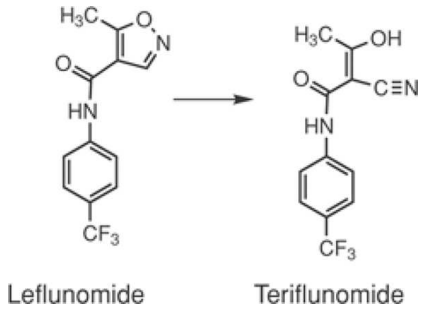

Fig. 36.28. Metabolism of leflunomide.

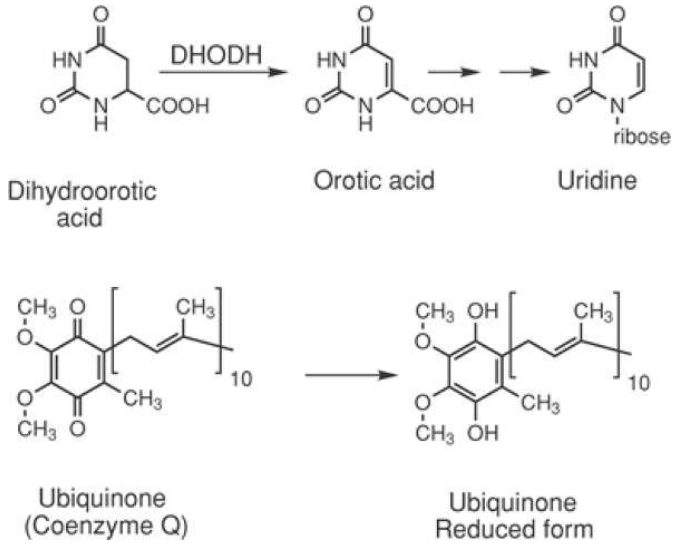

Fig. 36.29. Dihydroorotate dehydrogenase (DHOH) pathway with cofactor, coenzyme Q.

Leflunomide is inactive, but teriflunomide inhibits pyrimidine de novo synthesis at low therapeutic doses by inhibiting dihydroorotate dehydrogenase (the rate-determining enzyme for the synthesis of UMP), decreasing DNA and RNA synthesis, and arresting the cell proliferation cycle and production of antibodies. The reduction of dihydroorotate to orotate occurs concurrently with the reduction of its cofactor, ubiquinone (coenzyme Q) (Fig. 36.29). The inhibition of dihydroorotate dehydrogenase by teriflunomide demonstrates noncompetitive and uncompetitive kinetics. Administration of leflunomide in patients with rheumatoid arthritis results in progressive removal of B cells and down-regulation of the immune process. Teriflunomide not only inhibits B-cell proliferation but also T-cell proliferation, blocking the synthesis of immunosuppressive cytokines. At high therapeutic doses, leflunomide inhibits protein tyrosine kinases.

Leflunomide is administered orally as a single daily dose without regard to meals. Therapy may be initiated with a loading dosage given for 3 days, followed by the usual maintenance dose. It undergoes primarily enterohepatic circulation, extending its duration of action. Cholestyramine can be used to enhance its elimination in cases of toxicity.

Methotrexate

Methotrexate (Fig. 36.27) is an antifolate drug approved for the treatment of severe active rheumatoid arthritis in

adults who are intolerant to or have had an insufficient response to first-line therapy. Although the mechanism of action of methotrexate in rheumatoid arthritis is unknown, recent studies have shown that methotrexate reversibly inhibits dihydrofolate reductase, blocking the proliferation of B cells by interfering with DNA synthesis, repair, and replication. Oral absorption is dose-dependent, being well-absorbed at doses of 7.5–25 mg once a week. At this dose, oral bioavailability is approximately 60%, and food can delay absorption and reduce peak concentration. The volume of distribution is 0.4 to 0.8 L/kg. Protein binding is approximately 50%. It is metabolized to active metabolites, methotrexate

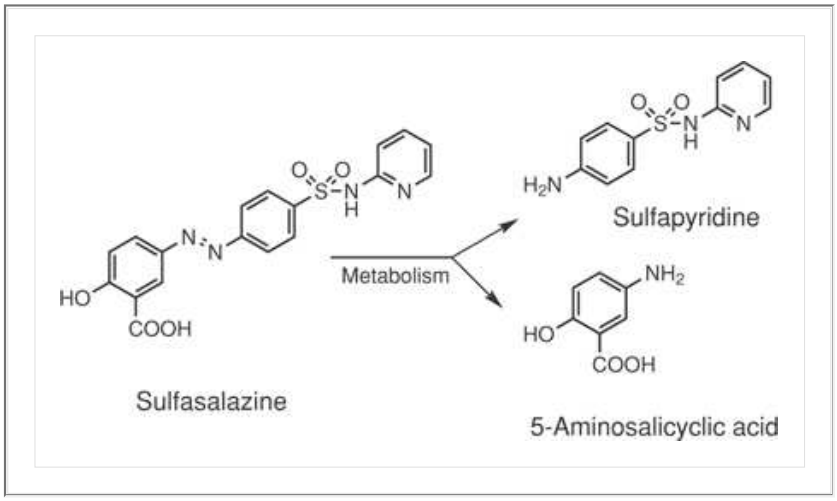
polyglutamates and 7-hydroxymethotrexate. Some metabolism occurs by intestinal flora after oral administration. Methotrexate is actively transported into the urine (80–90% unchanged in the urine within 24 hours) via the folate transporter, an organic anion transporter. Its elimination half-life is 3 to 10 hours.

Life-threatening drug interactions are known to occur between methotrexate and NSAIDs, probenecid, and penicillin G. The NSAIDs (salicylate, ibuprofen, ketoprofen, piroxicam, and indomethacin), probenecid, and penicillin G dose dependently inhibited methotrexate elimination into urine by human organic anion transporters (hOAT1, hOAT3, and hOAT4). The inhibitory effects of these drugs on hOAT3 were comparable, with therapeutically relevant plasma concentrations of unbound drugs. Thus, patients with rheumatoid arthritis should not take NSAIDs while taking methotrexate.

Methotrexate therapy requires monitoring of liver enzymes and is contraindicated in those with hepatic disease and in women considering pregnancy.

Sulfasalazine (Azulfidine)

Sulfasalazine is a pro-drug that is not active in its ingested form. It is broken down by colonic bacteria into 5-aminosalicylic acid (5-ASA; mesalamine) and sulfapyridine. Some controversy exists regarding which of these two products are responsible for the activity of azulfidine. 5-Aminosalicylic acid, however, is known to have a therapeutic benefit, although it is not clear whether sulfapyridine adds any further benefit. In the colon, the products created by the breakdown of sulfasalazine work as anti-inflammatory agents for treating colon inflammation. The beneficial effect of sulfasalazine is believed to result from a local effect on the bowel, although there also may be a beneficial systemic immune-suppressant effect. Sulfasalazine was approved in 1950.



Following oral administration, sulfasalazine is poorly absorbed, with approximately 20% of the ingested sulfasalazine reaching the systemic circulation. The remainder of the ingested dose is metabolized by colonic bacteria into its components, sulfapyridine and mesalamine (5-ASA). Most of the sulfapyridine metabolized from sulfasalazine (60–80%) is absorbed in the colon following oral administration, and approximately 25% of the 5-ASA metabolized from sulfasalazine is absorbed in the colon. The apparent volume of distribution of sulfasalazine in eight healthy volunteers was 64 L/kg, and that of sulfapyridine was 0.4 to 1.2 L/kg. Protein binding is approximately 99% for sulfasalazine, approximately 50% for sulfapyridine, and approximately 43% for 5-ASA. The absorbed sulfapyridine is acetylated and hydroxylated in the liver, followed by conjugation with glucuronic acid and, for 5-ASA, acetylation in the intestinal mucosal wall and the liver. The elimination half-life is 5 to 10 hours for sulfasalazine and 6 to 14 hours for sulfapyridine, depending on acetylator status of the patient, and 0.6 to 1.4 hours for 5-ASA. Time to peak serum concentration is 1.5 to 6 hours for oral sulfasalazine and 9 to 24 hours for oral sulfapyridine; for enteric-coated tablets, time to peak serum concentration is 3 to 12 hours for sulfasalazine and 12 to 24 hours for sulfapyridine. Approximately 5% of sulfapyridine and approximately 67% of mesalamine are eliminated in the feces, and 75 to 91% of sulfasalazine and sulfapyridine metabolites are excreted in urine within 3 days, depending on the dosage form

used. 5-Aminosalicyclic acid is excreted in urine mostly in acetylated form.

Sulfasalazine is used for the treatment of mild to moderate ulcerative colitis; as adjunct therapy in the treatment of severe ulcerative colitis, for the treatment of Crohn's disease, and for the treatment of rheumatoid arthritis or ankylosing spondylitis. Contraindications include hypersensitivity to sulfa drugs, salicylates, intestinal or urinary obstruction, and porphyria.

Biological Disease-Modifying Antirheumatic Drugs

Cytokine inhibitors

Tumor Necrosis Factor Blockers

T lymphocytes (T cells), a type of white blood cell, are important cells of the immune system. Patients with rheumatoid arthritis have increased numbers of T cells within the inflamed joints. These T cells are “activated”—that is, they multiply and release chemicals (cytokines) that promote the destruction of tissues surrounding the joints and cause the signs and symptoms of rheumatoid arthritis (84).

As discussed earlier in this chapter (see also Chapter 6 for a detailed discussion of cytokines), there is considerable expression of the cytokines, interleukin (IL)-1, IL-6, and tumor necrosis factor (TNF) α by the rheumatoid synovium. TNFα is a proinflammatory cytokine (cell protein) that plays a major role in the pathological inflammatory process of rheumatoid arthritis. TNF is an important mediator of local inflammation, and the release of TNFα from T-cells produces increased vascular permeability, release of nitric oxide with vasodilation, local activation of vascular endothelium, increased expression of adhesion molecules on endothelial blood vessels, and increased platelet activation and adhesion. As TNFα builds up in the joints, it leads to joint inflammation, which ultimately results in joint destruction. Because of its role in the progression of rheumatoid arthritis, methods for rendering TNFα inactive has

become a key focus of therapies for rheumatoid arthritis (84). Patients with rheumatoid arthritis display elevated levels of the cytokines, TNFα, IL-1, and IL-6 in synovial fluid and tissue, and there appears to be a correlation between the amount of these products present and the severity of the disease. A significant advance in the treatment of arthritic diseases was the observation that therapy directed toward diminishing the effects of TNFα appeared to also improve the symptoms of ankylosing spondylitis and psoriatic arthritis.

Two different approaches have been developed to decrease TNF activity that has resulted in marketable drugs: administration of soluble TNF receptors (TNFRs; etanercept), and treatment with anti-TNFα antibodies (e.g., infliximab, adsalimumab). These compounds are designed to target and neutralize the effects of TNF, helping to reduce pain, morning stiffness, and tender or swollen joints, usually within 1 or 2 weeks after treatment begins. Evidence suggests that TNF blockers also may halt the progression of the disease. These medications work synergistically with methotrexate and therefore are often taken with methotrexate. The TNF blockers approved for treatment of rheumatoid arthritis are etanercept, infliximab, adalimumab, and rituximab. Potential side effects include injection site irritation (adalimumab and etanercept), worsening congestive heart failure (infliximab), blood disorders, lymphoma, demyelinating diseases, and increased risk of infection. These drugs should not be taken if an active infection is present. Effectiveness is lost if the drugs are discontinued.

Because TNF also is important for host defense against infections, the effects of long-term use on toxicity require further study. Substantial improvements in the course of the disease have been noted with both therapeutic approaches.

Etanercept (Enbrel)

Etanercept (Fig. 36.30) is produced by recombinant DNA technology in a Chinese hamster ovary mammalian cell line and is the first biotechnology-derived drug to be introduced for the reduction of the signs and symptoms of moderately to severely active rheumatoid arthritis in patients who have not adequately responded to one or more of the synthetic DMARDs. It is a dimeric soluble form of the p75 TNFR capable of binding to two TNF molecules in the circulation. It consists of the extracellular ligand binding portion of the 75-kDa human TNFR fused to the Fc portion of human IgG1 (Fig. 36.30). The Fc component of etanercept contains the C_H2 domain, the C_H3 domain, and the hinge region, but not the C_H1 domain of IgG1. It consists of 934 amino acids and has an apparent molecular weight of approximately 150 kDa. Two TNFRs have been identified, a 75-kDa protein and a 55-kDa protein, that occur as monomeric molecules on cell surfaces and soluble forms in the blood. The biological activity of TNF requires its binding to either of the two cell surface TNFRs. Etanercept can bind specifically to two molecules of TNFα in the circulation, preventing its interaction with cell surface TNFRs. It can be used as monotherapy or in combination with methotrexate. Some concern exists because of reports that etanercept may, in some cases, cause serious infections and may have contributed to the deaths of several patients using the drug. An excellent review of the properties and

use of etanercept has recently appeared (6,85). Etanercept also binds TNFβ.

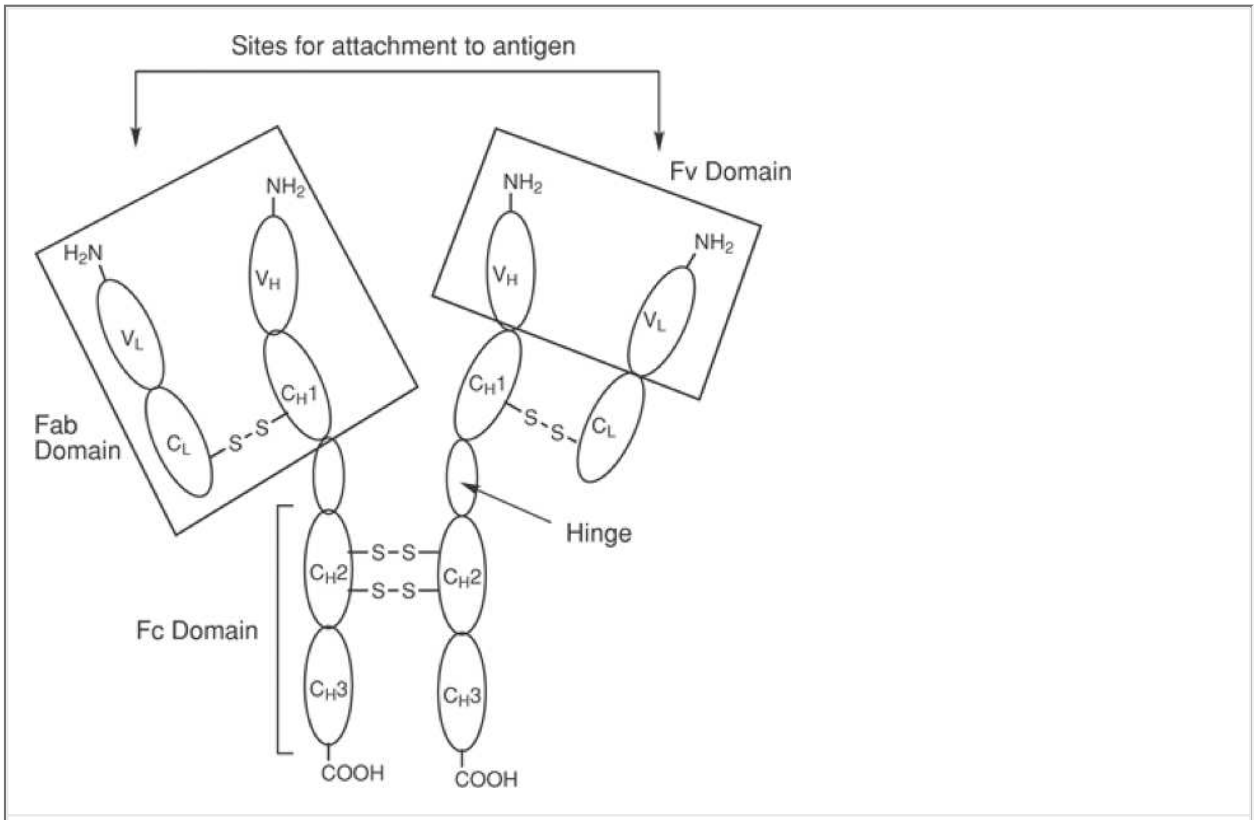


Fig. 36.30. Anti–tumor necrosis factor (TNF) agents. Etanercept is the extracellular portion of the human TNFR fused to the Fc domain of human immunoglobulin Ig G1. Infliximab is a partially humanized monoclonal antibody against TNFα. The Fv domains are derived from mouse antihuman sequences, whereas the Fc domain is composed of human IgG1 sequences. Adalimumab is fully humanized antibody to human TNFα (Fv and Fc derived from human sequences). Rituxan is a partially humanized monoclonal antibody against CD40. The Fv domains are derived from mouse antihuman sequences, and the Fc domain is composed of human IgG1 sequences.

Etanercept is available as a powder for injection in single-use vials containing 25 mg of the drug. The reconstituted solution that is administered as a twice weekly subcutaneous injection should be clear and colorless.

Etanercept has been approved for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis; for reducing signs and symptoms in patients with active arthritis in patients with psoriatic arthritis; and for reducing signs and symptoms in patients with active ankylosing spondylitis.

Infliximab (Remicade)

Infliximab is a chimeric (“humanized”) IgG1κ monoclonal antibody to human TNFα (see Chapter 6 for detailed discussions for monoclonal antibodies). By combining the Fv domain of the

mouse antibody responsible for recognizing TNFα with parts of the human Fc domain of IgG1 (IgG1κ), the fused protein looks more like normal human IgG1 molecule (“humanized”), so there is a better chance the fused protein will not be destroyed by the patient's own immune system. Infliximab has an approximate molecular weight of 149,100 daltons and binds specifically, with high affinity, to both the transmembrane and soluble forms of TNFα in the blood, thus neutralizing its biological activity (Fig. 36.30). It does not bind to TNFβ (lymphotoxin A), a related cytokine that uses the same receptors as TNFα. Infliximab is produced by a recombinant cell line cultured by continuous perfusion and is purified by a series of steps that includes measures to inactivate and remove viruses. Cells expressing transmembrane TNFα bound by infliximab can be lysed. The TNFα antibodies decrease synovitis and joint erosions

in a murine model of collagen-induced arthritis and, when administered after disease onset, allows eroded joints to heal.

After treatment with infliximab, patients with rheumatoid arthritis or Crohn's disease exhibited reduced infiltration of inflammatory cells and TNFα production in inflamed tissues and decreased levels of serum IL-6 and C-reactive protein compared to baseline. In psoriatic arthritis, treatment with infliximab resulted in a reduction in the number of T cells and blood vessels in the synovium and psoriatic skin as well as a reduction of macrophages in the synovium. Single IV infusions showed a linear relationship between the dose administered and the maximum serum concentration. The volume of distribution at steady state was independent of dose and indicated that infliximab was distributed primarily within the vascular compartment. The terminal half-life of infliximab is 8.0 to 9.5 days. No systemic accumulation of infliximab occurred on continued repeated treatment at 4- or 8-week intervals.

Infliximab is supplied as a sterile, white, lyophilized powder formulated for IV infusion. Following reconstitution with Sterile Water for Injection, the solution should be used immediately after reconstitution, because the vials do not contain antibacterial preservatives. The reconstituted solution should be colorless to light yellow and opalescent.

Infliximab is indicated for the treatment of rheumatoid arthritis in combination with methotrexate and for Crohn's disease. Long-term use may be associated with the development of anti-infliximab antibodies, an effect that does not appear when it is used with methotrexate. Warnings associated with the use of infliximab include risks of autoimmunity, infections, and hypersensitivity reactions. An excellent review of the properties and use of infliximab has recently appeared (84). Infliximab is more specific than etanercept, because etanercept binds to both TNFα and TNFβ whereas infliximab is an antibody that binds only to TNFα. Infliximab possesses a longer half-life giving a dosing schedule of approximately every 6 to 8 weeks.

Infliximab, in combination with methotrexate, is indicated for reducing signs and symptoms, inhibiting the progression of structural damage, and improving physical function in patients with moderately to severely active rheumatoid arthritis; for reducing signs and symptoms and maintaining clinical remission in patients with moderately to severely active Crohn's disease who have had an inadequate response to conventional therapy; for reducing signs and symptoms in patients with active arthritis and in patients with psoriatic arthritis; and for reducing signs and symptoms in patients with active ankylosing spondylitis.

Adalimumab (Humira)

Adalimumab is a recombinant human IgG1 monoclonal antibody targeted for human TNFα. Adalimumab is produced by recombinant DNA technology in a mammalian cell expression system using a protein-engineering strategy for creating a TNFα antibody with human-derived, heavy- and light-chain variable regions (Fab) and human IgG1κ constant regions. It consists of 1,330 amino acids and has a molecular weight of approximately 148 kDa (Fig. 36.30). Adalimumab, as an antibody, works by targeting and binding TNFα, thus neutralizing the effect of TNFα and, thereby, reducing the symptoms of rheumatoid arthritis and slowing the progression of structural joint damage caused by the disease. Adalimumab does not bind or inactivate TNFβ.

Adalimumab is supplied in single-use, prefilled, glass syringes as a sterile, preservative-free, colorless solution for subcutaneous administration. The pharmacokinetics of adalimumab were linear over the dose range of 0.5 to 10.0 mg/kg following a single IV dose. The mean elimination half-life was approximately 2 weeks.

Rituximab (Rituxan)

Rituximab is a genetically engineered, fused mouse/human anti-CD40 monoclonal antibody that targets B lymphocytes by binding specifically to CD20 antigen, a protein found on the surface of B cells at certain stages in their life cycle. Rituximab is composed of two heavy chains of 451 amino acids and two light chains of 213 amino acids with an approximate molecular weight of 145 kDa (Fig. 36.30). Its binding affinity for the CD20 antigen is approximately 8.0 nM. The mouse light- and heavy-chain Fab domains of rituximab, which binds to the CD20 antigen on B cells, is linked to the human Fc domains of IgG1κ. Once the rituximab molecule attaches to the B cells, it initiates B-cell lysis, inducing rapid and profound depletion of peripheral B cells, with patients showing near complete B-cell depletion within 2 weeks after receiving the first dose of rituximab. Because rituximab does not target B cells at the earliest stages of their development, however, these B-cell depletions usually are temporary. In clinical trials, the majority of patients showed peripheral B-cell depletion for at least 6 months, followed by subsequent gradual recovery. A small proportion of patients (4%) had prolonged peripheral B-cell depletion lasting more than 3 years after a single course of treatment.

Rituximab is a sterile, clear, colorless, preservative-free, liquid concentrate formulated for IV administration. It has changed the treatment of rheumatoid arthritis by showing that targeted B-cell therapy in combination with methotrexate can reduce signs and symptoms of rheumatoid arthritis in adult patients with moderately to severely active rheumatoid arthritis who have had an inadequate response to one or more TNF antagonist therapies. Although

B cells once were considered to be one of the main contributing factors in the pathogenesis of rheumatoid arthritis, recent evidence has shown that T cells, dendritic cells, and macrophages also were involved. Rituximab has rekindled interest in B cells, highlighting their important role in perpetuating the inflammatory process and showing how they may interact with other cell types and contribute to joint inflammation.

For rheumatoid arthritis, rituximab is given as two 1,000-mg IV infusions separated by 2 weeks. Glucocorticoids also are recommended to reduce the incidence and severity of infusion reactions. Rituximab is given in combination with methotrexate. Its administration has been associated with hypersensitivity reactions (non-IgE-mediated reactions), which may respond to adjustments in the infusion rate and in medical management. People who have not found relief using TNF blockers might consider using rituximab. Side effects include flu-like signs and symptoms such as fever, chills, and nausea. Some people experience an “infusion-reaction complex,” such as difficulty breathing and heart problems, that has resulted in fatalities.

Although originally approved for use in people with non-Hodgkin's lymphoma, rituximab was approved for rheumatoid arthritis in 2006.

Interleukin-1 Receptor Antagonist Anakinra (Kineret)

Anakinra is a recombinant, nonglycosylated form of the human IL-1 receptor antagonist (IL-1Rα) that neutralizes the inflammatory activity of IL-1 by competing with IL-1 for binding to its IL-1 type 1 receptor (IL-1R1). Interleukin-1 is a cytokine for which production is induced in response to inflammatory stimuli and which mediates various physiologic responses, including inflammatory and immunological responses that promotes inflammation. When IL-1 binds to IL-1R1, a signal is produced that increases the formation of nitric oxide, prostaglandin E_2 and collagenase in synovial cells, resulting in cartilage degradation as well as stimulation of bone resorption. Thus, IL-1Rα plays an important role for regulating synovial proinflammatory IL-1 activity by preventing IL-1 from binding to IL-1R1. Analysis of synovial fluid suggests that the rheumatoid synovium is characterized by an overexpression of IL-1. The resulting imbalance between IL-1 and IL-1Rα has been implicated in perpetuating the pro-inflammatory response and destructive tide of events in rheumatoid arthritis. If IL-1 is prevented from binding to IL-1R1, the inflammatory response decreases. The levels of the naturally occurring IL-IRα in synovium and synovial fluid from rheumatoid arthritis patients are insufficient to compete with the elevated amount of locally produced IL-1.

Therefore, anakinra neutralizes the proinflammatory activity of IL-1 by competitively inhibiting the binding of IL-1 to IL-1RI, similar to the endogenous antagonist, IL-1Rα. In vitro studies have shown that anakinra inhibits the induction of the inflammatory mediators, nitric oxide and prostaglandin E_2, and collagenase. Anakinra differs from native human IL-1Rα in that it has the addition of a single methionine residue at its amino terminus. Anakinra consists of 153 amino acids and has a molecular weight of 17.3 kDa. It is produced by recombinant DNA technology using an *Escherichia coli* bacterial expression system.

Anakinra is the first IL-1Rα to be approved for use in adults with moderate to severe active rheumatoid arthritis who have not responded adequately to conventional DMARD therapy. It may be used either alone or in combination with methotrexate. Anakinra is supplied in single-use, prefilled, glass syringes as sterile, clear, preservative-free solution that is administered daily as a self-administered subcutaneous injection under the skin. Some potential side effects include injection site reactions, decreased white blood cell counts, headache, and an increase in upper respiratory infections. There may be a slightly higher rate of respiratory infections in people who have asthma or chronic obstructive pulmonary disease. Persons with an active infection are advised not to use anakinra. Its elimination half-life after sc administration is 4 to 6 hours.

Costimulation Modulators

Two signals are required to activate a T-cell response to an antigen, called costimulation. Regulation of costimulatory molecules may be a mechanism whereby the immune system limits the extent of an immune response. If an unactivated antigen-presenting cell (APC; a cell that “presents” an antigen complex that is recognized by the T-cell receptor) presents an antigen to a T cell in the absence of an appropriate costimulatory signal, the T cell does not respond and becomes unreactive and nonresponsive to any further antigenic stimuli (Fig. 36.31). The T-cell costimulatory activation pathway is initiated, however, when an activated APC presents both an antigen and a costimulatory ligand, such as B7 (CD86) that interacts with CD28 on the surface of the T cell to form B7-CD28 complex, initiating T-cell proliferation and differentiation in response to the antigenic stimulus. This stimulus releases cytokines that bind to the T cell, further enhancing its activation. A counterbalance to CD28 is cytotoxic T-lymphocyte antigen-4 (CTLA-4), both of which are expressed on the surface of T cells. The CTLA-4, which is homologous with CD28, becomes expressed on T-cell activation, where it then competes with CD28 for binding to B7 ligands on the surface of APCs. The B7 ligands bind with much greater affinity to CTLA-4 than to CD28, preventing delivery of the costimulatory signal. This built-in limit prevents T-cell activation

from spiraling out of control. The CTLA-4 is not expressed constitutively, and its expression is up-regulated on T-cell

activation. Eventually, however, CD28 is down-regulated.

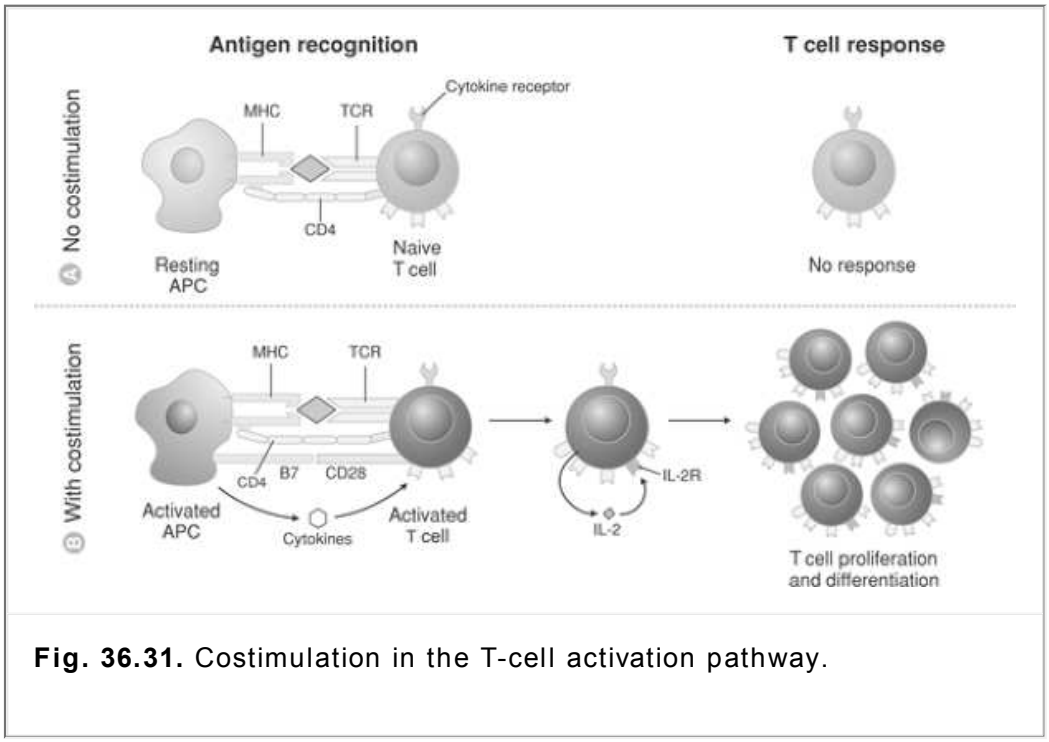

Fig. 36.31. Costimulation in the T-cell activation pathway.

Because the formation of a B7-CD28 complex between the APC and the T cell results in T-cell proliferation and the release of inflammatory cytokines, whereas the B7–CTLA-4 interaction inhibits the T-cell responses, the design of a pharmacological agent that prevents costimulation would preferentially inhibit only reactive T cells and be effective in treatment of rheumatoid arthritis. Thus, the discovery of abatacept.

Abatacept (Orencia)

Abatacept, the first in a new class of immunosuppressant agents, known as costimulation modulators, acts by down-regulating T-cell activation for the treatment of rheumatoid arthritis (86). Abatacept is a novel chimeric CTLA-4–IgG1 fused protein created from the fusion of the extracellular domain of the mouse CTLA-4 with the modified heavy-chain constant region of human IgG1.

Abatacept, therefore, acts like an antibody that binds with great affinity to B7 ligands, preventing these ligands from interacting with CD28 on activated T cells. In patients with rheumatoid arthritis, blocking this response by abatacept prevents the generation of positive costimulation signals and stimulation of T-cell activation, suppressing the proliferation of reactive T-cells and the release of more cytokines that destroy tissue, causing the symptoms and signs of arthritis. The extracellular CTLA-4 portion of abatacept is responsible for the affinity of B7. Thus, abatacept slows the damage to bones and cartilage and relieves the symptoms and signs of arthritis.

People with moderate to severe active rheumatoid arthritis who have not been helped by TNF blockers might consider abatacept, which is administered IV monthly. Side effects may include headache, nausea, and mild infections, such as upper respiratory tract infections. Serious infections, such as pneumonia, can occur. There is some concern that blocking of the suppressive signal from B7 to CTLA-4 may have a negative effect on regulatory T cells and, thus, eventually, promote autoimmunity.

Herbs

At least a dozen different herbs are used to ease the symptoms of rheumatoid arthritis; most are considered to be anti-inflammatories. Herbs that have been tried include powdered ginger, borage seed oil, or devil's claw to reduce pain and swelling. Stinging nettles or turmeric also may lessen pain, stiffness, and inflammation. Because these herbs can interact with each other or with prescription comedications, lack of careful studies means that little is known about long-term effects and drug interactions.

Ayurvedic medicine also uses herbal compounds both internally and externally for symptom relief. Topical curcumin may relieve the inflammation of rheumatoid arthritis. When taken in capsule form, it can reduce morning stiffness and boost endurance. A combination of *Withania somnifera*, *Boswellia serrata*, and *Cucurma longa* also caused a significant drop in pain and disability for study participants with osteoarthritis.

Two herbs that have been used for centuries to treat headaches, fever, sore muscles, and rheumatism are white willow bark and meadowsweet, commonly described as “Nature's aspirin.” White willow bark (*Salix alba*) contains salicin, a glycoside of salicylic acid. Once in the stomach, the salicin hydrolyzes into salicylic acid, which is the active principle for reducing pain and fever. White willow bark has been mentioned in ancient Egyptian, Assyrian, Greek, and Chinese manuscripts, and it was used to treat pain and fever by the ancient physicians Galen, Hippocrates, and Dioscorides. Native Americans used it for headaches, fever, sore muscles, rheumatism, and chills. In the mid-1700s, it was used to treat malaria. Salicin was isolated and identified in the early 1830s, but it was not conclusively shown to reduce the aches and soreness of rheumatism until 1874. White willow bark is recommended for headaches, backache, nerve pain, toothache, and injuries.

Meadowsweet (*Filipendula ulmaria*) is a common wild plant in Britain, Europe, and North America that also contains salicin, but it is not as potent as willow bark which has a higher salicin content. Its primary medicinal actions are antirheumatic, anti-inflammatory, carminative, antacid, antiemetic, astringent, and diuretic. The flower buds of meadowsweet are the source for salicin and methyl salicylate. Ingestion of the flower buds in a tea results in the breakdown of salicin to salicylic acid. Nicholas Culpeper, a seventeenth-century English pharmacist, mentioned the use of meadowsweet flower buds to help break fevers and promote sweating during a cold or flu.

Drugs Used to Treat Gout

Pathophysiology

Gout is an inflammatory disease characterized by elevated levels of uric acid (as urate ion) in the plasma and urine and may take two forms, acute and chronic. Acute gouty arthritis results from the accumulation of needle-like crystals of monosodium urate monohydrate within the joints, synovial fluid, and periarticular tissue and usually appears without warning. Initiating factors may be minor trauma, fatigue, emotional stress, infection, overindulgence in alcohol or food, or drugs, such as penicillin or insulin. Chronic gout symptoms develop as permanent erosive joint deformity appears. The increase in extracellular urate may result from increased uric acid biosynthesis, decreased urinary excretion of uric acid, or perhaps, a combination of both. The formation of uric acid from adenine and guanine is illustrated in Figure 36.32. Uric acid is formed by the oxidation of xanthine by the enzyme xanthine oxidase. Xanthine is a metabolic product of adenine (via hypoxanthine) and guanine formed by the enzymes adenine deaminase and guanine deaminase, respectively. Thus, uric acid is the excretory product of purine metabolism in humans as well as the scavenging of potential harmful oxygen free radicals in the body. In other mammals, uric acid is hydrolyzed to allantoin by the enzyme uricase, which is then subsequently hydrolyzed by allantoinase to allantoic acid. Hydrolysis of allantoic acid by allantoicase yields the final products, urea and glyoxylic acid.

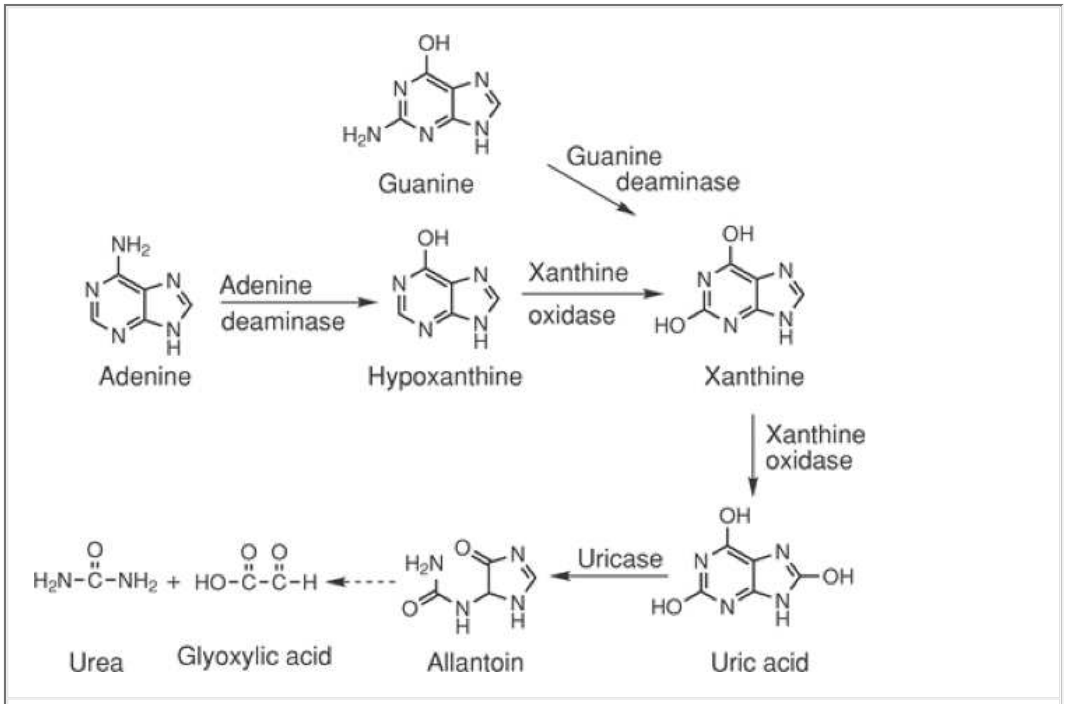

Fig. 36.32. Formation of uric acid, urea, and glyoxylic acid from purines.

Normal pool levels of uric acid are approximately 1,000 to 1,200 mg in males and half that in females. In patients suffering from gout, these levels may be as high as two- or three times the normal levels. Uric acid is a weak acid with two pK_a values 5.7 and 10.3, with very low water solubility (~6 mg/100 mL). At physiological pH, it exists primarily as the monosodium salt, which is approximately 50 times more soluble in aqueous media than the free acid. Blood levels of urate are maintained by a careful balance between its formation and excretion. The kidney plays a dominant role in urate elimination, excreting about 70% of the daily urate production. The excretion of urate has been implicated in the development of hyperuricemia that leads to gout. In humans, the excretion of urate requires the urate anion transporter (URAT1) located in renal proximal tubule cells, which plays a central role in urate homeostasis. The URAT1 is targeted by uricosuric and antiuricosuric agents that affect urate excretion.

When levels of uric acid in the body increase, either as a result of decreased excretion or increased formation, the solubility limits of sodium urate are exceeded, and precipitation of the salt from the resulting supersaturated solution causes deposits of urate crystals to form. It is the formation of these urate crystals in joints and connective tissue that initiate attacks of gouty arthritis. The control of gout has been approached from the following therapeutic strategies: 1) control of acute attacks by drugs that reduce inflammation caused by the deposition of urate crystals (these drugs may possess only an anti-inflammatory component, such as colchicine, or both anti-inflammatory and analgetic actions, such as indomethacin, phenylbutazone and naproxen), 2) increasing the rate of uric acid excretion (by definition, these drugs are termed “uricosuric drugs” and include probenecid and sulfinpyrazone), and 3) inhibiting the biosynthesis of uric acid by inhibiting the enzyme xanthine oxidase by drugs such as allopurinol.

Treatment of Acute Gout

The management of gout has been approached with the following therapeutic strategies: 1) control of acute attacks with drugs that reduce inflammation caused by the deposition of urate crystals, and 2) control of chronic gout by increasing the rate of uric acid excretion (“uricosuric drugs”) and inhibiting the biosynthesis of uric acid by inhibiting the enzyme xanthine oxidase. Treatment of acute gout includes NSAIDs, such as indomethacin, colchicines, and glucocorticoids. The choice of an NSAID generally is based on the side effect profile.

Colchicine

Colchicine is a pale-yellow powder that is obtained from various species of *Colchicum*, primarily *Colchicum autumnale*

L. Its total chemical synthesis has been achieved, but the primary source of colchicine currently remains alcohol extraction of the alkaloid from the corm and seed of *C. autumnale* L. It darkens on exposure to light and possesses

moderate water solubility. Colchicine has a pK_a of 12.4. Its use in the treatment of gout dates back to the sixth century AD. Unlike those drugs that will be discussed next, colchicine does not alter serum levels of uric acid. It does, however, appear to retard the inflammation process initiated by the deposition of urate crystals. Acting on polymorphonuclear leukocytes and diminishing phagocytosis, it inhibits the production of lactic acid, causing an increase in the pH of synovial tissue and, thus, a decrease in urate deposition, because uric acid is more soluble at the higher pH. Additionally, colchicine inhibits the release of lysosomal enzymes during phagocytosis that also contributes to the reduction of inflammation. Because colchicine does not lower serum urate levels, it has been found to be beneficial to combine colchicine with a uricosuric agent, particularly probenecid. It is a potent drug, being effective at doses of approximately 1 mg, but doses as small as 7 mg have caused fatalities.

Absorption and metabolism

Colchicine is absorbed on oral administration, with peak plasma levels being attained within 0.5 to 2 hours after dosing. Plasma protein binding is only 31%. It concentrates primarily in the intestinal tract, liver, kidney, and spleen and is excreted primarily in the feces, with only 20% of an oral dose being excreted in the urine. It is retained in the body for considerable periods of time, being detected in the urine and leukocytes for 9 to 10 days following a single dose. Metabolism occurs primarily in the liver, with the major metabolite being the amine resulting from amide hydrolysis.

Side effects

Colchicine may produce bone marrow depression, with long-term therapy resulting in thrombocytopenia or aplastic anemia. At maximum dose levels, GI disturbances (e.g., nausea, diarrhea, and abdominal pain) may occur. Acute toxicity is characterized by GI distress, including severe diarrhea resulting in excessive fluid loss, respiratory depression, and kidney damage. Treatment normally involves measures that prevent shock as well as morphine and atropine to diminish abdominal pain. A number of drug interactions have been reported. In general, the actions of colchicine are potentiated by alkalinizing substances and are inhibited by acidifying drugs, consistent with its mechanism of action of increasing the pH of synovial fluid. Responses to CNS depressants and to sympathomimetic drugs appear to be enhanced. Clinical tests may be affected; most notably, elevated alkaline phosphatase and SGOT (serum glutamate oxaloacetate transaminase) values and decreased thrombocyte values may be obtained.

Dosing

Colchicine is indicated for the treatment of acute attacks of gout and is very effective. The usual dose is 1.0 to 1.2 mg, followed by 0.5 to 1.2 mg every 1 to 2 hours until either pain relief is observed or symptoms of GI distress are observed. When a rapid response is required, or if GI reactions warrant discontinuance of oral administration, IV administration (usually 2 mg initially) may be indicated. It is available as 0.5- or 0.6-mg tablets and as an injectable solution of 1 mg in 2-mL ampoules. It often is given in combination with probenecid, and combination products of the two are available in tablets containing 500 mg of probenecid and 0.5 mg of colchicine.

Treatment of Chronic Gout

Drugs That Increase Uric Acid Secretion

Probenecid

Probenecid is insoluble in water and acidic solutions but is soluble in alkaline solutions buffered to pH 7.4. Probenecid initially was synthesized as a result of studies in the 1940s on sulfonamides that indicated the sulfonamides decreased the renal clearance of penicillin, extending the half-life of penicillin as supplies diminished. Probenecid thus was initially used—and is still indicated—for that purpose. Probenecid promotes the excretion of uric acid by inhibiting the urate anion exchange transporter (URAT1), decreasing the reabsorption of uric acid in the proximal tubules. The overall effect is to decrease plasma uric acid concentrations, thereby decreasing the rate and extent of urate crystal deposition in joints and synovial fluids. Within the series of N-dialkylsulfamyl benzoates from which probenecid is derived, renal clearance of these compounds is decreased as the length of the N-alkyl substituents is increased. Uricosuric activity increases with increasing size of the alkyl group in the series methyl, ethyl, and propyl.

Probenecid is essentially completely absorbed from the GI tract on oral administration, with peak plasma levels observed within 2 to 4 hours. Like most acidic compounds, probenecid (pK_a = 3.4) is extensively plasma protein bound (93–99%). The primary route of elimination of probenecid and its metabolites is the urine. It is extensively metabolized in humans, with only 5 to 10% being excreted as unchanged drug. The major metabolites detected result from glucuronide conjugation of the carboxylic acid, ω-oxidation of the n-propyl side chain and subsequent oxidation of the resulting alcohol to the carboxylic acid derivative, ω_1-oxidation of the n-propyl group, and N-dealkylation.

Those metabolites possessing a free carboxylic acid function generally possess some uricosuric activity. Probenecid appears to be generally well tolerated, with few adverse reactions. The major side effect is GI distress (e.g., nausea, vomiting, and anorexia), but these occur in only 2% of patients at low doses. Other effects include headache, dizziness, urinary frequency, hypersensitivity reactions, sore gums, and anemia. Overdosages do not appear to present major difficulties; a case of a 49-year-old man who recovered from the ingestion of 47 g in a suicide attempt has been reported. Should overdosage occur, treatment consists of emesis or gastric lavage, short-acting barbiturates (if CNS excitation occurs), and epinephrine (for anaphylactic reactions). A number of drug interactions have been reported. Despite

the high degree of plasma protein binding, displacement interactions with other drugs bound to plasma proteins does not appear to occur to any significant extent. Salicylates counteract the uricosuric effects of probenecid. Because probenecid inhibits their renal excretion, increased plasma levels of the following drugs may be observed: aminosalicylic acid, methotrexate, sulfonamides, dapsone, sulfonylureas, naproxen, indomethacin, rifampin, and sulfinpyrazone. (The effects on penicillin plasma levels were discussed previously.)

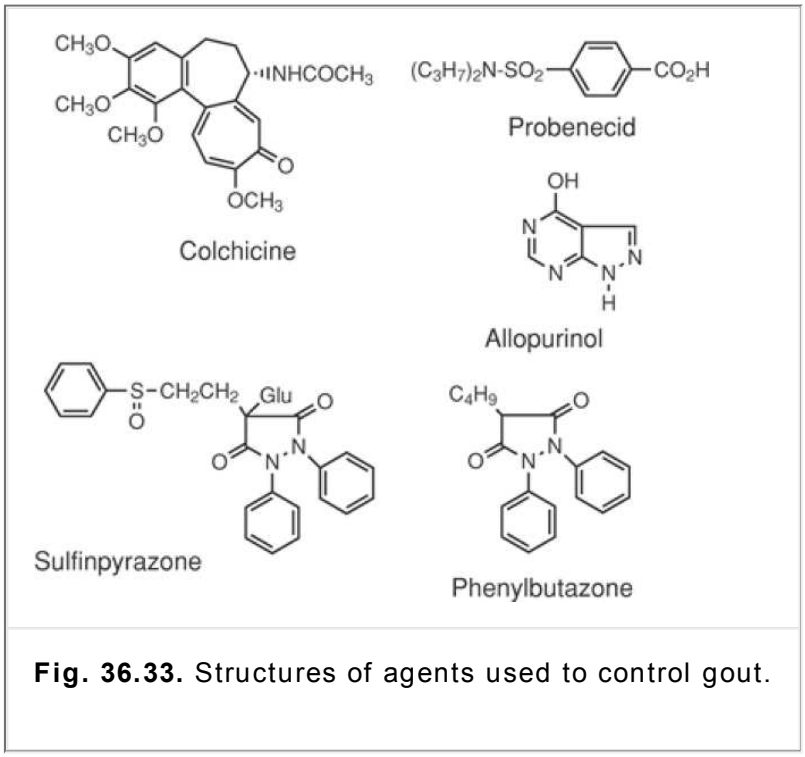

Fig. 36.33. Structures of agents used to control gout.

Probenecid is indicated for the treatment of hyperuricemia associated with gout and gouty arthritis and for the elevation and prolongation of plasma levels of penicillins and cephalosporins. In gout, treatment should not begin until an acute attack has subsided. It is not recommended in individuals with known uric acid kidney stones or blood dyscrasias or for children under 2 years of age.

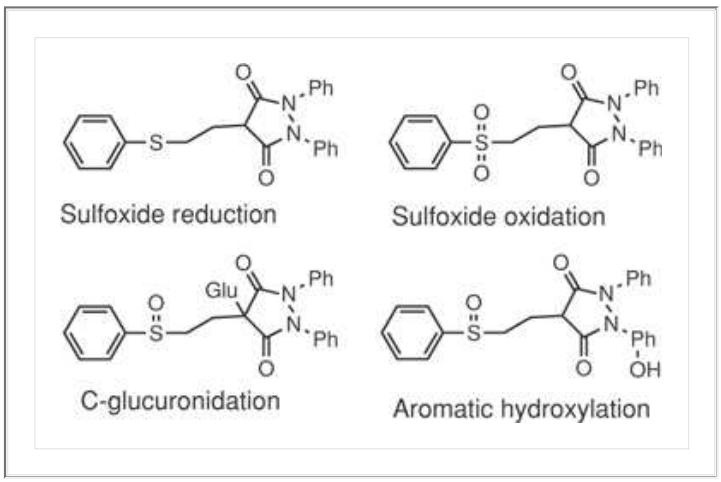
Sulfinpyrazone

Sulfinpyrazone (Fig. 36.33) is soluble in alkaline solutions. Its synthesis is similar to that of phenylbutazone (87) (Fig. 36.33). It produces its uricosuric effect in a manner similar to that of probenecid. A dose of 35 mg produces a uricosuric effect equivalent to that produced by 100 mg of probenecid, whereas 400 mg/day of sulfinpyrazone produces an effect comparable to that obtained with doses of 1.5 to 2 g of probenecid. It also possesses, not surprisingly, some of the properties of phenylbutazone. It is an inhibitor of human platelet prostaglandin synthesis at the cyclooxygenase step, resulting in a decrease in platelet release and a reduction in platelet aggregation. This antiplatelet effect suggests a role for sulfinpyrazone in reducing the incidence of sudden death, which can occur in the first year following a myocardial infarction; however, it lacks the analgetic and anti-inflammatory effects of phenylbutazone.

Sulfinpyrazone is a strong acid (enolic OH pK_a = 2.8), a factor that is important in the production of the uricosuric effect, because within a series of pyrazolidinedione derivatives, the stronger the acid, the more potent the uricosuric effect. Polar substitution on the side chain also influences uricosuric activity, as discussed previously with regard to the pyrazolidinediones.

Oral administration results in rapid and essentially complete absorption, with peak plasma levels being attained

within 1 to 2 hours of administration. It is highly bound (98–99%) to plasma proteins, and it is excreted in the urine primarily (50%) as unchanged drug.



The metabolites produced result from sulfoxide reduction, sulfur and aromatic oxidation, and C-glucuronidation of the heterocyclic ring in a manner similar to that for phenylbutazone. The metabolite resulting from *p*-hydroxylation of the aromatic ring possesses uricosuric effects in humans. The sulfide metabolite, a major metabolic product, may contribute to the antiplatelet effects of sulfinpyrazone but not to the uricosuric effects. The most frequent adverse reactions are GI disturbances; however, the incidence is relatively low. It has been suggested that sulfinpyrazone is a much weaker inhibitor of prostaglandin synthesis in bovine stomach microsomes than either aspirin or indomethacin, a factor that may account for its gastric tolerance. Much rarer have been reports of blood dyscrasias and rash. Overdosage produces symptoms that are primarily GI in nature (e.g., nausea, diarrhea, and vomiting) but also may involve impaired respiration and convulsions. Treatment consists of emesis or gastric lavage and supportive care. Like probenecid, its uricosuric effects are antagonized by salicylates, and probenecid markedly inhibits the renal tubular secretion of sulfinpyrazone. It potentiates the actions of other drugs that are highly plasma protein bound, such as coumarin-type oral anticoagulants, antibacterial sulfonamides, and hypoglycemic sulfonylureas.

Sulfinpyrazone is indicated for the treatment of chronic and intermittent gouty arthritis.

Drugs That Decrease Uric Acid Formation

Allopurinol

Mechanism of Action

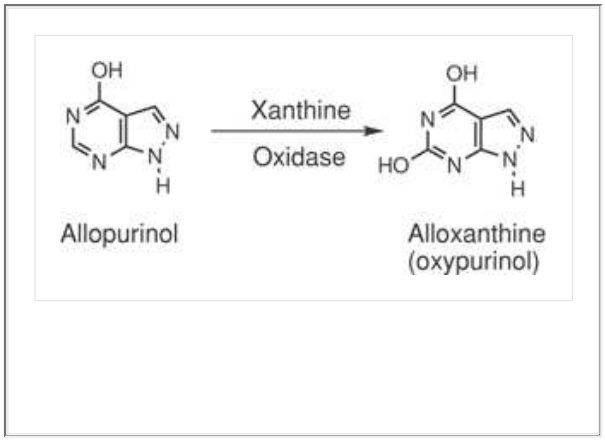
The biosynthesis of uric acid from the immediate purine precursor xanthine that results from adenine, via the intermediate hypoxanthine, or from guanine is illustrated in Figure 36.32. The enzyme xanthine oxidase (a molybdenum hydroxylase enzyme) is involved in two steps, the conversion of hypoxanthine to xanthine, and the final step, the conversion of xanthine to uric acid. Allopurinol originally was designed

as an antineoplastic antimetabolite to antagonize the actions of key purines inasmuch as it differs from normal purines only by the inversion of the nitrogen and carbon atoms at the 7- and 8-positions of the purine ring system but was found to have little or no effect on experimental tissues. It was subsequently found that allopurinol serves as a substrate for xanthine oxidase (15 to 20 times the affinity of xanthine) and reversibly inhibits that enzyme. Normally, uric acid is a major metabolic end product in humans. When allopurinol is administered, however, xanthine and hypoxanthine are elevated in the urine, and uric acid levels decrease. When the synthesis of uric acid is inhibited, plasma urate levels decrease, supersaturated solutions of urate are no longer present, and urate crystal deposits dissolve, eliminating the primary cause of gout. The increased plasma levels of hypoxanthine and xanthine pose no real problem, because they are more soluble than uric acid and are readily excreted.

Absorption and Metabolism

Allopurinol was synthesized in 1956 as part of a study of purine antagonists (88). It is well absorbed on oral administration, with peak plasma concentrations appearing within 1 hour. Decreases of uric acid can be observed within 24 to 48 hours. Excretion of allopurinol and its metabolite occurs primarily in the urine, with approximately 20% of a dose being excreted in the feces. Allopurinol is rapidly metabolized via oxidation and the formation of numerous

ribonucleoside derivatives. The major oxidation metabolite, alloxanthine or oxypurinol, has a much longer half-life (18–30 hours versus 2–3 hours) than the parent drug and is an effective, although less potent, inhibitor of xanthine oxidase. The longer plasma half-life of alloxanthine results in an accumulation in the body during chronic administration, thus contributing significantly to the overall therapeutic effects of allopurinol. The major adverse effects are primarily dermatological in nature (e.g., skin rash and exfoliative lesions). Other effects, such as GI distress (e.g., nausea, vomiting, and diarrhea), hematopoietic effects (e.g., aplastic anemia, bone marrow depression, and transient leukopenia), neurological disorders (e.g., headache, neuritis, and dizziness), and ophthalmological effects (e.g., cataracts) are less commonly encountered. Allopurinol also may initiate attacks of acute gouty arthritis during the early stages of therapy and may require the concomitant administration of colchicine. Drug interactions include those drugs that normally also are metabolized by xanthine oxidase. For example, the oxidation of 6-mercaptopurine, a useful antineoplastic agent, is inhibiting, permitting a reduction in the therapeutic dose. Allopurinol also has an inhibitory effect on liver microsomal enzymes, thus prolonging the half-lives of drugs, such as oral anticoagulants, that normally are metabolized and inactivated by these enzymes, although this effect is quite variable. The incidence of ampicillin-related skin rashes increases with the concurrent administration of allopurinol.



Allopurinol is indicated for the treatment of primary and secondary gout, for malignancies such as leukemia and lymphoma, and for the treatment of patients with recurrent calcium oxalate calculi.

Case Study

Victoria F. Roche

S. William Zito

PR is a 15-year-old female gymnast who has just been named to the U.S. Olympic Team after months of grueling and highly competitive trials. Her specialty events are the uneven parallel bars and the “horse,” but she has performed well enough on all events to earn this coveted spot on the team. She is ecstatic but understandably nervous, because she is, by nature, a private person and the media spotlight has been intense since the announcement.

PR has consulted the team physician about dysmenorrhea that has become increasingly worse over the past 6 months. The cramping is now almost incapacitating for 2 to 3 days out of each period, and it has been interfering with her training. She knows just when the “big pain” will start, because PMS symptoms routinely begin 36 hours before the onset of bleeding. She has looked ahead, and if her cycles remain regular, she is due to have her period during the week of the summer Olympic games. From her medication history, the MD can see that PR takes OTC chlorpheniramine maleate (Chlortrimeton) fairly frequently for seasonal and pet-related allergies. Despite her young age, she has complained of a “nervous stomach,” which has prompted her to try Prilosec OTC (omeprazole), especially before competitions when her emotions and GI distress are heightened. PR speaks of her very jam-packed schedule of school and training, and she asks for once-daily therapy to treat her menstruation-related pain if possible. As the pharmacist for the team, consider the following NSAID therapeutic choices, and prepare to make a recommendation.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and

make a therapeutic decision.

5. Counsel your patient.

Chapter 37

Antihistamines and Related Antiallergic and Antiulcer Agents

Wendel L. Nelson

Drugs covered in this chapter:

Antihistamines

- Acrivastine
- Azelastine
- Carebastine
- Cetirizine
- Cromolyn
- Desloratadine
- Ebastine
- Emedastine
- Epinastine
- Fexofenadine
- Ketotifen
- Levocetirizine
- Levocobastine
- Lodoxamide
- Loratadine
- Mizolastine
- Nedocromil
- Olopatadine
- Pemirolast
- Terfenadine

Antiulcer agents

- Cimetidine
- Esomeprazole
- Famotidine
- Lansoprazole
- Metoclopromide
- Misoprostol
- Nizatidine
- Omeprazole
- Pantoprazole
- Rabeprazole
- Ranitidine
- Sucralfate

Introduction

Histamine [2-(imidazol-4-yl)ethylamine] was synthesized and its effects in model biological systems were studied before it was found physiologically. Its synthesis occurs in many tissues, including mast cells, parietal cells of the gastric mucosa, and neurons of the central nervous system (CNS) and the periphery. Early hypotheses about its physiological function were based on the observed, dramatic effects of histamine in guinea pigs. These effects

include massive bronchial spasm and effects on smooth muscle and the vasculature that resemble anaphylactic shock. Marked species differences in the observed effects occur, however, and these dramatic effects are not observed in humans.

Histamine is located in many tissues, and on release, its effects are principally local ones, because it functions as an autocoid or paracrine (1). Its physiological function is complex and not completely understood. Histamine is one of the many mediators involved in allergic inflammatory responses, and it has an important role in regulating the secretion of gastric acid. These observations have led to development of many important drugs that antagonize its effects and are useful in treatment of allergic inflammatory disorders (H_1 antihistamines) and in the treatment of gastric hypersecretory disorders (H_2 antihistamines).

Besides its role in allergic inflammatory processes and gastric acid secretion, a physiological role at axons in several regions of the CNS has established its role in the regulation of sleeping and waking, in energy and endocrine homeostasis, and in cognition and memory. Histamine modulates the release of neurotransmitters via H_3 auto- and heteroreceptors located at histaminergic and nonhistaminergic neurons both centrally and peripherally. A novel H_4 receptor also been described where histamine facilitates the synthesis and release of other proinflammatory mediators and modulates the chemotactic responses, principally at mast cells and eosinophils.

Chemistry

Histamine has pK_a values of 5.80 (imidazole) and 9.40 (aliphatic primary amine) (2). At physiological pH, it exists as an equilibrium mixture of tautomeric cations, with the monocation making up more than 96% of the total and the dication approximately 3%, with only a very small amount of the nonprotonated species. At lower pH values (e.g. the pH of acidic lipids), a much larger proportion of the dication exists. The two protonated species (mono- and dication) often are considered to be the biologically active forms. Penetration of membranes by histamine would be expected to occur via the nonprotonated species, and the unprotonated imidazole group would be expected to participate readily in proton-transfer processes physiologically. Several aromatic ring congeners of histamine with weakly and very weakly basic heteroaromatic rings (e.g., 4-chloroimidazole, 1,2,4-triazole, thiazole, and pyridine) exhibit histamine agonist activity (Table 37.1) (3), although they are less potent than histamine. These data suggest that the monocation (protonated aliphatic amine) is sufficient for agonist activity and that protonation of the heterocyclic ring is not an absolute requirement.

In aqueous solutions, the tautomeric equilibrium of the imidazole ring apparently favors the N^{τ}-H tautomer by approximately 4:1. The free base also prefers the N^{τ}-H tautomer. In the crystalline form of the monohydrochloride salt of histamine, however, where intermolecular crystal

packing forces are important, the N^{π}-H tautomer is preferred. Changes in tautomeric composition of analogues occur with changes in the 4-substituent (e.g., Me versus Cl), where the proportion of N^{τ}-H tautomer is decreased in the chlorine-substituted congener to 12%, compared with 70% for 4-methylhistamine, and decreased agonist potency is observed. An interpretation of these results is that tautomeric composition might be important in the agonist–receptor interaction (2).

Clinical Significance

The antihistamines and other agents presented in this chapter represent the extremes of many spectrums. Traditional antihistamines, like promethazine, have been marketed for more than 50 years; proton pump inhibitors have had new dosage forms approved as

recently as 2005. Some of the agents are inexpensive, whereas others cost several dollars per dose. Indications for these medications range from minor allergic eye irritations to serious conditions, such as Zollinger-Ellison syndrome. The most important comparison to make between the drug classes and specific agents within each class is the chemical structure of the product. The differences and similarities of each structure define the function, potency, and side effect profile of the medication. Therefore, an understanding of the effect of chemical structure modifications is imperative to distinguish between the advantages and disadvantages of a treatment regimen.

This effort is well rewarded, because these products are commonly prescribed for medical treatments and many of these agents are available without a prescription. The accessibility of these drugs presents a significant opportunity for pharmacists to assist patients with proper product selections. To provide appropriate and pertinent therapeutic recommendations, the clinician must possess a thorough comprehension of the unique attributes for each medication, which can be determined by studying the chemical structure.

Results of conformational studies performed on histamine and its congeners indicate both *trans* and gauche conformations exist in solution (Fig. 37.1) (2). The *trans* conformation of 4-methylhistamine, however, which is a selective H_2 agonist, cannot readily adopt the fully extended *trans* conformation because of interaction of the 4-methyl group with the aliphatic two-carbon chain. Because α- and β-methylhistamine exist predominantly as gauche conformers and both are very weak H_1 and H_2 agonists, it has been suggested that the *trans* conformation of histamine is preferred at both H_1 and H_2 receptors. A gauche conformation has been suggested for histamine at the H_3 receptor, because α-methylhistamine and some other more conformationally restricted analogues are potent H_3 agonists.

Addition of other alkyl substituents onto the histamine molecule generally produces compounds with decreased potency at H_1 and H_2 receptors. 2-Methylhistamine is a selective H_1 agonist (versus 4-methylhistamine, a selective H_2 agonist), but imidazole N-substitution (N^1 or N^3) with methyl groups results in nearly inactive agents. Similarly, aliphatic amine nitrogen substitution results in decreasing activity (NH_2 > NHMe > NMe_2 > N^+Me_3 [quaternary ammonium salt]) at both H_1 and H_2 receptors (2).

Physiological Characteristics of Histamine

Synthesis and Metabolism of Histamine

Histamine is synthesized in the Golgi apparatus of mast cells and basophils by enzymatic decarboxylation of histidine.

This conversion is catalyzed by L-histidine decarboxylase, with pyridoxal phosphate serving as a cofactor for this process. The reaction mechanism for this decarboxylation probably involves the formation of an imine intermediate, followed by the loss of carbon dioxide, a mechanism demonstrated to occur for decarboxylation of many α-amino acids (Fig. 37.2). Pyridoxal phosphate provides an important catalytic function, and in the final step, the product is released by hydrolysis of the enzyme-bound Schiff base of histamine. Mechanism-based inhibitors of this process, such as α-fluoromethylhistidine, decrease the rate of synthesis of histamine and, thus, deplete cells of histamine. As such, α-fluoromethylhistidine is an important pharmacological tool (4). This approach, however, has not been successfully developed into agents for the treatment allergic inflammatory disorders, peptic ulcer, or motion sickness.

Table 37.1. Histamine-Related Agonists[a]

Once released, histamine is rapidly metabolized in vivo (based on products from radiolabeled histamine administered intradermally) to nearly inactive metabolites by two major pathways: N-methylation, and oxidation (Fig. 37.3). Methylation (S-adenosylmethionine), which is catalyzed by the intracellular enzyme N-methyltransferase, yields an inactive metabolite. A portion of the N-methylated metabolite is oxidized sequentially via monoamine oxidase and then via aldehyde oxidase to the corresponding N-methylimidazole acetic acid. Histamine also is oxidized to imidazole acetic acid by diamine oxidase (histaminase). A small amount of this acid intermediate is converted to the corresponding ribotide, an unusual metabolite (5).

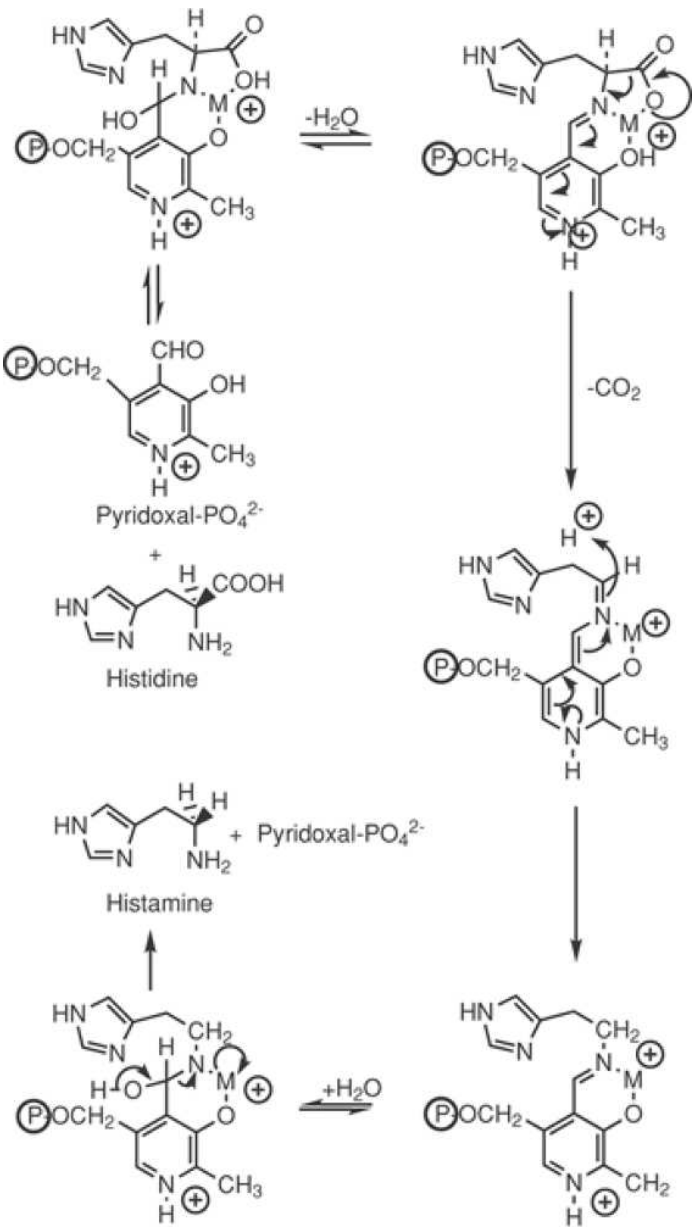

Fig. 37.2. Formation of histamine by decarboxylation of histidine.

Storage and Release of Histamine

In mast cells, histamine is stored in secretory granules as a complex with acidic residues of the proteoglycan heparin and in basophils in the blood as a complex with chondroitin sulfate (6,7). Mast cells are distributed in areas of skin and mucous membranes of the respiratory, gastrointestinal, and genitourinary tracts and in tissue adjacent to blood and lymph vessels. Although histamine is secreted at low levels from these mast cells and basophils, the primary mechanism of release is associated with cell activation by immunoglobulin (IgE)–mediated hypersensitivity processes (Fig. 37.4). Immediate hypersensitivity is initiated when allergen molecules cross-link to Fab components of adjacent IgE antibody molecules bound to high-affinity FcεRI receptors on the surface of these cells (FcεRI[1] cells). Dimerization of occupied IgE-Fc receptors results in several membrane and cytosolic events. These include release of preformed mediators

from secretory granules by exocytosis, synthesis and release of chemotactic mediators and

neutral proteases (e.g., tryptase), synthesis and release of other lipid mediators (e.g., leukotrienes and prostaglandins), and stimulation of synthesis of cytokines and their subsequent release. Other cell activation stimuli for the release of histamine include concanavalin A, substance P, polyamines, opiates, and several lymphokines and cytokines. Different subpopulations of cells respond differently to these stimuli. With the exocytotic response, histamine rapidly dissociates from the partially solubilized granule matrix. In basophils, the release process may be slightly different, occurring without degranulation. Other cell types, including lymphocytes, platelets, neutrophils, monocytes, and some macrophages, secrete histamine-releasing factors. These cells also have distinct low-affinity receptors for IgE, which when occupied result in secretion of mediators that selectively recruit and activate secondary effector cells in the inflammatory process.

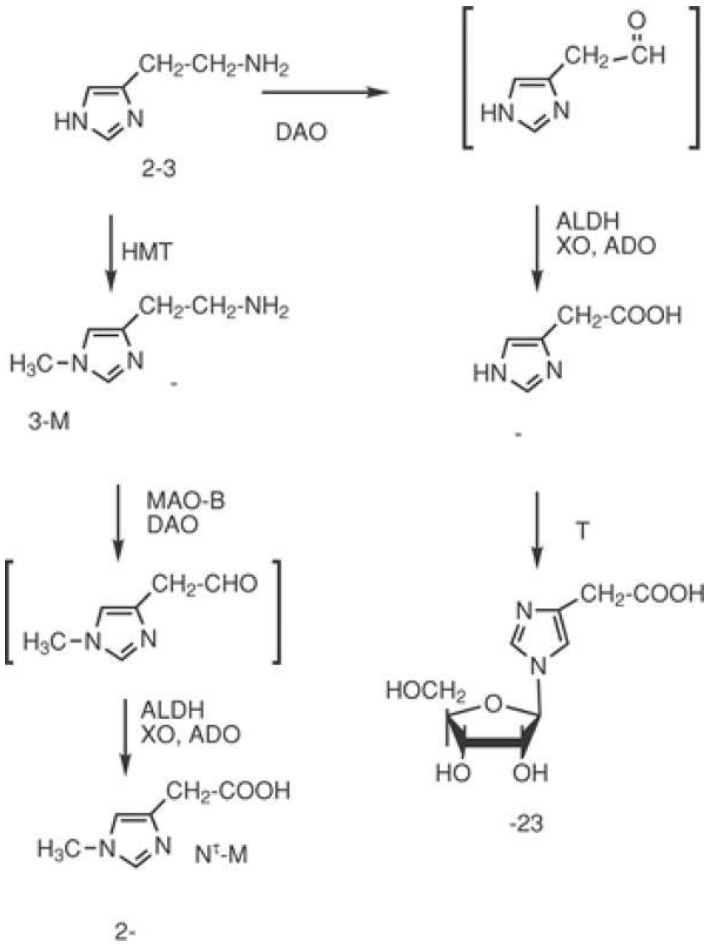

Fig. 37.3. Major metabolic pathways of histamine, from intradermal histamine as measured in the urine in 12 hours in human males (5). HMT, histamine N-methyltransferase; MAO-B, monoamine oxidase type B; DAO, diamineoxidase; ALDH, aldehyde dehydrogenase; ADO, aldehyde oxidase; XO, xanthine oxidase; PRT, phosphoribosyl transferase.

Mast cells play an important role in the early response to allergens, and they provide mediators that lead to initial and late stages of the process and, subsequently, to chronic inflammatory reactions (8,9,10). Early stages appear to be related to degranulation and the release of many mediators, including histamine, prostaglandin D_2 (PGD_2) and leukotriene C_4, platelet-activating factor, adenosine triphosphate (ATP), kinins, and some enzymes (e.g., tryptase and chymase). Thus, additional important mediators other than histamine have very

significant roles. These mediators include platelet-activation factor, substance P, neurokinin A, and others. Besides processes of vasodilation and edema, activation of secondary inflammatory cells occurs, as do adherence of neutrophils and migration of eosinophils and T cells to postcapillary venule endothelial cells. This latter process is mediated by specific cell adhesion molecules. A further array of mediators and cellular responses follows. A series of interleukins are generated and secreted by subtypes of T cells. Stimulation of many NFκB-mediated gene transcription pathways occurs via H_1 receptor activation. Important cytokines are produced and liberated, including tumor necrosis factor α (TNF-α), interleukin-4 (IL-4), IL-5, IL-1, and IL-6, which are involved in chemokine secretion and regulation of cell maturation and proliferation processes, changes that occur in late-stage inflammatory processes. Thus, the inflammatory cascade is a complex and intricate one, and the effects of histamine are only a small part of the process. Inhibition of the production of many of the proinflammatory cytokines occurs in the presence of many of the H_1 antihistamines.

As a result of occupation of H_1 receptors by histamine, constriction of bronchial and gastrointestinal smooth muscle occurs. Spasm of the bronchi to inhaled histamine at one time was a test for airway reactivity. Intradermal injection of histamine produces vasodilation of arterioles as the first step in the "triple response" mediated via H_1 and H_2 receptors. A flare response follows this stimulation, resulting in release of substance P and other neuropeptides. Edema from exudation of plasma fluids follows because of contraction of endothelial cells of the postcapillary venules. The wheal and flare responses are mostly H_1 receptor mediated.

Histamine Receptors—Molecular and Mechanistic Aspects

Histamine receptors are found in various tissues. Among these are the H_1 receptors in smooth muscle of the bronchi, gut, and uterus. Contraction of the bronchi leads to restriction of air flow in the lungs. Histamine increases the permeability of capillary walls. Plasma constituents flow into extracellular spaces because of contraction of endothelial cells; this process leads to edema. At the level of the CNS, histamine secretion appears to be associated with wakefulness, because H_1 receptor antagonism centrally is associated with drowsiness. In the stomach, parietal cell stimulation increases production and secretion of acid, mediated through H_2 receptors. The H_2 receptors play a minor role in allergic inflammatory processes. The H_3 receptor is principally an autoreceptor in the CNS at histaminergic neurons, and it is a heteroreceptor on neurons that release other neurotransmitters, also in the brain. The H_4 receptor is expressed primarily on eosinophils and mast cells, where it is associated with chemotactic responses.

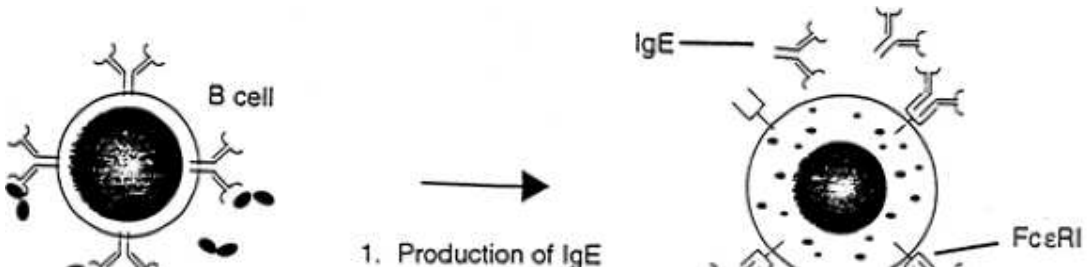

Fig. 37.4. Sequence of events in immediate hypersensitivity. Initial contact with an antigen leads to specific IgE synthesis by B cells. Secreted IgE binds to mast cells or basophils through high-affinity Fce receptors (FceRI). On subsequent exposure to the antigen, an immediate hypersensitivity reaction is triggered by cross-linking the IgE molecules.

All the histamine receptors appear to have constitutive receptor G-protein signaling activity independent of the presence of histamine (11). Most of the antihistamines studied are not antagonists, but some are inverse agonists. They reduce constitutive G-protein signaling activity. Occasionally, some antihistamines are neutral antagonists, i.e., they do not reduce the constitutive G protein–coupled activity of the receptor. A two-state model of inactive and active conformations of the receptor is consistent with this observation.

The human H_1 receptor gene encodes for a 487-amino-acid protein with the signature structural features of G protein–coupled receptors (seven transmembrane domains, N-terminal glycosylation sites, phosphorylation sites for protein kinases A and C, and a large intracellular loop with several serine and threonine residues) (11,12). It is coupled (via $G_{q/11}$ proteins) to phosphatidyl inositol turnover as the second-messenger system. The H_1 receptor shows 40% homology with the muscarinic M_1 receptor and the M_2 receptor. An aspartic acid in the third transmembrane domain is highly conserved in several species, and it is suggested to be a recognition site for the protonated aliphatic amine function of histamine at both H_1 and H_2 receptors. Based on mutation studies and homologous positions to α-adrenergic receptors, suggestions for sites of binding of the imidazole portion of histamine to amino acids threonine and/or asparagine in the fifth transmembrane have been made.

Signal transduction processes begin with $G_{q/11}$-coupled hydrolysis of phosphatidylinositide to inositol-1,4,5-triphosphate and 1,2-diacylglycerol, which occurs via activation of phospholipase C. Elevation of intracellular calcium ion from intracellular stores occurs. Voltage-gated calcium channels may be opened by activation of ion channels permeable to Na^1 and K^1 ions. Calcium channel antagonists block some effects of histamine on intestinal smooth muscle. In addition, the H_1 receptor can activate other signaling pathways, including phospholipase D and

phospholipase A_2, and stimulate NFκB-mediated gene transcription.

The H_2 receptor is a 359-amino-acid protein in humans. It has some features similar to the H_1 protein (e.g., N-terminal glycosylation sites) and phosphorylation sites in the C-terminal. An aspartic acid residue in the third transmembrane loop appears to be critical to agonist and antagonist binding, and threonine/aspartate and tyrosine/aspartate couples in the fifth transmembrane domain appear to be important for interaction of the imidazole part of the histamine molecule. It is positively coupled via $G_{\alpha s}$ to activate adenylyl cyclase for synthesis of cyclic adenosine monophosphate (cAMP) as a second messenger. In some systems, it is coupled through G_q proteins to stimulate phospholipase C. It appears in some cells that other processes, such as breakdown of phosphoinositides, control of intracellular calcium ion levels, and phospholipase A_2 activity, can be regulated by other cAMP-independent pathways.

The highest density of H_3 receptors occurs in the brain, principally in the striatum, substantia nigra, and the cortex and to a much lesser extent at peripheral nerve terminals. It is a presynaptic auto- and heteroreceptor where activation leads to a decrease in neurotransmitter release. The most widely studied H_3 receptor is 445 amino acids, but many splice variants have been observed (13). It is activated via $G_{\alpha i/o}$ proteins (coupled negatively to adenylyl cyclase) to the activation of protein kinase A to modulate gene transcription. The H_3 receptors, via $G_{\alpha i/o}$ proteins, may activate phospholipase A_2, mitogen-activated protein kinase, and phosphatidyl inositol-3-kinase. The H_3 receptors have low sequence homology with H_1 and H_2 receptors (~20% each). Activation of histaminergic neurons centrally, which promotes arousal and attention and improves learning in animals, is a potential target for H_3 receptor antihistamines. Like the H_1 and H_2 antihistamines, the H_3 antihistamines function primarily as inverse agonists.

The H_4 receptors appear to be limited to cells of the hematopoietic system, with expression occurring primarily on eosinophils, basophils, dendritic cells, and T cells. Histamine stimulation results in a chemotactic response, cell migration. The presence of H_4 receptors on these cells suggests that this receptor plays a role in the inflammatory response. Evidence suggests that it may be regulated via inflammatory stimulation of TNF-α and IL-6. The H_4 receptor has 390 amino acids and is coupled to inhibition of adenylyl cyclase via $G_{\alpha i/o}$. It has highest homology with the H_3 receptor (~35–40%), with greater homology (58%) of the transmembrane segments. Thus, antihistamines could be useful agents to antagonize the inflammatory response. Agents studied to date also appear to be inverse agonists.

Inhibitors of Histamine Release

Mechanism of Action

The bronchodilatory activity of khellin, a chromone obtained from a plant source (*Ammi visnaga*) used by ancient Egyptians for spasmolytic activity, stimulated the search for related compounds with similar pharmacological properties (14). From a study of many bischromones, cromolyn sodium was developed and marketed (Fig. 37.5). Although it prevents bronchospasm, it does not reverse antigen-induced bronchiolar constriction. Thus, it and other agents like it that followed prevent the release of histamine and do not block the effects of histamine at its receptors.

The mechanism by which cromolyn and nedocromil inhibit degranulation of mast cells has been investigated (15). Both agents stimulate phosphorylation of moesin, a 78-kDa protein that is phosphorylated by isozymes of protein kinase C. It is suggested that phosphorylation results in conformational changes that exposes domains that promote association with actin and other proteins of the secretory granules. This association results in immobilization of the granules and inhibition of exocytosis. Cromolyn and nedocromil (vide infra) apparently inhibit function of cells other than mast cells; these effects may occur during later stages of inflammatory responses. Cromolyn does not have intrinsic antihistaminic or anti-inflammatory activity.

Mast cell stabilizers used in the treatment of asthma are additionally discussed in Chapter 44.

Therapeutic Applications of Specific Drugs

Cromolyn (Intal, Nasalcrom, Gastrocrom)

Cromolyn generally is used prophylactically for bronchial asthma (as an inhaled powder), for prevention of exercise-induced bronchospasm, and for seasonal and perennial allergic rhinitis (nasal solution). Topically, it also is used as eye drops for allergic conjunctivitis and keratitis. In

the management of asthmatic conditions, it is administered using a power-operated nebulizer. The bioavailability is very low with oral administration because of poor absorption. By inhalation, the powder is irritating to some patients. After inhalation, much less than 10% of the dose reaches the systemic circulation. An oral dosage form is used for mastocytosis.

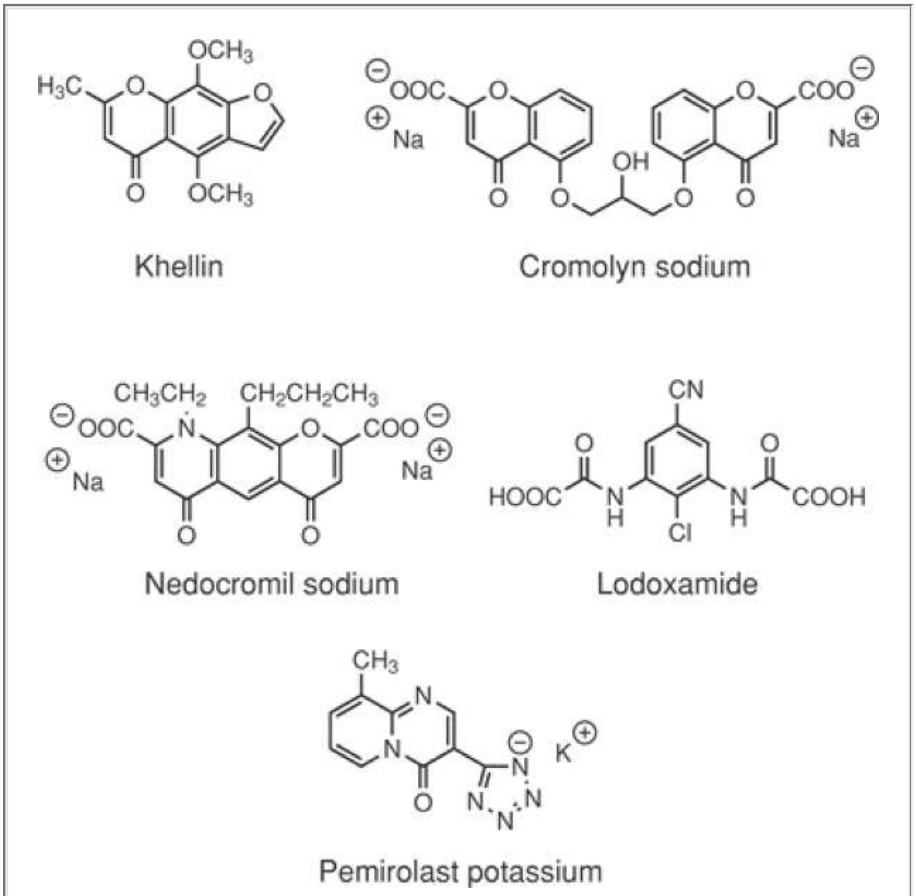

Fig. 37.5. Mast cell degranulation inhibitors.

Nedocromil (Alocril, Tilade)

Nedocromil is a chromone analogue also used by inhalation as an aerosol, primarily in the prophylaxis of asthma and reversible obstructive airway disease. It inhibits release of allergic mediators, and it is effective in a broad range of patients. An ophthalmic solution is available for the treatment of seasonal and perennial allergic conjunctivitis. Other structurally related compounds are not currently available in the United States but are available in other markets.

Lodoxamide (Alomide)

Lodoxamide, which shows some structural similarities to cromolyn and nedocromil, also is a mast cell stabilizer that inhibits the immediate hypersensitivity reaction, preventing increases in vascular permeability associated with antigen-IgE–mediated responses. Its precise mechanism of action is not completely understood. It is used topically in the eye, principally for conjunctivitis and keratitis associated with vernal allergens.

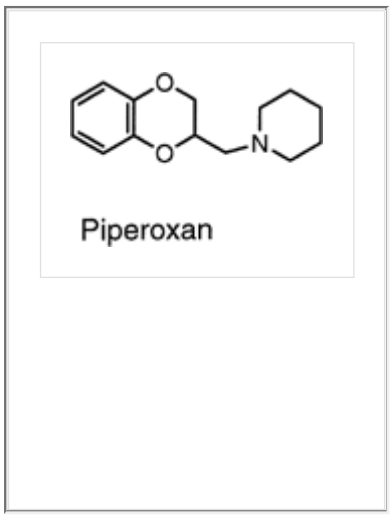
Pemirolast (Alamast)

Pemirolast, with an acidic tetrazole isosteric replacement for a carboxylic acid functionality, is used topically in the eye to prevent itching associated with allergic conjunctivitis. It is an inhibitor of the release of histamine and other inflammatory mediators, including leukotrienes. Significant use as a systemic agent has been reported, and it has been shown to be of value in preventing restenosis after percutaneous coronary angiopathy.

Inhibitors of Released Histamine

Historical Background

The first antihistamine was discovered by Forneau and Bovet (16), who observed that piperoxan protected guinea pigs against histamine-induced bronchospasm. The sensitivity of the guinea pig was initially thought to make it a good model for anaphylaxis. Piperoxan also has important effects related to antagonism of norepinephrine at α-adrenergic receptors.



Antihistamines, specifically H_1 antihistamines (17,18), are useful in the treatment of allergy and inflammatory disorders, in which many but not all effects are mediated via histamine. Compounds that had antagonistic effects in these assays did not antagonize the effects of histamine on the stomach (acid secretion) and heart (positive chronotropic and inotropic effects). These differences led to suggestion of the presence of H_1 and H_2 receptors and, ultimately, to the development of selective H_2 antihistamines to diminish the secretion of gastric acid. A third class of histamine receptors, H_3 receptors, appears primarily to consist of autoreceptors that control the synthesis and release of histamine presynaptically and of heteroreceptors that control the release of other transmitters, primarily in the CNS. The most recent class of histamine receptors, H_4 receptors, are expressed principally on eosinophils and mast cells, where they may play a role in the inflammatory response, especially during the late stages. Classical H_1 antihistamines do not bind to this histamine receptor, and H_4 receptors do not modulate degranulation of mast cells.

The first-generation H_1 antihistamines are useful and effective in the treatment of allergic responses (e.g., hay fever, rhinitis, urticaria, and food allergy). These agents also have effects at cholinergic, adrenergic, dopaminergic, and serotonergic receptors. Adverse central effects include sedation, drowsiness, decreased cognitive ability, and somnolence. Peripheral side effects associated with cholinergic blockade include blurred vision, dry mouth, urinary retention, and constipation. Other observed effects have included appetite stimulation, muscle spasm, anxiety, confusion, and occasionally, irritability, tremor, and tachycardia. Of all the side effects, CNS depression is the most common, and it can be so pronounced that some of these agents with short durations of action are used as over-the-counter (OTC) sleep aids. The separation of CNS depressant and anticholinergic effects from peripheral antihistaminic effects in later agents led to the second-generation antihistamines (vide infra).

Structural classes of H_1 antihistamines can be represented by a general structure of two aromatic groups linked through a short chain to a tertiary aliphatic amine (Fig. 37.6). The aromatic groups (Ar_1, Ar_2) usually are phenyl or substituted phenyl, thienyl, or pyridyl. These substituents are attached to the X group, which is a nitrogen atom in the ethylenediamines, a carbon attached to

an ether oxygen atom in the ethanolamine ether series, or only a carbon atom in the alkyl amines. The spacer usually is two or three carbons in length, and it may be in a ring, may be branched, and may be saturated or unsaturated. The R groups attached to the aliphatic amine

usually are simple alkyl groups, generally methyl or, occasionally, aralkyl groups. One of the early thiophene-containing analogues was carcinogenic in rats. After thiophene versus benzene replacement in other series of compounds demonstrated some toxic effects, thiophene was relegated to one of the low-priority choices for isosteric replacement of a phenyl group.

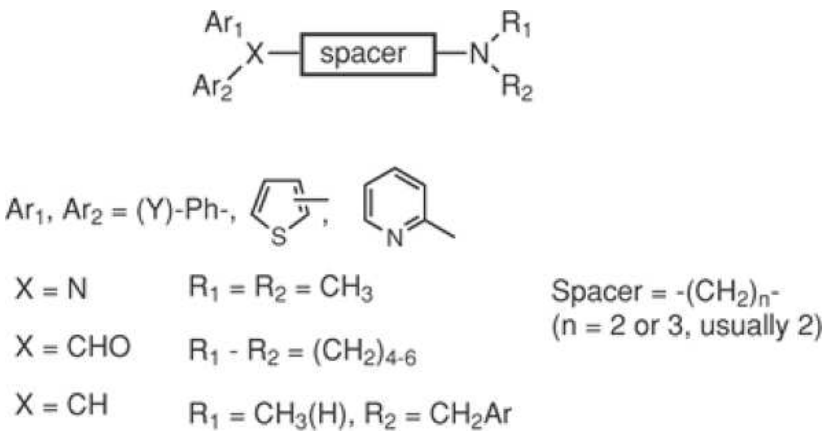


Fig. 37.6. General structure of first-generation antihistamines.

Most H_1 antihistamines are inverse agonists rather than neutral antagonists. Like other histamine receptors, H_1 receptors have constitutive G protein–coupled activity in the absence of the agonist histamine that results in activation of second-messenger signaling pathways, such as phospholipase C activity and NFκB-mediated gene transcription (19). A model of active and inactive conformations of histamine receptors has been advanced to accommodate these biochemical findings. Inverse agonists bind to the inactive conformation of the receptor, shifting the equilibrium toward the inactive state. Neutral antagonists interact with both conformations of the receptor.

First-Generation H_1 Antihistamines

Ethylenediamines

The earliest series of H_1 antihistamines is the ethylenediamines. Two 2-carbon spacers may appear between the two nitrogen atoms in the piperazine series (vide infra). Examples of agents in the ethylenediamine class, of which phenbenzamine was the first of these agents, appear in Table 37.2. Compounds with several different but closely related aromatic rings are useful, such as phenyl, 2-pyridyl, halogen- and methoxy-substituted phenyl, or pyrimidyl. Thiazole-, furanyl-, and thiophene-ring congeners also were available in the past. The small alkyl substituents on basic nitrogen usually are methyl groups. A number of these agents are still used. With the exception of antazoline, all have the ethylenediamine spacer. In antazoline, the alkyl tertiary amine in phenbenzamine is replaced with an imidazoline group. Central nervous system effects, usually sedation, are very common among agents in this class.

Information regarding pharmacokinetic and metabolic disposition is limited, because this early group of compounds was not studied in depth. Only later, with second-generation H_1 antihistamines, and/or when issues of potential toxicity have arisen concerning some of the early compounds, has the metabolic disposition been examined more completely. Thus, the available information concerning the metabolism on these early antihistamines is sparse. From some of the ethylenediamines, expected products of N-demethylation and subsequent deamination have been reported. In addition, some produce quaternary N-glucuronides as

urinary metabolites, a process that occurs, to some extent, in many relatively unhindered tertiary aliphatic amines among the antihistamines and also in other lipophilic aliphatic tertiary amine drug classes.

Ethanolamine Ethers

Structure activity relationships

The prototype of the aminoalkyl ethers is diphenhydramine, a benzhydryl ether which more than a half-century after its introduction remains still widely used for allergic conditions. Structural analogues with various ring substituents (Me, OMe, Cl, and Br) in one of the aromatic rings also have been developed, as have compounds with a 2-pyridyl group replacing one of the phenyl groups (Table 37.3).

Significant anticholinergic side effects are observed among members of the group (e.g., dry mouth, blurred vision, tachycardia, urinary retention, and constipation). It should be noted that diphenydramine is used in the treatment of parkinsonism because of its central anticholinergic properties. Other anticholinergic agents that are structurally related to the benzydryl ether antihistamines also are used in the treatment of parkinsonism (see Chapter 25). Sedative properties are very common as well. Sedation, accompanied by a short half-life and a wide margin of safety, allows some of these compounds to be used as OTC sleep aids. The 8-chlorotheophyllinate salt of diphenhydramine is marketed as dimenhydrinate for use in the treatment of motion sickness. The compound with the aryl groups *p*-Cl-Ph and 2-pyridyl is carbinoxamine, a potent antihistamine. Substitution of a methyl group at the carbon α to the ether function affords the related compound doxylamine, in which the aryl groups are phenyl and 2-pyridyl. Clemastine, a

homologue with an additional carbon atom between the oxygen and the basic nitrogen, which is incorporated into a ring, is a recent addition to the group, with less sedative properties. Other analogues are used elsewhere. For example, setastine, a compound with the alkyl amine substituent being incorporated into a 7-membered hexahydroazepine ring, is available in Europe.

Table 37.3. Ethanolamine Ether Antihistamines

Antihistaminic versus anticholinergic activity

Besides the structural analogues in Table 37.3 that possess increased selectivity for histamine H_1 receptors over muscarinic receptors, introduction of alkyl substituents at C-2' or C-4' of one aromatic ring results in significant changes in selectivity in tissue-based assays for antihistaminic versus anticholinergic activity. With increasing alkyl group size (Me, Et, iPr, and tBu) at C-2', large decreases in antihistaminic activity and increases in anticholinergic activity are observed (20). With larger alkyl groups, the possible spatial orientations of the two aromatic rings with regard to each other are limited because of increasing rotameric restrictions. Introduction of these alkyl substituents at C-4' decreases anticholinergic activity and yields small increases in antihistaminic activity. A chiral center is introduced with these changes, and differences in pharmacological properties of the enantiomers of each compound are observed. Two examples are shown in Table 37.4.

Stereochemical and structural effects

The observed differences in potency of enantiomers in tissue-based assays suggest significant stereoselective interactions of antagonists at the receptor level. Differences in

affinity of 60- to 200-fold are noted between enantiomers in several analogues where the chiral center results because of differences in the two aromatic rings, such as Ph and 2-pyridyl, or Ph and *p*-Br-Ph (21). Enantiomers with the *S*-absolute configuration usually are more potent. Clemastine, a more complex homologue, is marketed as the *R*,*R*-enantiomer, which is the more potent of the *R*,*R*- and *S*,*S*-enantiomeric pair and more potent than either the *R*,*S*- and *S*,*R*-enantiomers of the other diastereomer (22). Consistent with results from related compounds, the chiral center at the benzhydryl carbon has a significant influence on potency, whereas the one in the pyrrolidine ring is of lesser importance (Table 37.5).

Table 37.4. Antihistamine and Anticholinergic Activity of Enantiomers of Ring Substituted Ethanolamine Ethers (20)

Very small changes in the arrangement of aromatic groups in the members of the ethanolamine ether series significantly alter the scope of their pharmacological properties. Previous work has shown that the two aromatic rings in diphenhydramine can be located slightly differently with respect to each other, as in phenyltoloxamine, a potent antihistamine. A retro arrangement of carbon and oxygen atoms, however, prepared in an

attempt to investigate structural requirements for antihistamines, afforded significantly different pharmacological properties and, ultimately, led to a series of very important selective serotonin reuptake inhibitors, such as fluoxetine (Fig. 37.7). Unlike the bio-isosteric oxygen to nitrogen atom replacement, conversion of the oxygen atom to a sulfur atom in the diphenhydramine series results in a compound with greatly decreased antihistaminic activity (23).

Metabolism

Only limited information regarding the metabolic disposition of this group of compounds is available. As expected, N-demethylation (formation of the corresponding secondary amine) and subsequent deamination (formation of the carboxylic acid metabolite) is a major pathway for diphenydramine (Fig. 37.8) and some of its analogues. Although the early experiments are relatively incomplete, it appears that the N-demethylation products have shorter half-lives than the corresponding parent drugs, and they probably contribute very little to the observed antihistaminic properties. Minor metabolites that are conjugates of the carboxylic acid products of deamination or of ether cleavage products have been found in some animal species. Compounds with shorter half lives, like diphenhydramine, when used as antihistamines require repeated administration, but a very short half life is an advantage

when the same drugs are used as sleep aids (17,18).

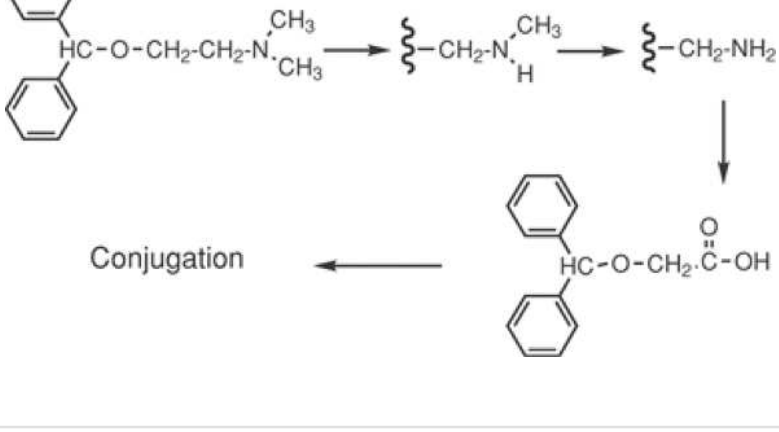

Fig. 37.8. Metabolism of diphenhydramine.

Alkyl Amines

A third class of analogues is one in which a carbon atom replaces the heteroatom spacer in the general structure. Examples are pheniramine, chlorpheniramine, brompheniramine, and the *E*-isomers of olefinic homologues (Fig. 37.9). The ring halogen–substituted compounds are widely used OTC antihistamines for mild seasonal allergies. These agents are characterized by a long duration of antihistaminic action and by a decreased incidence of central sedative side effects compared to the ethylenediamines and ethanolamine ether series. This structural change introduces a chiral carbon when the two aromatic rings are different (e.g., Ph and 2-pyridyl). These were the most extensively used antihistamines until the more selective second-generation antihistamines appeared.

Structural and stereochemical effects

E- and *Z*-isomers of the alkenes in this series show very large differences in potency in tissue-based assays. For example, *E*-pyrrobutamine is more potent than its *Z*-isomer by 165-fold, and *E*-triprolidine (Fig. 37.9) is more potent than its *Z*-isomer by approximately 1,000-fold (2). Dimethidene has many of the structural features of both of these two agents in a more complex, cyclized structure. The observed difference in potency between the *E*- and *Z*-isomers shows that the two aromatic rings probably have quite different binding environments at the receptor (24). These observations provide evidence suggesting that a 5- to 6-Å distance between the tertiary aliphatic amine and one of the aromatic rings is required at the site of receptor binding (Fig. 37.10) (25).

Differences in potency between the enantiomers of the conformationally mobile amino-alkanes also have been

observed. The *S*-enantiomers have greater affinity for H_1 histamine receptors, occasionally by very large amounts, such as 200- to 1,000-fold in radioligand displacement assays and in tissue-based assays for *S*-(+)- versus *R*-(–)-chlorpheniramine, with the (+)-enantiomer being more potent (Ar=R-Ph, 2-pyridyl) (Fig. 37.9). Greater selectivity for H_1 receptors versus muscarinic and adrenergic receptors is observed as well. For members of the series, the chiral center of the more potent enantiomer correlates stereochemically with the more active enantiomer of the oxygen congener carbinoxamine (Table 37.3) (2,26). Single enantiomers of these agents are available (e.g., dexchlorpheniramine and dexbrompheniramine).

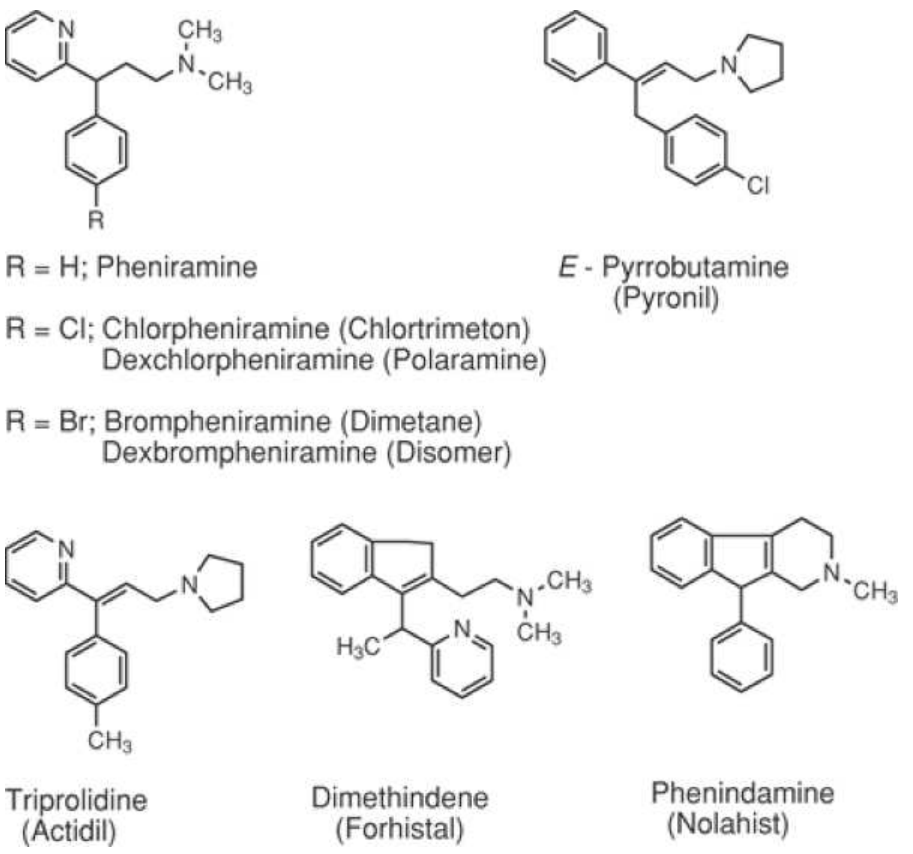

Fig. 37.9. Examples of alkane and alkene antihistamines.

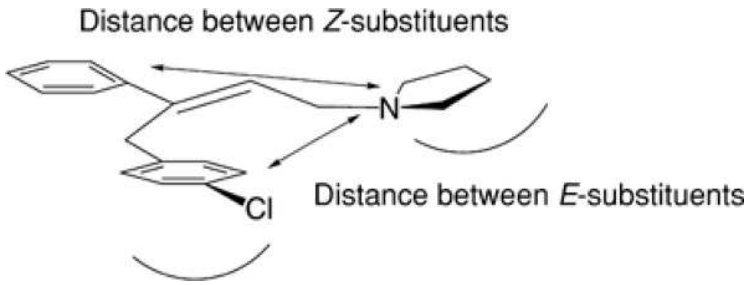

Fig. 37.10. Potential binding sites based on E/Z-configurations.

Half-life and metabolism

The alkyl amines have significantly less CNS-depressant effects than benzhydryl ethers of ethanolamines. Additionally, these compounds have long half-lives and extended durations of action. These agents have decreased antiemetic effects and decreased anticholinergic properties compared to ethanolamine ethers. Many are available in OTC preparations for hay

fever and other mild allergic conditions, sometimes in combination with adrenergic decongestants. Most are suitable for once-a-day dosing because of their long half-lives (up to 24 hours), although they are routinely administered more frequently.

Information concerning the metabolic disposition of some these agents has been reported. As expected, N-dealkylation is a major pathway, with the corresponding secondary and primary amines, as well as the parent drug, being found in the plasma.

Piperazines

Members of the piperazine class of agents are structurally related to both the ethylenediamines and the benzhydryl ethers of ethanolamines. Their structures include the 2-carbon separation between nitrogen atoms, which is incorporated into the piperazine ring (Table 37.6).

Diarylmethylene groups (benzhydryl substituents, as in diphenhydramine) are attached to one of the nitrogen atoms, and an alkyl or aralkyl substituent is attached to the other nitrogen. Early compounds, such as cyclizine, chlorcyclizine, meclizine, buclizine, and hydroxyzine, have been widely used as antihistamines and as agents for treatment of motion sickness, because they have useful central antiemetic effects.

These agents also have significant anticholinergic and antihistaminic properties. Anticholinergic side effects and drowsiness are common. The primary use of these compounds remains treatment of motion sickness and vertigo and suppression of nausea and vomiting. Although teratogenic effects of cyclizine and meclizine have been observed in rodents, large studies have not demonstrated adverse fetal effects in humans; however, these agents are used cautiously in pregnant women and children. Oxatomide is used in Europe principally in allergic rhinitis, urticaria, and in combination with albuterol in asthma. Drowsiness and sedation are noted. Hydroxyzine is used in treatment of pruritis, and at higher dosages, it is used in the management of anxiety and emotional stress. Its acid metabolite, cetirizine, which is formed from oxidation of the terminal primary alcohol to the corresponding carboxylic acid, usually is classified with the second-generation, nonsedating antihistamines. The amphoteric nature of cetirizine, having both the tertiary aliphatic amine and carboxylic acid functional groups, appears to be associated with decreased, but not absent, sedative side effects.

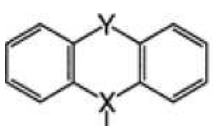
Table 37.6. Examples of Tricyclic Antihistamines

Tricyclic H_1 Antihistamines

The two aromatic groups noted in several of the classes of antihistamines can be connected to each other through additional atoms (e.g., heteroatoms like sulfur or oxygen) or through a short, 1- or 2-carbon chain. They have a general structure shown in Figure 37.11. The earliest potent tricyclic antihistamines (Table 37.7) were phenothiazines (Y=S, X=N). The phenothiazine antihistamines contain a 2- or 3-carbon, branched alkyl chain between the nonbasic phenothiazine nitrogen and the aliphatic amine. They differ from the antipsychotic phenothiazine derivatives in which the chain usually is three

carbons long, unbranched, and usually, without substituents in the aromatic ring. Besides useful antihistaminic effects, most have pronounced sedative effects and long durations of action. Other uses include the treatment of nausea and vomiting associated with anesthesia and for the treatment of motion sickness.



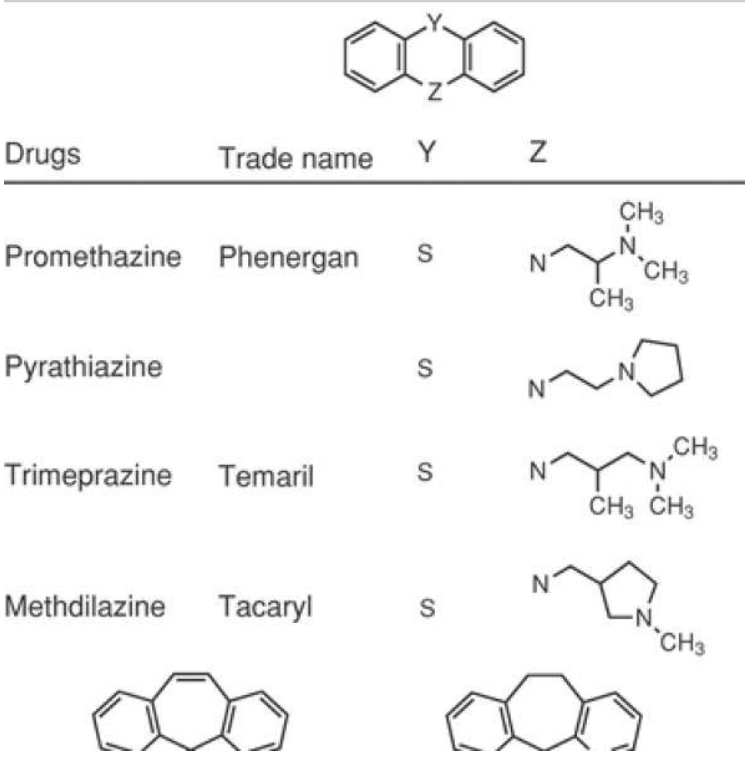
X = C, CH, N, etc.

Y = CH_2, S, O, NH, CH_2O,

Fig. 37.11. General structure of tricyclic antihistamines.

Conformational and stereochemical effects

In the active agents, the steric restrictions and decreased degrees of conformational freedom resulting from the connection of the two aromatic rings together suggests that certain spatial relationships between these two rings are acceptable in the drug–receptor interaction of H_1 antihistamines. These ring systems are not flat but, rather, are somewhat puckered, with the two aromatic rings not in the same plane. Usually, however, the conformations undergo rapid intraconversion. In some closely related systems, in which this intraconversion is very slow, conformational enantiomers (atropisomers) have been obtained and studied, including cyproheptadine, doxepine, and hydroxylated metabolites of loratadine (27,28). The enantiomers of 3-methoxycyproheptadine have significantly different pharmacological potency as antihistamines, antiserotonin, and anticholinergic agents (Fig. 37.12) (29). The (–)-isomer retained antihistaminic, antiserotonin, and appetite-stimulating effects similar to cyproheptadine, whereas the (+)-enantiomer had greater anticholinerigic potency. Differences of 9- to 60-fold have been observed in the reported assays.



Drugs	Trade name	Y	Z
Promethazine	Phenergan	S	
Pyrathiazine		S	
Trimeprazine	Temaril	S	
Methdilazine	Tacaryl	S	

Table 37.7. Examples of Tricyclic Antihistamines.

Promethazine, an early agent in the series, has many useful pharmacological affects other than being an antihistamine. It has significant antiemetic and anticholinergic properties. It also has sedative-hypnotic properties and has been used to potentiate the effects of analgesic drugs. Subsequent analogues, such as trimeprazine and methdilazine, are used as antipruritic agents in the treatment of urticaria.

Compounds in which the sulfur atom is replaced with another bridge (e.g., two methylene groups) also are available. Some have a pyridine ring replacing one of the benzenoid systems. Cyproheptadine, with a 2-carbon spacer between the aromatic rings, also has anticholinergic, antiserotonergic, and appetite-stimulating properties, which are useful in treatment of anorexic nervosa and in cachexia. The pyridine analogue apparently lacks most of these qualities. Doxepine, an oxygen-containing congener of cyproheptadine, also has significant affinity for other receptors, and it has CNS-depressant qualities. It exists as a mixture of *Z*- and *E*-isomers (15:85) in its olefinic, nonpiperidine side chain. In tissue-based assays, the *Z*-isomer is more potent than the *E*-isomer by more than threefold (27). The most widely used among the group is loratadine, which is considered to be in the category of nonsedating, second-generation antihistamines (vide infra).

Metabolism

Information regarding the metabolic disposition and pharmacokinetic properties of agents in this group is limited, including incomplete identification of primary metabolic pathways, results of liver microsomal metabolic experiments, and only occasionally, pharmacokinetic information. In humans, products from the

phenothiazines include products of N-demethylation, aromatic hydroxylation, and occasionally, sulfoxidation. From tricyclic analogues, metabolites resulting from N-demethylation, aromatic hydroxylation, and formation of N-quaternary glucuronides have been reported (30).

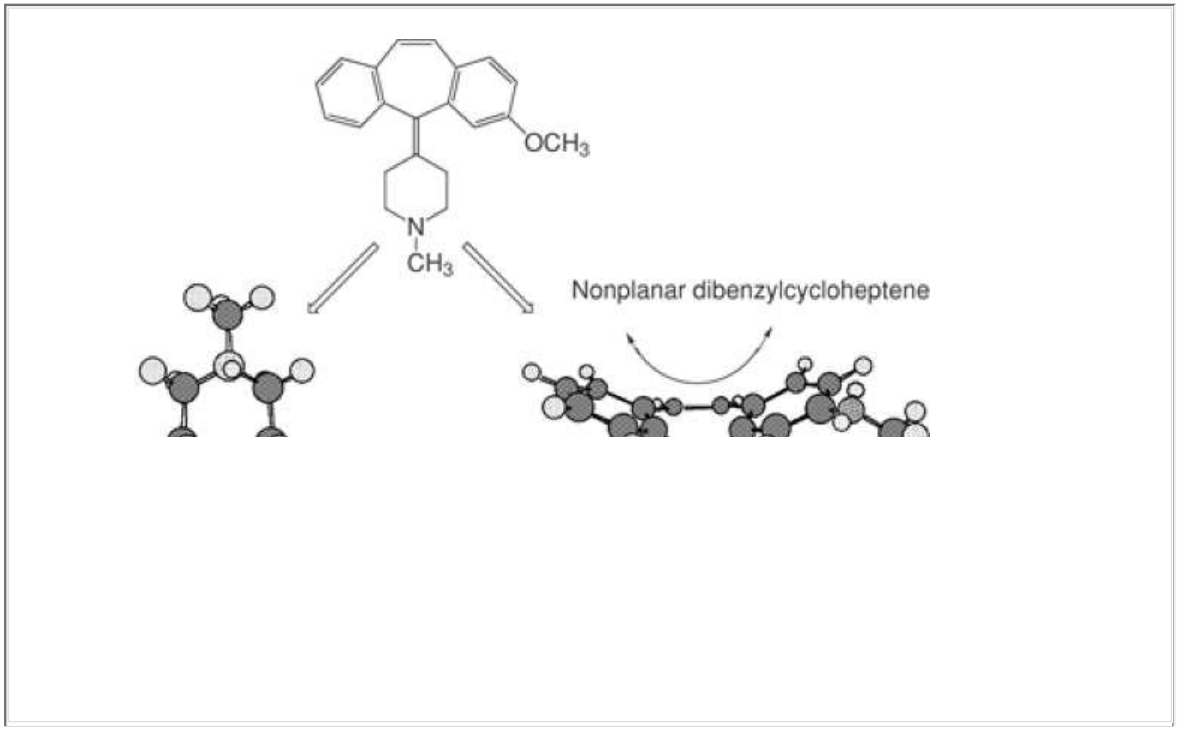


Fig. 37.12. Enantiomers (antropisomers) of 3-methoxycyproheptadine.

Second-Generation Nonsedating H_1 Antihistamines

Background

The second-generation antihistamines marketed over the last 20 to 25 years have improved H_1 selectivity, have little or no sedative qualities, and they may have antiallergic effects apart from antihistaminic activity (31). They vary widely in structure (Table 37.8) but less so in pharmacological properties, having effects principally in the periphery. Structural resemblance to the first-generation H_1 antagonists is not always obvious. because some of these agents were discovered while investigating new molecular structures for other pharmacological targets. These agents possess selective peripheral H_1 antihistaminic effects, and they usually have less anticholinergic activity. Furthermore, they also have decreased affinity for adrenergic and/or serotonergic receptors and limited CNS effects. The active agents apparently do not penetrate the blood-brain barrier significantly, perhaps because of their amphoteric nature (most are zwitterionic at physiological pH) and partitioning characteristics and/or because they are substrates for the drug efflux P-glycoprotein transporter or organic anion transporter proteins. A slow rate of dissociation from H_1 receptors also is reported for some of the agents. Several have antiallergic properties that are separate from their antihistaminic properties, which are not thoroughly understood. In most cases, the parent drug or its important metabolites have half-lives that are sufficiently long to account for the extended duration of action (32). Most are administered once daily.

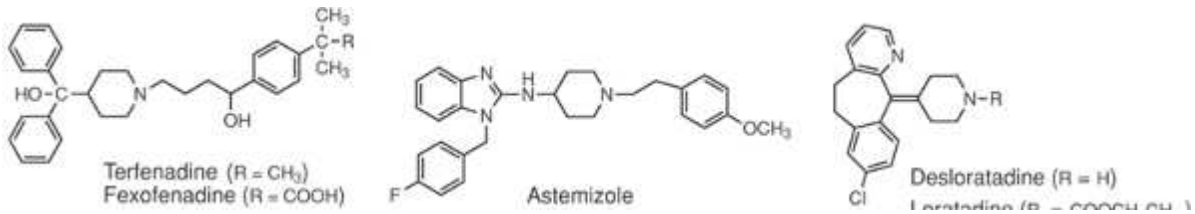

Table 37.8. Second Generation Non-sedating Antihistamines

Specific Drugs

Fexofenadine (Allegra) and terfenadine

Pharmacological Effects

This group of nonsedating antihistamines usually is thought to include fexofenadine and its parent terfenadine, astemizole, cetirizine, and loratadine and its metabolite desloratadine. Terfenadine was synthesized as an analogue of azacyclanol in a search for antipsychotic agents. The initial reports of its antihistaminic properties included the observation of similar effects of it acid metabolite fexofenadine (33). Whereas terfenadine is no longer available, it was once a very widely used nonsedating antihistamine. Extensive clinical experience resulted in the reports of dangerous cardiac arrhythmias occurring occasionally when certain other drugs were taken concomitantly. These cardiac arrhythmias included prolongation of the QT interval and torsades de pointes, a life-threatening ventricular arrhythmia. These cardiac effects are now known to be associated with blockade of the hERG (human ether-a-go-go) gene product, the α-subunit of an inward rectifying cardiac K^+ channel (34,35). These effects are associated only with the parent molecule. The side effects occur primarily at high concentrations of this lipophilic amine and, usually, in the presence of other CYP3A4 substrates, such as ketoconazole or macrolide antibiotics (e.g., triacetyloleandomycin). In the presence of competing CYP3A4 substrates and inhibitors,

high plasma concentrations of the parent agent have resulted.

Metabolism

Fexofenadine, the carboxylic acid metabolite of terfenadine, is widely available (Fig. 37.13). It accounts for the antihistaminic properties of terfenadine, which is very rapidly metabolized via CYP3A4-catalyzed processes. Members of the organic anion transporter protein family and the drug efflux transporter P-glycoprotein are involved in the disposition of fexofenadine. Fexofenadine does not have the antiarrhythmic side effects of terfenadine.

Terfenadine and other lipophilic amines (e.g. astemizole, another second-generation antihistamine that is no longer marketed, grepafloxacin, thioridazine, sertrindole, and cisapride) are all aliphatic amines containing one or more aromatic groups (34). Each has been associated with life-threatening cardiac arrhythmias associated with binding to the hERG K^1 ion channel. The disposition of each depends significantly on CYP3A4 for its oxidative metabolism so that in the presence of inhibitors or competitive substrates, significantly elevated plasma levels are observed. Screening of potential drug candidates for interaction with this ion channel in radioligand displacement assays is done routinely to attempt to develop safe new drugs. Similarly, proof of safety of agents that are primarily CYP3A4 substrates is required. Studies regarding the effect of high-dose ketoconazole on the plasma levels of the drug in vivo usually are required.

Loratadine (Claritin) and desloratadine (Clarinex)

Pharmacological Effects

Loratadine (Table 37.8) is related to the first-generation tricyclic antihistamines and to antidepressants. It is nonsedating, and neither it nor its major metabolite, desloratadine (descarboethoxyloratadine), is associated with the potentially cardiotoxic effects reported for terfenadine and astemizole. On chronic dosing, the AUC (plasma concentration–time curve) for the metabolite is greater than that for the parent drug, and its half-life is longer. Desloratadine is a more potent H_1 antagonist and more potent inhibitor of histamine release. This metabolite, which probably accounts for the effects of loratadine, has been marketed. The hydroxylated metabolite of desloratadine, the 3′-hydroxylated product, may contribute to the pharmacological properties of desloratadine (36).

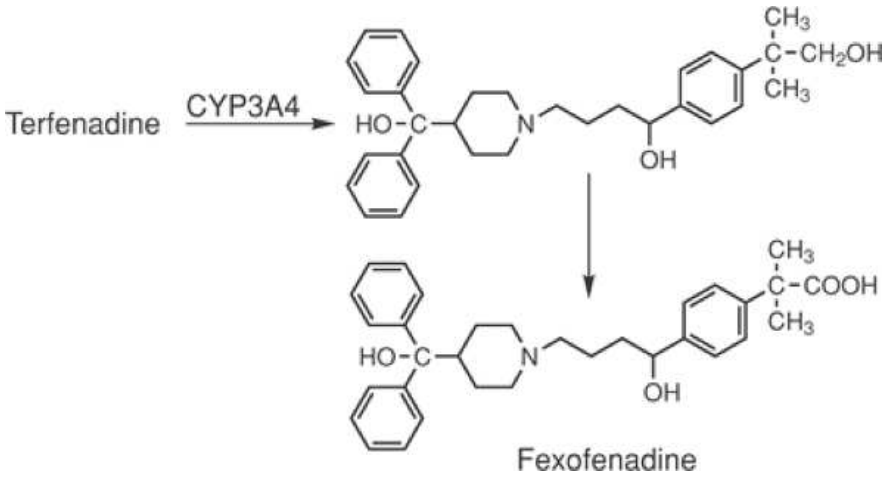

Fig. 37.13. Metabolism of terfenadine leading to fexofenadine.

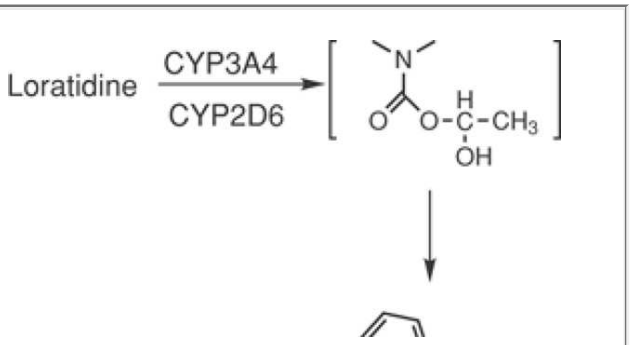

Fig. 37.14. Metabolism of loratidine.

Metabolism

The metabolic conversion of loratadine to descarboethoxyloratadine occurs via an oxidative process and not via direct hydrolysis (Fig. 37.14). Both CYP2D6 and CYP3A4 appear to be the CYP450 isozymes catalyzing this oxidative metabolic process (37). Apparently, the metabolite does not reach the CNS in significant concentrations. Among the nonsedating second-generation antihistamines, this metabolite appears to be the only nonzwitterionic species. The failure of zwitterionic molecules to reach CNS sites in significant concentrations can be rationalized readily, but a similar explanation is not apparent for loratadine or its metabolite. Competitive substrates for CYP3A4 do not produce a significant drug–drug interaction, because the parent molecule lacks effects on hERG K^1 channel in cardiac tissue.

Cetirizine (Zyrtec) and levocetirizine (Xysal, Xusal)

Cetirizine, the acid metabolite from oxidation of the primary alcohol of the antihistamine hydroxyzine (Fig. 37.15 and Table 37.6), is a widely used antihistamine (38). It has a long duration of action and is highly selective for H_1 receptors. No cardiotoxicity has been reported, but some drowsiness occurs. The *R*-enantiomer of cetirizine, levocetirizine, is marketed in Europe. Levocetirizine has higher affinity than its *S*-enantiomer for the H_1 receptor (>30-fold) and is more slowly dissociated by more than 20-fold from the receptor (39). Thus, the antihistaminic

properties of cetirizine probably are accounted for by the *R*-enantiomer. Similar large differences in ratios of dissociation rates and K_i values for closely related enantiomers also are reported.

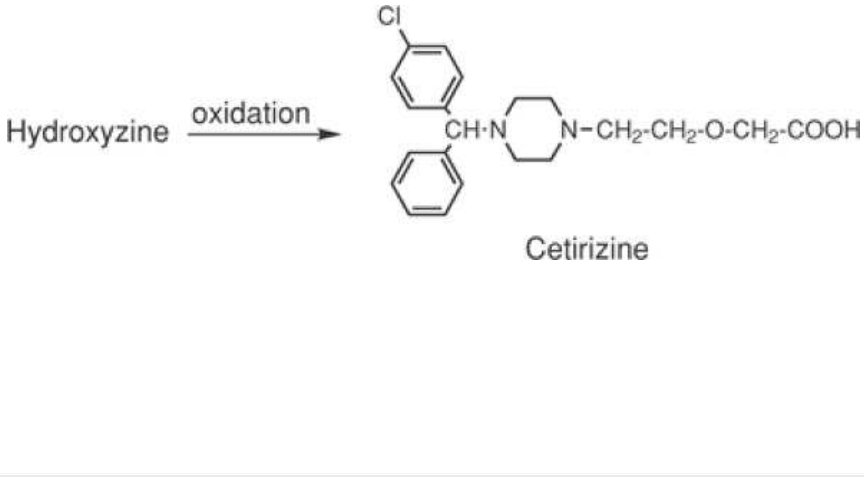

Fig. 37.15. Metabolism of hydroxyzine to cetirizine.

Acrivastine (Semprex)

Acrivastine, an acidic congener of triprolidine in which a carboxylic acid–substituted chain has been attached, also is a second-generation, nonsedating antihistamine. Penetration of the blood-brain barrier is limited, and it is less sedating than triprolidine. It is used principally in a combination with a decongestant.

Ebastine (Kestine) and carebastine

Benzhydryl ethers of piperidinols also are useful antihistamines. Those with large N-substituents, like those in terfenadine and other nonsedating antihistamines, are most successful. Ebastine (Table 37.8), which is similar structurally to terfenadine, is a potent selective H_1 antihistamine as measured in radioligand displacement assays. In these assays, its acid metabolite has significantly higher affinity than the parent molecule. It is nonsedating and, apparently, free of anticholinergic effects (40). Like some other second-generation antihistamines, ebastine blocks release of PGD_2 and leukotriene C_4/D_4 in cellular assays. Pharmacokinetic data indicate that its acid metabolite carebastine is responsible for its antihistaminic properties, because the parent drug has a very short half-life and the active metabolite a much longer one (Fig. 37.16). In an animal model of torsades de pointes, ebastine, at a high dose, produced significant cardiac conduction abnormalities (e.g., prolongation of the QT interval), whereas the metabolite did not. At lower doses, these effects occurred only in the presence of competitive CYP3A4 substrates. Some in vitro data, however, suggest CYP450 isozymes other than CYP3A4 may be important in the initial hydroxylation. The pharmacologically active acid metabolite carebastine is metabolically analogous to fexofenadine (oxidation of a t-butyl group), the acid metabolite of terfenadine.

Ebastine is marketed in several countries but not in the United States.

Mizolastine (Mizollen)

Misolastine (Table 37.8) is a second-generation, nonsedating antihistamine that structurally resembles astemizole (41). It has an extended half-life of 7.3 to 17.1 hours and is highly bound to plasma protein (~95%). Metabolism occurs primarily through glucuronidation, and only small amounts of the compound are metabolized oxidatively. The AUC increases approximately twofold in the presence of ketoconazole, a CYP3A4 substrate and inhibitor. Only weak interaction with the hERG K^1 channel is reported, along with weak interactions with muscarinic receptors. Presently, it is only available in Europe.

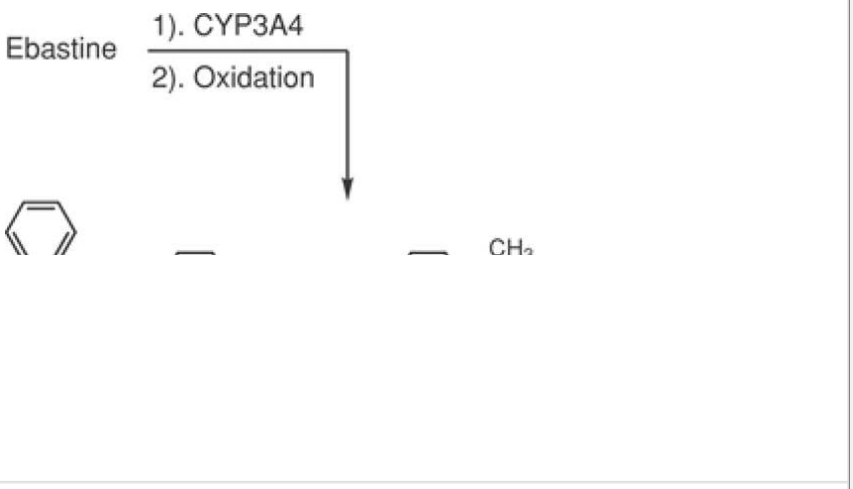

Fig. 37.16. Metabolism of ebastine to carebastine.

Topical H_1 Antihistamines

Therapeutic Applications

Topical application of H_1 antihistamines to the eye is made to relieve itching, congestion of the conjunctiva, and erythema (15,42). The density of mast cells in the conjunctiva is high, and the histamine concentrations in tear film are significant in the ocular allergic response. From eye drops, only small amounts of the antihistamine (1–5%) penetrate the cornea. More of the compound is absorbed via the conjunctiva and nasal mucosa, and still more ends up swallowed from tear duct and nasal drainage. Until recently, topical ocular antihistamines were limited to two classical agents: antazoline (Table 37.2), from the ethylenediamine series, and pheniramine (Fig. 37.9), from the alkylamine series. Both are used in combination with sympathomimetic vasoconstrictors.

A slow rate of receptor dissociation of H_1 antagonists is associated with long duration of action systemically, which occurs with the more recently available ocular antihistamines. Based on correlations of pK_a values and lipophilicity data, it appears that compounds with a log D (the sum of the partition coefficients of both the ionized and unionized species) near 1.0 60.5 at pH 7.4 are most efficacious, and their water-soluble salts also show a low incidence of ocular irritation. Relationships between partitioning characteristics of these and other antihistamines indicate (at least moderate) receptor affinity and that a particular range of optimal lipophilicity for topical ocular antihistamines with minimal ocular irritation (43). Some of these compounds are currently available (Table 37.9) or are being evaluated as nasal sprays, and some also are occasionally used as systemic antihistamines.

Specific Drugs

Olopatadine (Patanol)

Olopatadine (Table 37.9) is structurally related to the tricyclic antihistamines. It has a long duration of action when applied topically, and it also appears to inhibit the release of inflammatory mediators (e.g., histamine, tryptase, and PGD_2) from mast cells. Its selectivity for H_1 receptors in tissue assays (over H_2 and H_3 receptors) is very high, and its selectivity for H_1 receptor blockade over α-adrenergic, dopaminergic, serotonergic, and muscarinic receptors also is very high. Olopatadine is reported to have a rapid onset of action and a long duration of action, consistent with high

histamine receptor affinity and a slow rate of receptor dissociation. The presence of the carboxylic acid side chain apparently is responsible for the observed lack of muscarinic receptor affinity. This feature also may be responsible for limited penetration. Olapatadine also a mast cell stabilizer as well. The mechanism for this activity has not been delineated, but it has been shown to stabilize model cell membranes by interaction with phospholipid monolayers.

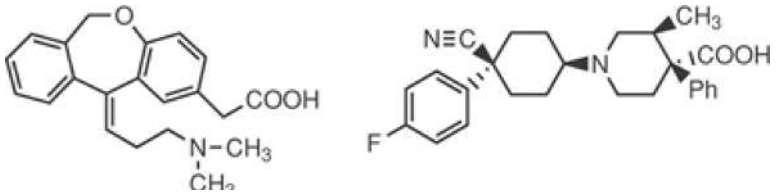

Table 37.9. Topical Antihistamines

Levocobastine (Livostin)

Levocobastine is a potent, selective H_1 receptor antagonist used topically in eye drops for

seasonal allergic conjunctivitis. A small amount of systemic absorption of the compound is reported. The agent also prevents release of transmitters from mast cells. A nasal spray used for allergic rhinitis is available outside the United States.

Emedastine (Emadine)

Emedastine also is a newer antihistamine used topically in the eye for conjunctivitis. It has very high H_1 receptor selectivity characteristics, and it is structurally related to the benzimidazoles, such as astemizole. Inhibition of mast cell release of inflammatory mediators has been noted.

Azelastine (Astelin)

Azelastine, although not a close structural analogue to the benzimidazoles, has some structural similarities to them. It is used as a nasal spray for allergic rhinitis and as eye drops for allergic conjunctivitis. Like olopatadine, azelastine also stabilizes mast cells, preventing degranulation and subsequent release of histamine, leukotrienes, and PGD_2. It is available in Europe for systemic use in the treatment of asthma and seasonal allergies. Besides antihistaminic effects, it also may block release of histamine and other inflammatory mediators from mast cells. When administered orally, the N-dealkylated metabolite appears to contribute significantly to its pharmacological effects.

Ketotifen (Zaditor)

Ketotifen is a potent, selective H_1 antihistamine that also prevents release of transmitters from mast cells. It is approved in the United States for topical use to prevent itching of the eye because of allergic conjunctivitis, It is used as a systemic antiallergy agent in several countries outside the United States for the treatment of seasonal allergic rhinitis, hay fever, and asthma. Being structurally analogous to the cyproheptadine-like antihistamines, differences in activity of the two enantiomers (atropisomers) has been noted, being approximately six- to seven-fold in ligand displacement and rodent-based assays (44). Ketotifen has been shown to stabilize mast cells and to inhibit degranulation of eosinophils. Like olopatadine, it has been shown to interact with model membranes, stabilizing them by interaction with phospholipids monolayers.

Epinastine (Elestat)

Epinastine is a potent, long-acting H_1 antihistamine and an inhibitor of the release of histamine and other transmitters from mast cells. It has some affinity for H_2 receptors as well. It is used as an eye drop for allergic conjunctivitis. It does not penetrate into the CNS and is classified as a nonsedating antihistamine.

Antiulcer Agents

Background

The secretion of gastric acid occurs at the level of parietal cells of the oxyntic gland in the gastric mucosa (Fig. 37.17), producing 2 to 3 L of gastric juice per day, pH 1 in hydrochloric acid. Ultimately, this secretory process occurs via an H^+,K^1-ATPase that exchanges hydronium ion (H_3O^+) with uptake of a potassium ion. Several mediators regulate this secretion by way of receptor systems on the basolateral membrane. The H_2 histaminergic pathway is cAMP dependent. Gastrin and muscarinic receptors also regulate the secretion of gastric acid through calcium ion dependent pathways. In parietal cells, E-series prostaglandins work in opposition to the histaminergic pathway, inhibiting histamine-stimulated adenylyl cyclase activity. Other epithelial cells in the mucosal lining under the influence of prostaglandin-mediated pathways secrete bicarbonate and mucus, both of which are important in protecting the gastric lining from the effects of acid secretion. In many cases,

hypersecretion of gastric acid appears to be associated with *Helicobacter pylori* infection, which may contribute to defects in mucosal protective defenses. Evidence suggests that some H_2 antihistamines, particularly cimetidine and ranitidine, have regulatory effects on T-cell lymphocyte proliferation by augmenting cytokine production and Ig

production. These effects may not be associated with histamine receptors and may not be shared by nizatidine and famotidine.

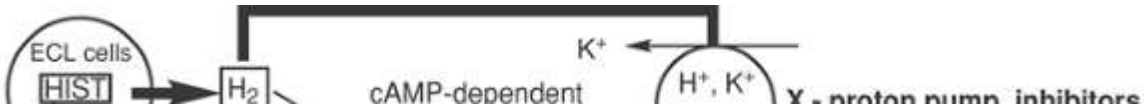

Fig. 37.17. Secretion of gastric acid and peptic ulcer disease. Histamine is secreted from and endochromaffin-like (ECL) cell, which is innervated by muscarinic receptors (M) via the enteric nervous system and by gastrin receptors (G). Agonist occupation of histamine H_2 receptors in parietal cells lead to gastric acid secretion. Other input at parietal cells includes the prostaglandins (PGs), gastrin, and muscarinic receptors. (Adapted from Hoogerwerf WA, Pasricha PJ. Pharmacotherapy of gastric acidity, peptic ulcers, and gastroesophageal reflux disease. In: Hardman JG, Limbird LE, Mollinoff PB, et al., eds. Goodman and Gilman's The Pharmacological Basis of Therapeutics. 11th Ed. New York: McGraw-Hill, 2005:968; with permission.)

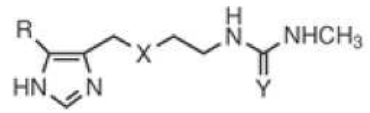
Therapeutic Applications of H_2 Antihistamines

The H_2 antihistamines are used in the treatment of duodenal ulcers, gastric ulcers, gastroesophageal reflux disease (GERD), pathological hypersensitivity disorders, and upper gastrointestinal bleeding in critically ill patients and are sold OTC for acid indigestion (45).

They also are included in multidrug treatment protocols for eradication of *H. pylori* in treatment of peptic ulcers and before surgery to prevent aspiration pneumonitis. Like H_1 antihistamines, H_2 antihistamines are inverse agonists that block the basal level of activity at this receptor. Combinations of H_1 and H_2 antihistamines are useful in idiopathic urticaria not responding to H_1 antihistamines alone and in itching and flushing of anaphylaxis, pruritis, and contact dermatitis.

Structural requirements

The H_2 antihistamines specifically designed to decrease the secretion of gastric acid are based on an extensive investigative approach to drug design that began from the structures of partial agonist molecules very closely related to histamine (46). Ultimately, this work resulted in the development of cimetidine (Table 37.10), in which the imidazole ring like that of histamine is maintained. The imidazole ring is substituted with a C-4 methyl group, which in histamine agonists affords H_2 selectivity; a four-atom side chain, which includes one sulfur atom (the sulfur atom increases potency compared to carbon and oxygen congeners); and a terminal polar nonbasic unit, in this case an N-cyanoguanidine substituent. Guanidines substituted with electron-withdrawing groups have significantly decreased basicity compared to guanidine, and they are neutral (nonprotonated) at physiological pH. Thus, these are logical substituents to replace the terminal thiourea feature in unsuccessful earlier homologous candidates, metiamide and burimamide. The former agent was not marketed because of untoward effects, including agranulocytosis, and the latter agent lacked significant oral bioavailability. Subsequently, the nitromethylene unit was a replacement of the N-cyanoimino group in the substituted guanidine analogues, affording compounds of increased potency. Replacement for the imidazole ring with other heteroaromatic rings resulted in other useful analogues.



Drug	Trade name	R	X	Y

Table 37.10. H_2 Receptor Antihistamines

Metabolism

Cimetidine, ranitidine, and famotidine are subject to first-pass metabolism, and each has oral bioavailability of approximately 50%. The oral bioavailability of nizatidine is approximately 90%. All have half-lives of 1.5 to 4.0 hours, with that of nizatidine being the shortest. Significant amounts of each of these H_2 antihistamines are excreted unchanged, with small amounts of urinary products of sulfoxidation being a common metabolic feature. As expected, hydroxylation of the imidazole C-4 methyl group of cimetidine occurs. Ranitidine is excreted largely unchanged, but minor metabolic pathways include N-demethylation as well as N- and S-oxidation. The metabolites are not thought to contribute to the therapeutic properties of the parent drugs, with the exception of nizatidine, from which the N-desmethyl metabolite retains H_2 antihistamine activity (47).

Side effects and drug interactions

Cimetidine, the earliest of these agents, shows the greatest number of drug interactions (48). Among them are somnolence and confusion in elderly patients with decreased renal function. Gynecomastia, presumably related to increased prolactin secretion, has been reported. Cimetidine inhibits CYP450-dependent metabolic processes, affording increased concentration of several agents, the most important being those having narrow therapeutic concentration windows (e.g., phenytoin, theophylline, some benzodiazepines, warfarin, and

quinidine). Inhibition of several CYP450 oxidative processes is associated with the presence of imidazole ring of cimetidine, which apparently replaces the histidine that serves as a ligand to the porphyrin iron in CYP450 enzymes. Other agents in this group contain heterocyclic rings other than imidazole and do not show this effect. Cimetidine is an inhibitor of renal tubular secretion of some drugs (e.g., procainamide). These tubular secretion effects also are less prevalent or even absent with other agents in this class. The other agents in the group are more potent than cimetidine, and significant differences are noted among them. Of these, ranitidine is the most widely used. The agents have OTC status and are widely available for gastric hyperacidity.

Proton Pump Inhibitors

Proton pump inhibitors are widely used in the treatment of duodenal and gastric ulcer, erosive esophagitis, GERD, GERD-related laryngitis, and hypersecretory conditions (e.g., Zollinger-Ellison syndrome) (49,50). The final step in acid secretion in parietal cells of the gastric mucosa is a process mediated by H^+,K^+-ATPase, the gastric proton pump, an enzyme with significant homology to Na^+,K^+-ATPase. This H^+,K^+-ATPase has some similarities to the H^+,K^+-ATPase in osteoclasts, which is involved in bone resorption. Gastric acid secretion can be inhibited in many ways. These include by antagonists at muscarinic, gastrin, or histamine H_2 receptors; by agonists at inhibitory receptors for prostaglandins and somatostatin; by proton pump inhibitors; or by carbonic anhydrase inhibitors.

Mechanism of action

Omeprazole, lansoprazole, and related analogues (Table 37.11), produce inhibition of stimulated gastric acid secretion irrespective of the receptor stimulation process. Nearly all the compounds are close structural relatives, being weakly basic 2-pyridylmethylsulfinylbenzimidazoles. An analogue, tenatoprazole, which is an imidazopyridine isostere, is currently in clinical trials.

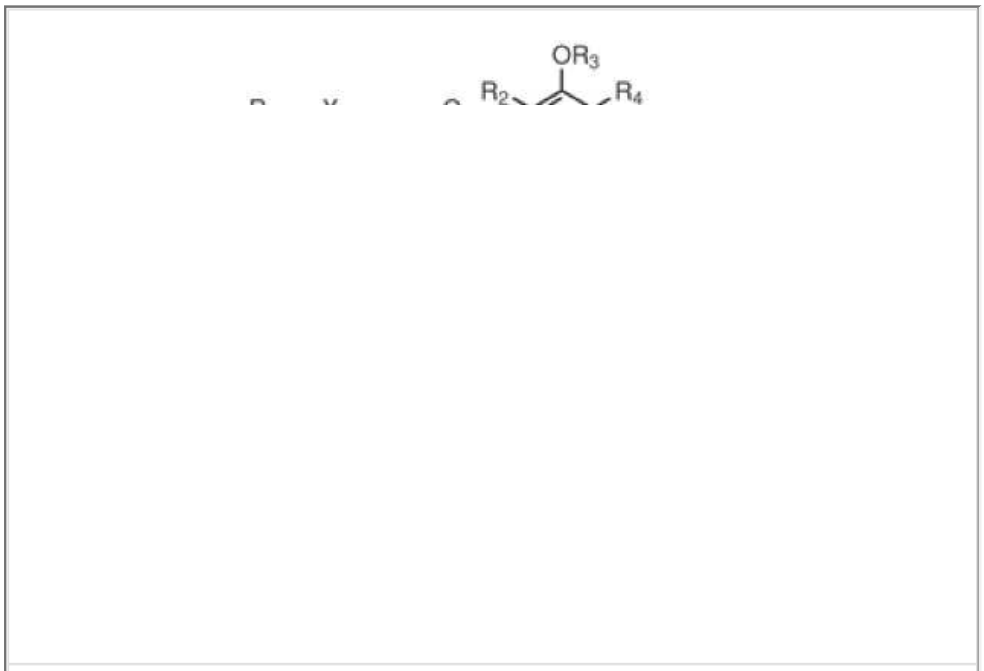


Table 37.11. H^+/K^+-ATPase Proton Pump Inhibitors

Only a few successful changes of the heterocyclic rings are possible (51). These agents have irreversible effects on the secretion of gastric acid, because the molecule rearranges in the strongly acidic environment of the parietal cell. Covalent binding of the rearranged inhibitor to

the H^+,K^+-ATPase results in inactivation of the catalytic function of the proton pump. Evidence indicates that two molecules of the intermediate from omeprazole are bound to the active site; one of these sites has been identified as cysteine-813 (and, probably, cysteine-892 and/or -822) of the cysteine-rich H^+,K^+-ATPase (52). These cysteines are in different environments (e.g., exposed to the lumen or in the membrane), and different proton pump inhibitors bind differentially to them and other sulfhydryl groups. In the covalent binding, disulfide bonds are formed with the receptor. Analogous, but slightly different, results are reported for lansoprazole, pantoprazole, and rabeprazole (53). A chemical mechanism for the process is shown in Figure 37.18.

Because the initial rearrangement only occurs at a strongly acidic pH, acid-stable oral dosage forms are used that allow dissolution, release, and absorption of drug in the duodenum (e.g., enteric-coated granules in capsules or enteric-coated tablets). More recently, granular preparations of lansoprazole (enteric-coated granules) and omeprazole (with sodium bicarbonate) have become available. Intravenous dosage forms of lansoprazole, pantoprazole and esomeprazole are also available. The acid-catalyzed rearrangement of absorbed drug then occurs selectively in the acidic environment of the canaliculus, as it is secreted into the gastric lumen from the parietal cells. Some differences may occur in the sites of binding of the agents, and differences have been noted in recovery times, with rabeprazole have a shorter duration of action (54). Tenatoprazole has the longest plasma half-life and, in testing, appears to offer better control of nocturnal hyperacidity (55).

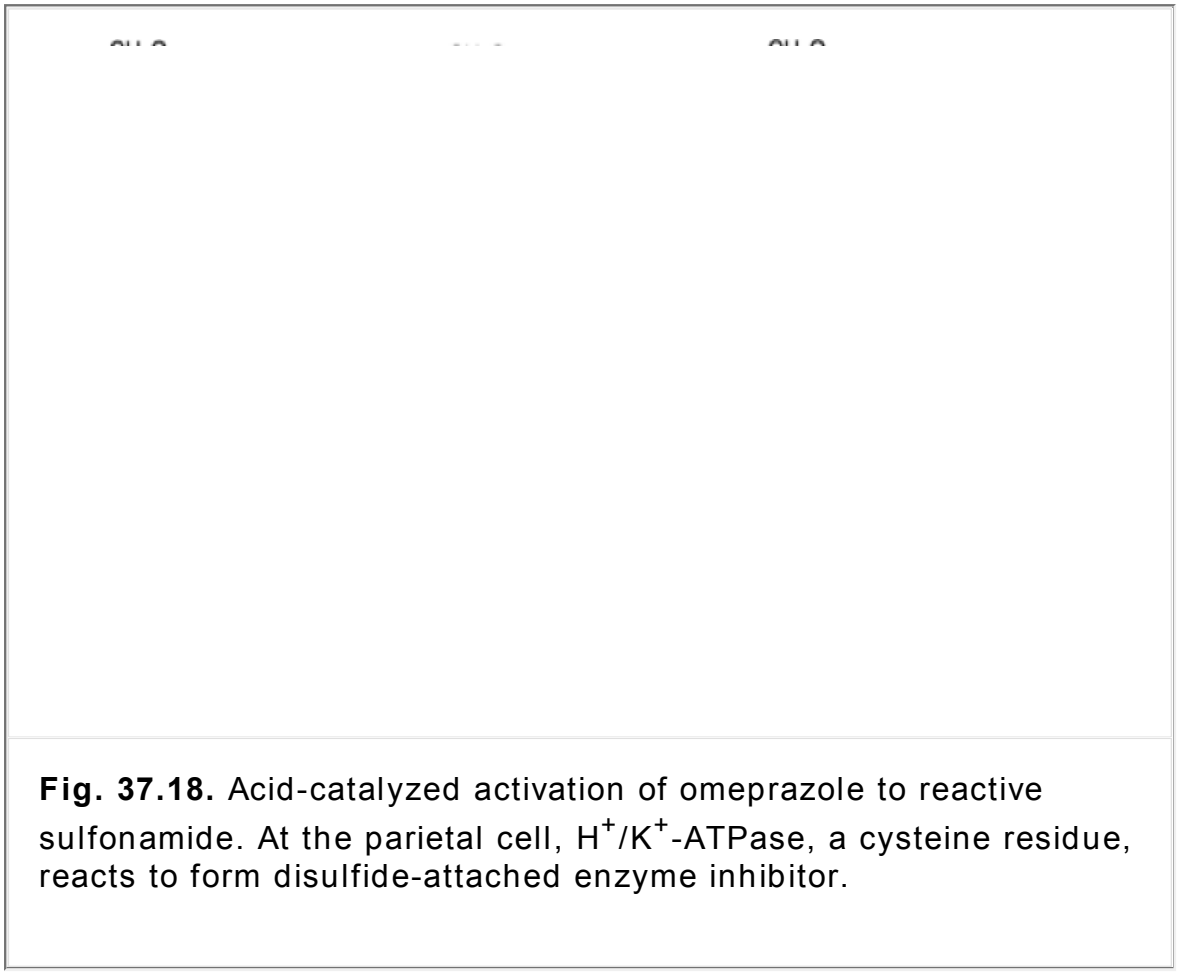

Fig. 37.18. Acid-catalyzed activation of omeprazole to reactive sulfonamide. At the parietal cell, H^+/K^+-ATPase, a cysteine residue, reacts to form disulfide-attached enzyme inhibitor.

CYP450 metabolism

Metabolism of omeprazole and other proton pump inhibitors occurs primarily in the liver (Fig. 37.19). The sulfone, hydroxylated, and O-demethylated metabolites have been reported as products. Omeprazole is a substrate primarily for CYP2C19 and may elevate concentrations of other substrates for this enzyme (e.g., diazepam) when given concurrently. The CYP3A4 contributes to a lesser extent. Further oxidation of the sulfone affords additional metabolites,

which are excreted in the feces. Lansoprazole is metabolized by analogous routes (56). Fewer drug interactions with lansoprazole have been reported, although it also is a substrate for CYP2C19.

These sulfoxides have a chiral sulfur atom, and recent publications have been reported on the effects of stereochemistry on pharmacological and dispositional characteristics. The oxidative metabolism of omeprazole is catalyzed principally by CYP2C19 (primarily 5'-hydroxylation and, to a lesser extent, benzimidazole O-demethylation) (57). In human liver microsomes, the *R*-(+)-enantiomer is cleared more rapidly, and it is almost exclusively metabolized by CYP2C19. The clearance of the *S*-(–)-enantiomer is more dependent on oxidation by CYP2C19 than on CYP3A4-mediated metabolism, primarily sulfone formation. The marketed single enantiomer, esomeprazole, provides greater bioavailability in those who are CYP2C19 extensive metabolizers and less interindividual variation in those who are CYP2C19 poor metabolizers (~3% of Caucasians and up to 15–20% of Asians). Thus, the impact of variant alleles of CYP2C19 is less on the *S*-(–)-enantiomer than on the parent racemate. Higher blood levels and greater AUCs are observed, and increases in the time at a gastric pH greater than 4.0 are observed, which are correlated with healing rates.

Different proton pump inhibitors depend differently on CYP2C19 for oxidative metabolism, and the enantiomers show variation in dependence on CYP2C19 and other pathways (principally CYP3A4). Pantoprazole and lansoprazole show greater metabolism via CYP2C19, with the enantiomers being affected differently, than rabeprazole, which is metabolized only to a small extent by oxidative CYP450 enzymes.

Fig. 37.19. Oxidation sites and CYP450 isozymes in the metabolism of omeprazole.

Combination therapy in Helicobacter pylori infections

The majority of peptic ulcers are related to *H. pylori* infections and nonsteroidal anti-inflammatory drug (NSAID) therapy. *Helicobacter pylori* apparently penetrates the layer of gastric mucus by producing ammonia and carbon dioxide (urease-catalyzed hydrolysis of urea) to withstand the acidic environment of the stomach. More than 90% of patients with duodenal ulcer, excluding those with gastrinoma or taking NSAIDs, show the presence of *H. pylori*. Determination of *H. pylori* infection is routinely performed by measuring production of carbon dioxide (breath) or bicarbonate (blood) after oral administration of ^{13}C- or ^{14}C-labeled urea. Endoscopic examination and antigen-based serological tests may be used as confirmation (58). Eradication of *H. pylori* markedly decreases the incidence of ulcer recurrence. Several regimens of antibiotic therapy, widely used with proton pump inhibitors or

less commonly with H_2-antagonists, are effective. Double- and triple-drug combinations, such as proton pump inhibitors with amoxicillin and clarithromycin or metronidazole, are used.

Competitive K^+ Inhibitors

Newer agents that block gastric acid secretion at the H^+,K^+-ATPase by binding as competitive inhibitors at the K^+ binding site are under development (Fig. 37.20) (45,49). An initial compound, SCH 28080, was hepatotoxic. Newer agents have included soraprazan and revaprazan. Each of them binds ionically to the proton pump at or near the K^+ binding site. Revaprazan has reached clinical trials. Studies to determine whether these or other related compounds can become useful drugs are ongoing.

Prokinetic Agents

Prokinetic drugs like metoclopramide, cisapride, and levosulpiride increase esophageal sphincter pressure and enhance peristalsis and gastric emptying, thus counteracting factors that lead to esophagitis (Fig. 37.21) (59). These agents appear to be 5-HT_4 partial agonists in the enteric nervous system, leading to release of acetylcholine. In addition, metoclopramide and levosulpiride are dopamine D_2 antagonists. Metoclopromide is used in GERD, in diabetic gastroparesis, and in nausea and vomiting of emetogenic cancer chemotherapy. Cisapride was removed from the U.S. prescription market because of metabolism-based interactions. In the presence of competing CYP3A4 substrates, high concentrations of the parent molecule lead to life-threatening cardiac arrhythmias via interaction with the hERG K^+ channel, similar to H_1 antihistamines terfenadine and astemizole. It is available only through an investigational limited-access program. Levosulpiride is available in Europe. Tegaserod (Zelnorm), also a selective 5-HT_4 partial agonist used in irritable bowel syndrome in women, has been used successfully in critically ill patients with gastroparesis.

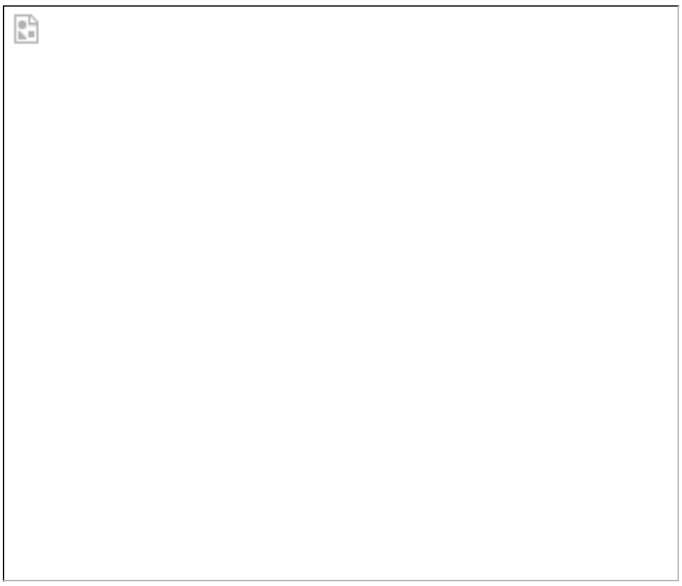

Fig. 37.20. Examples of proton pump competitive K^+ inhibitors.

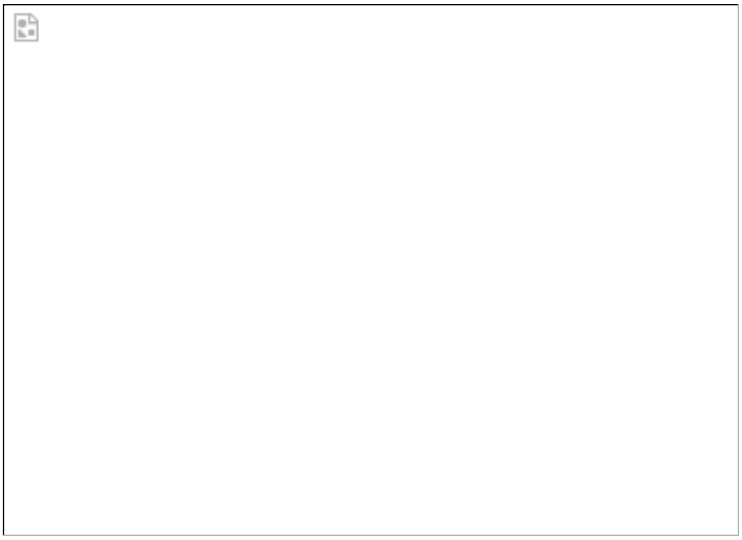

Fig. 37.21. Examples of prokinetic agents.

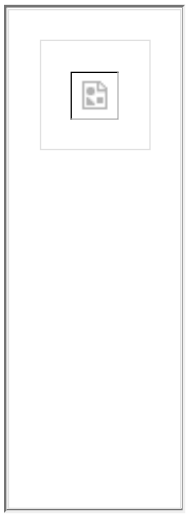
Prostaglandins

Prostaglandins have antisecretory effects on gastric acid (Fig. 37.17). Besides inhibiting adenylyl cyclase activity in parietal cells, which results in secretion of gastric acid, prostaglandins stimulate secretion of mucus and bicarbonate in adjacent superficial cells. Cytoprotective effects of endogenous E-series prostaglandins and of other, more stable synthetic congeners are observed. The only available oral prostaglandin in the United States is misoprostol. The orally administered carboxylic acid ester is hydrolyzed to the pharmacologically active carboxylic acid. It is a synthetic analogue of prostaglandin E_1, in which structural changes at C-13,14,15,16 are made to prevent rapid metabolic conversion to inactive products. The presence of the tertiary alcohol 1-carbon removed to C-16 obviates the usual conversion of the allylic secondary alcohol ($\Delta^{13,14}$-15-alcohol) of prostaglandins to the corresponding saturated ketones. A mixture of diastereomers of misoprostol is used; most of the activity arises from the 11*R*,16*S*-isomer (60). Misoprostol reduces basal levels of gastric acid secretion, but it has considerable smooth muscle contraction effects.



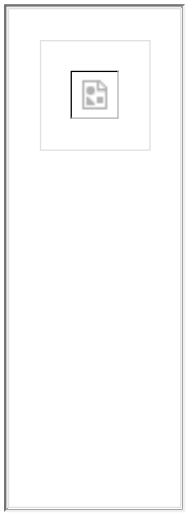
Therapeutic applications and side effects

In the United States, misoprostol is administered with some current NSAIDs to reduce the risk

of complications of gastric ulceration and bleeding. A primary mechanism of action by NSAIDs is derived from their inhibition of formation of prostaglandins from arachidonic acid. A prostaglandin may be added for the duration of NSAID therapy. A combination product of diclofenac (an NSAID) and misoprostol is available. Unlabelled uses of misoprostol include treatment of duodenal ulcers, for which it appears to be effective, and in the treatment of duodenal ulcers unresponsive to H_2 antagonists. In other countries, it has been used in the treatment of duodenal ulcers.

Significant side effects are those associated with its abortifacient properties and other smooth muscle contraction effects, e.g., diarrhea and abdominal pain. Misoprostol also is an effective cervical ripening agent (by vaginal application) for the induction of labor. Other unlabeled uses include the treatment of postpartum hemorrhage and, with mifepristone, termination of pregnancy.

Sucralfate and Insoluble Bismuth Preparations



Sucralfate is a complex of the sulfuric acid ester of sucrose and aluminum hydroxide. Secondary polymerization with aluminum hydroxide forms intermolecular bridges between molecules of sulfate esters with aluminum (61). Limited dissociation of the complex occurs in gastric acid, but these anionic sulfate esters form insoluble adherent complexes with the proteinaceous exudate at the abraded surface of a crater of the ulcerated area in the stomach. This physical complex protects the ulcer from the erosive action of pepsin and bile salts. Sucralfate also stimulates synthesis and release of prostaglandins, bicarbonate, and epidermal and fibroblast growth factors. Significant ulcer healing effects are noted in placebo-controlled trials. Only small amounts of sucralfate are absorbed systemically. In renal impairment, there is a risk of accumulation of absorbed aluminum from the drug. Sucralfate reduces absorption of other drugs, including H_2 antihistamines, quinolone antibiotics, phenytoin, and perhaps, warfarin (62).

Bismuth-containing preparations (e.g., those containing colloidal bismuth subcitrate) have effects similar to those of sucralfate, apparently because of their similar physical properties and coating effects. A combination of ranitidine–bismuth citrate is used with clarithromycin for eradication of *H. pylori* in the treatment and prevention of recurrence of duodenal ulcers. Combinations of bismuth subcitrate with other antibiotics and with H_2 antihistamines also are used. Bismuth subsalicylate is used in this way as well.

H3 Receptor Agonists and Antagonists

Physiological Role of H_3 Receptors

The H_3 receptor was identified as an autoreceptor that regulates the release of histamine. Histaminergic neurons are located primarily in the hippocampus, projecting to all major areas

of the brain. These neurons are involved with the regulation of sleep and wakefulness and in feeding and memory (13). The H_3 receptor also is a heteroreceptor in the CNS, where it is involved in the regulation of synthesis and release of other neurotransmitters. In addition, H_3 heteroreceptors have been identified in peripheral tissues, including the airway and gastrointestinal tract.

H_3 Agonists and Antagonists

Several H_3 agonists and antagonists have been studied (Table 37.12). *R*-α-methylhistamine is a more potent agonist than histamine. The addition of methyl groups to the side chain or to the aliphatic amine nitrogen of histamine usually results in potent H_3 agonists, such as α,α-dimethylhistamine, *R*-α,*S*-β-dimethylhistamine, and N-methyl- and N-ethylhistamine, unlike the deleterious effect of these

changes on H_1 and H_2 agonist activity. Other selective agonists are the isothiourea imetit, immepip and its N-methyl analogue (methimepip), both substituted piperidines, immethridine, a pyridine congener of immepip, and SCH 50971. All retain the imidazole ring of histamine.

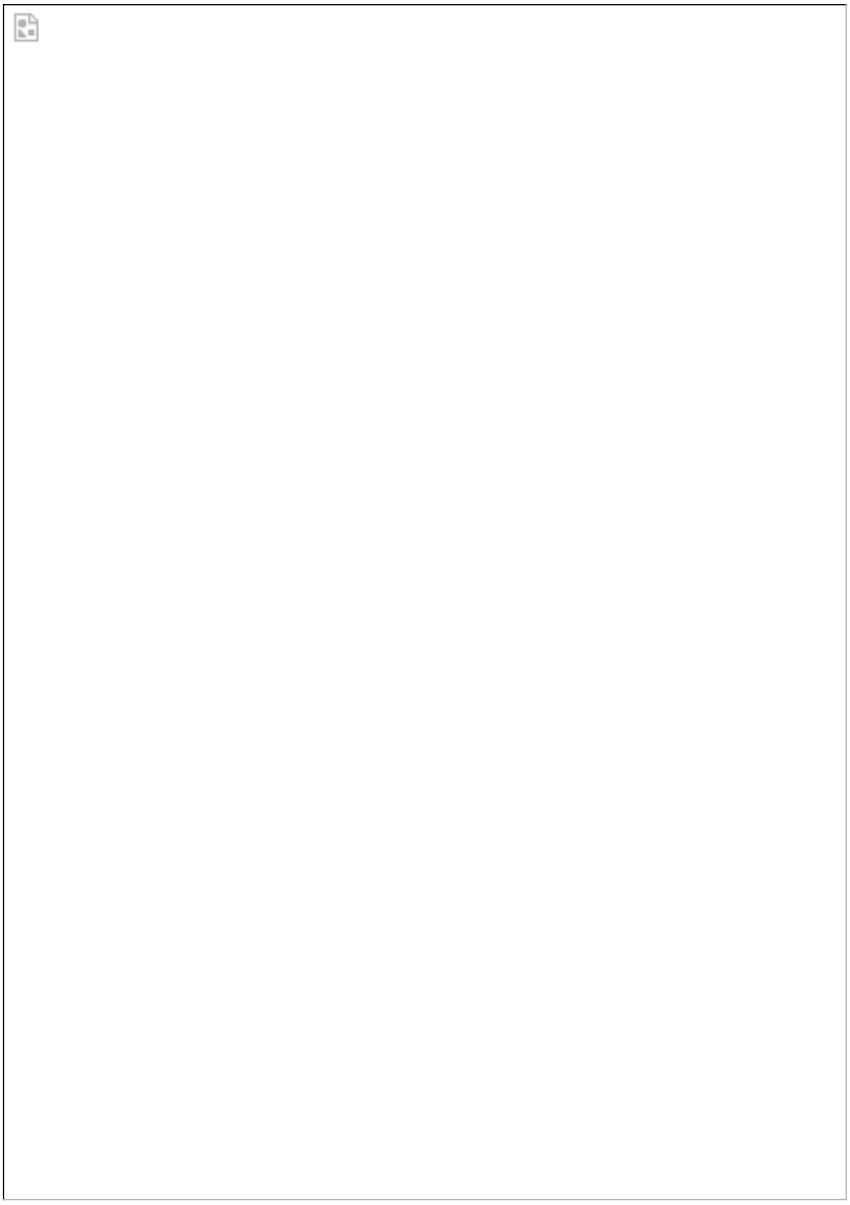


Table 37.12. Examples of H_3 Agonists and Antagonists

Early H_3 antagonists, like thioperamide and clobenpropit analogues of immepip and imetit, respectively, are primarily pharmacological tools. Like the H_3 agonists, these agents retain the imidazole group but possess widely varying N-substituents. Some of the imidazole-containing agonist and antagonist analogues have affinity for other receptors (e.g., some α-adrenergic receptor subtypes), and they have the potential to interact with CYP450 enzymes as an iron–porphyrin ligand. Thus, nonimidazole-containing ligands have been sought.

Allergic rhinitis is one condition in which H_3 antihistamines may be useful. Thioperamide and clobenpropit are effective in animal models alone and in combination with H_1 antihistamines. Dual H_1/H_3 antihistamines are being studied, including a chlorpheniramine analogue that incorporates the imidazole alkylamine group of many H_3 antagonists (Table 37.12).

Centrally acting H_3 antagonists are under study by several drug companies. Agents are sought for a variety of disorders. These include treatment of depression, mild cognitive impairment, Alzheimer's disease, schizophrenia, narcolepsy, obesity, and attention-deficient hyperactivity disorder. Two examples are JNJ 5207852 (63), a compound that increases

wakefulness, and ABT-239, a compound that is being evaluated for treatment of cognition related disorders (64).

H_4 Receptor Agonists and Antagonists

Physiological Role of H_4 Receptors

The H_4 receptor is expressed in mast cells, eosinophils, and other cells of hematopoietic lineage, including basophils and T cells. It is a relatively recent discovery; thus, much is not yet understood about its physiological role. It is thought to play a role in inflammatory responses, especially in the mediation of chemotactic responses. Its sequence homology is greatest with the H_3 receptor (35–40%) and is very low versus H_1 and H_2 receptors (65).

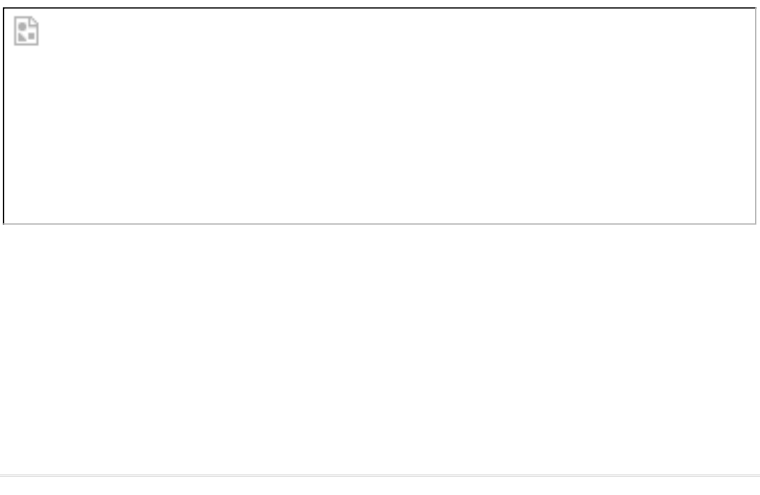

Fig. 37.22. Other ligands at the H_4 receptor.

H_4 Agonists and Antagonists

Classical leukocyte chemoattractant effects that occur are blocked by thioperamide, an H_3/H_4 antihistamine. Other H_3 receptor ligands, such as *R*-α-methylhistamine and imetit, also are agonists at H_4 receptors, but they have lower affinity than at H_3 receptors (Table 37.12). Clobenpropit is a partial agonist at H_4 receptors, but it is an H_3 antihistamine (inverse agonist). Thioperamide is an inverse agonist at H_4 and H_3 receptors. 4-Methylhistamine (Fig. 37.22) has greater affinity (>100-fold) for H_4 receptors than other histamine receptor subtypes (66).

A selective H_4 antihistamine has recently been reported, JNJ 7777120 (Fig. 37.22). It blocks many mediated functions, including histamine-induced chemotaxis in mast cells and eosinophils (67). Conditions in which H_4 antagonists might be useful include autoimmune inflammatory and allergic disorders, including rheumatoid arthritis, asthma, and allergic rhinitis. Nasal stuffiness and blockage in allergic rhinitis, conditions that are poorly treated with H_1 and H_2 antihistamines, suggest the possible use of H_4 antihistamines in these conditions as well.

Case Study

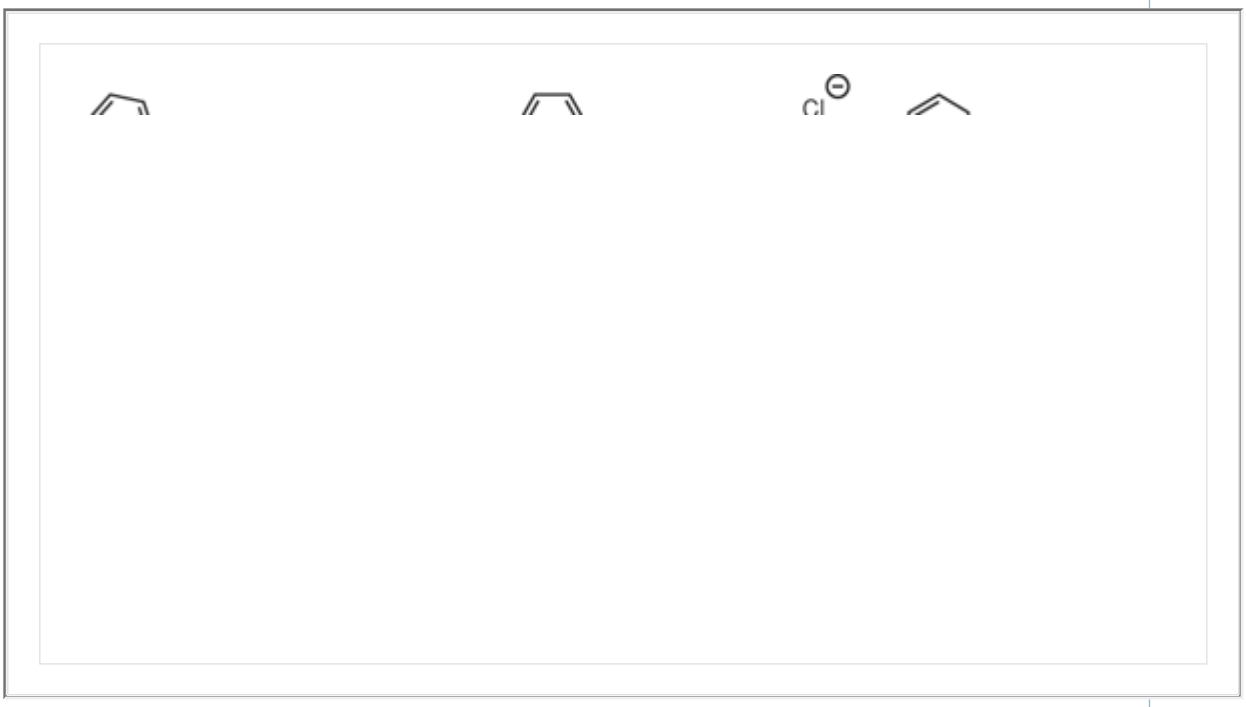
Victoria F. Roche

S. William Zito

BL is a 71-year-old financial advisor on vacation at the Gulf Coast with his wife of 47

years. It has been a therapeutic getaway, especially for Mrs. BL, who lost her central vision to exudative macular degeneration 18 months ago. While they hate to see their week of surf, sun, and relaxation come to an end, they are really looking forward to the drive to Albuquerque they will begin tomorrow for the wedding of their only granddaughter. On their last Gulf Shore night, they made reservations for a gala evening aboard the cruise ship *Chichibabin*, complete with dancing to the area's best Dixieland jazz band and a sumptuous buffet of Cajun foods. They had a ball, but unfortunately, BL experienced a severe allergic reaction to the crayfish he consumed (he ate two dozen) and had to be taken off the ship to the emergency room, where he received an injection of hydrocortisone. Although he can now breathe easier, he still has a red, itchy, and unsightly rash on the upper half of his body, including his arms, hands, and face. In addition to being uncomfortable, he is worried about how he will look for his granddaughter's big day.

Before heading out on their drive to Albuquerque, BL and his wife stop at a local pharmacy for some calamine lotion and an antihistamine to keep BL comfortable on the trip. He will be behind the wheel the whole way, because his wife can no longer see well enough to drive. As the pharmacist on duty that day, consider the antihistaminic structures below, and provide this couple with some much-needed pharmaceutical care.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 38

Antibiotics and Antimicrobial Agents

Lester A. Mitscher

Thomas L. Lemke

Elmer J. Gentry

Drugs covered in this chapter:

Antibacterials

- Methenamine
- Phosphomycin
- Quinolone class
- Sulfonamide class
- Trimethoprim

Antibiotics

- Penicillin class
  - Ampicillin
  - Amoxacillin
  - Bacampicillin
  - Benzylpenicillin
  - Carbenicillin and indanyl carbenicillin
  - Clavulanic acid
  - Methicillin
  - Mezlocillin and piperacillin
  - Nafcillin
  - Oxacillin, cloxacillin, and dicloxacillin
  - Phenoxymethyl penicillin
  - Piperacillin and tazobactam
  - Sulbactam
  - Ticarcillin
- Cephalosporin class
  - Cefaclor
  - Cefadroxil
  - Cefamandole nafate
  - Cefazolin
  - Cefdinir
  - Cefditoren pivoxil
  - Cefepime
  - Cefixime
  - Cefmetazole
  - Cefonicid
  - Cefoperazone
  - Cefotaxime

- Cefotetan
- Cefoxitin
- Cefpodoxime proxetil
- Cefprozil
- Ceftazidime
- Ceftibuten
- Ceftizoxime
- Ceftriaxone
- Cefuroxime
- Cephalexin
- Cephapirin
- Cephradine
- Loracarbef

- Carbapenems
  - Ertapenem
  - Imipenem
  - Meropenem
- Monobactams
  - Aztreonam
- Aminoglycosides
  - Amikacin
  - Gentamicin
  - Kanamycin
  - Neomycin
  - Spectinomycin
  - Tobramycin
- Macrolides and ketolides
  - Azithromycin
  - Clarithromycin
  - Erythromycin estolate
  - Erythromycin ethylsuccinate
  - Erythromycin stearate
  - Telithromycin
  - Lincosamides
    - Clindamycin
    - Lincomycin
  - Tetracyclines and glycylcyclines
    - Demeclocycline
    - Doxycycline
    - Oxytetracycline
    - Minocycline
    - Tetracycline
    - Tigecycline
  - Bacitracin
  - Chloramphenicol

- Daptomycin
- Linezolid
- Mupirocin
- Polymyxin B
- Quinupristin/dalfopristin
- Vancomycin

Introduction

Antibiotics are microbial metabolites or synthetic analogues inspired by them that, in small doses, inhibit the growth and survival of microorganisms without serious toxicity to the host. Selective toxicity is the key concept. Antibiotics are among the most frequently prescribed medications today, although microbial resistance resulting from evolutionary pressures and misuse threatens their continued efficacy. In many cases, the clinical utility of natural antibiotics has been enhanced through medicinal chemical manipulation of the original structure, leading to broader antimicrobial spectrum, greater potency, lesser toxicity, more convenient administration, and additional pharmacokinetic advantages. Through customary usage, the many synthetic substances that are unrelated to natural products but still inhibit or kill microorganisms are referred to as antimicrobial agents instead.

Because of a significant decrease in the pace of novel anti-infective discovery, increased regulatory constraints, and greater profits to be made by the use of medications for chronic conditions, there is presently a decreased research emphasis on antimicrobial agents. This coincides with a dramatic increase in microbial resistance to chemotherapy, that portends a bleak future in which humankind may once again face infectious diseases with few available countermeasures.

Our environment, body surfaces, and cavities support a rich and characteristic microbial flora. These cause us no significant illness or inconvenience as long as our neighbors or we do not indulge in behavior that exposes us to exceptional quantities or unusual strains of microbes or introduces bacteria into parts of the body where they are not normally resident. Protection against this happening is obtained primarily through public

health measures, healthful habits, intact skin and mucosal barriers, and a properly functioning immune system. All parts of our bodies that are in contact with the environment support microbial life. It is estimated that 1 g of feces contains approximately 10^{13} microorganisms! All our internal fluids, organs, and body structures, however, are sterile under normal circumstances, and the presence of bacteria, fungi, viruses, or other organisms in these places is diagnostic evidence of infection. When mild microbial disease occurs, the otherwise healthy patient often will recover without requiring treatment. Here, an intact, functioning immune system is called on to kill invasive microorganisms. When this is insufficient to protect us, appropriate therapeutic intervention is indicated.

Clinical Significance

The treatment of bacterial infections is one of the few disease states that all clinicians are guaranteed to be challenged with at some time in their career. Because bacteria are constantly changing, the selection of appropriate antimicrobial therapy is crucial in providing efficacious treatment of infections. It is of the utmost importance that clinicians understand the medicinal chemistry of antimicrobial agents to choose the most effective therapy for their patients. Antimicrobial resistance trends are constantly changing and vary from institution to institution, so a complete understanding of the structural relationship differences between antibiotics, even in the same class, is helpful in selecting the most appropriate therapy for an individual patient. In addition, side chains and subtle structural differences within antimicrobial classes can change the side-effect profiles of these agents. The informed clinician therefore can optimize their treatment choices from patient to patient while avoiding severe adverse effects.

The development of newer and more effective antimicrobial agents is essential in the fight against

infectious diseases. Understanding the medicinal chemistry of the older and newer antimicrobial agents helps the clinician to comprehend their differences in antimicrobial spectrum and side-effect profile. Newer antibiotics are continuously being developed; however, many of them are from antimicrobial classes already established, with only small changes on the functional groups and/or side chains leading to dramatic differences in their antimicrobial spectrum. As stated previously, bacteria are constantly changing, as are antimicrobial susceptibility patterns. To optimize patient care, a clinician needs to stay informed about the effects of the medicinal chemistry differences as newer drugs come to market and antimicrobial resistance trends change.

Elizabeth Coyle Pharm.D.
Clinical Assistant Professor, Department of Clinical Sciences & Administration, University of Houston College of Pharmacy

The chronicle of civilization before the discovery of bacteria and their role in infectious disease and, subsequently, the discovery of antibiotics and antimicrobial agents is punctuated by the outbreak of recurrent, devastating pandemics. An example is the successive waves of bubonic plague that dramatically decreased the population of Europe during the Middle Ages. Humankind was mystified as to the cause of infectious disease and what one might constructively do for prevention and cure. In warfare, infections often disabled or killed more individuals than the action of generals did. Our own family histories record the premature loss of loved ones, particularly small children, to one infection or another, and in the Third World, this pattern remains all too common today. This depressing picture was altered dramatically in the 20th century by the discovery and application of the powerful therapeutic agents described in this chapter. Fortunately, it no longer is common for persons to live short lives, and it now is rare for parents to bury their children. Public health measures, such as purification of water supplies, proper sewage disposal, routine preventive vaccination, pasteurization of milk, improved personal hygiene, and avoidance of unhealthy behavior (e.g., spitting in public places) also have greatly diminished our exposure to infection.

Considering that the first truly effective antimicrobial agents date from the mid-1930s (the sulfonamides) and the first antibiotics came into use in the 1940s (the penicillins), it is amazing that we have already grown complacent. Diseases that very recently seemed to be on their way to extinction, such as tuberculosis and gonorrhea, are once again becoming serious public health problems because of societal changes, persistent poverty, lack of education, ease of international travel, and the emergence of resistance by pathogens. It is disturbing to consider that previously unknown infectious diseases, such as acquired immunodeficiency syndrome (AIDS), Ebola virus infections, and Legionnaires' disease, are an increasing feature of modern life. Unfortunately, we can no longer confidently depend on the discovery of increasing numbers of novel antibiotics and antimicrobial agents to keep infectious diseases under control, but we must increasingly pay attention to neglected public health measures and concentrate on using antibiotics only when those measures fail.

History

Humankind has been subject to infection by microorganisms since before the dawn of recorded history. One presumes that humankind has been searching for suitable

therapy for nearly as long. This was a desperately difficult enterprise given the acute nature of most infections and the nearly total lack of understanding about their origins that was prevalent until the last century. One can find indications in old medical writings of folkloric use of plant and animal preparations, soybean curd, moldy bread and cheese, counterinfection with other microbes, the slow development of public health measures, and an understanding of the desirability of personal cleanliness, but these factors were erratically and inefficiently applied and, when they were applied, often failed. Until the discovery of bacteria 300 years ago and the subsequent understanding of their role in infection about 150 years ago, there was no hope for rational therapy.

In Germany during the 19th century, Robert Koch showed that specific microorganisms could always be isolated from the excreta and tissues of people with particular infectious diseases and that these same microorganisms usually were absent in healthy individuals. They could then be grown on culture media and be administered to healthy individuals to reproduce in those healthy individuals all the classic symptoms of the same disease. Finally, the identical microorganism could then be isolated from this deliberately infected

person. Following these rules, at long last, a chain of evidence connecting cause and effect was forged between certain microorganisms and specific infectious diseases. This work laid the foundation for rational prevention of and therapy for infectious diseases.

In 1877, Louis Pasteur reported that when what he termed “common bacteria” were introduced into a pure culture of anthrax bacilli, the bacilli died, and that an injection of deadly anthrax bacilli into a laboratory animal was harmless if “common bacteria” were injected along with it. This did not always work, but it did lead to the appreciation of antibiosis, wherein two or more microorganisms competed with one another for survival. Not until more than a half century later, however, did the underlying mechanisms begin to be appreciated and applied to achieve successful therapy.

The modern anti-infective era opened with the discovery of the sulfonamides in France and Germany in 1936 as an offshoot of Paul Ehrlich's earlier achievements in treating infections with organometallics and his theories of vital staining. The discovery of the utility of sulfanilamide was acknowledged by the awarding of a Nobel Prize in 1938. The well-known observation of a clear zone of inhibition (lysis) in a bacterial colony surrounding a colony of contaminating airborne *Penicillium* mold by Alexander Fleming in England in 1929, and the subsequent purification of penicillin from it in the late 1930s and early 1940s by Florey, Chain, Abraham, and Heatley, provided important additional impetus. With the first successful clinical trial of crude penicillin on February 12, 1941, and the requirements of wartime, an explosion of successful activity ensued that continues some 65 years later. In rapid succession, deliberate searches of the metabolic products of a wide variety of soil microbes led to the discovery of tyrothricin (1939), streptomycin (1943), chloramphenicol (1947), chlortetracycline (1948), neomycin (1949), and erythromycin (1952). These discoveries ushered in the age of the so-called “miracle drugs.”

Microbes of soil origin remain to this day the most fruitful sources of antibiotics, although the specific means employed for their discovery are infinitely more sophisticated today than those employed 50 years ago. Initially, extracts of fermentations were screened simply for their ability to kill pathogenic microorganisms in vitro. Those that did were pushed along through ever more complex pharmacological and toxicological tests in attempts to discover clinically useful agents. Today, many thousands of such extracts of increasingly exotic microbes are tested each week, and the tests now include sophisticated assays for agents operating through particular biochemical mechanisms or possessing particular desirable properties.

Today, combinatorial chemical synthesis coupled with high-throughput screening make it possible to screen, in a short time, hundreds of thousands of compounds for antimicrobial activity. This is coupled with dramatic advances in all the relevant sciences. One would logically suppose that this would lead to the emergence of a large number of new antimicrobial agents. That this is yet to happen, however, is a measure of the complexity of the task. The impact of genomics and proteomics is predicted to have a favorable impact on this effort. The genome of *Haemophilus influenzae* was determined in 1995, and a decade later, more than 200 microbial genomes have been deciphered and are publicly available (http://www.ncbi.nlm.nih.gov /genomes/Complete.html). Of the 1,709 genes of *H. influenzae*, it is thought that 256 are potentially essential and, thus, are targets for antimicrobial drug development. These exciting new possibilities have yet to yield practical results, however, because of to the inherent complexity of the task.

In the year 2005, annual worldwide commerce in antibiotics was measured in multiple tons and was valued in excess of $10 billion. About half of this was associated with β-lactam antibiotics alone. Approximately 20% of the most frequently prescribed outpatient medications in the United States are anti-infective agents. Approximately 100 antibiotics have seen substantial clinical use, representing the most attractive of more than 20,000 known natural antibiotics and an order of magnitude more semisynthetic and totally synthetic antimicrobial agents. These agents have had a major impact on the practice of medicine and pharmacy and on the lives of persons still living, who remember well the perils and uncertainties of life before antibiotics became available.

This salubrious picture has an increasing dark side, however, because of the growing impact of bacterial resistance. Intrinsic resistance to antimicrobial agents (resistance present before exposure to antibiotics) was recognized from the beginning. Some bacteria are immune to treatment from the outset, because they do not take up the antibiotic or lack a susceptible target. Starting in the 1940s, however, and encountered with

increasing frequency to this day, bacteria that previously were expected to respond were found to be resistant. Alarmingly, many became resistant during the course of chemotherapy, and others were simultaneously resistant to several different antibiotics. The latter were found to be capable of passing on

this trait to other bacteria—even to those belonging to different genera. Similar findings are now encountered with fungi, viruses, and even tumors, indicating that this is a general biological phenomenon. The spread of this phenomenon is abetted by their short generation time (measured in fractions of an hour) and genetic versatility as well as by poor antibiotic prescription and utilization practices. Some authorities predict an impending return to the defenseless days of the preantibiotic era. For example, in the United Kingdom, resistance of the important Gram-positive pathogen *Staphylococcus aureus* has risen from approximately 2% in the 1990s to nearly 42% by the year 2000. Resistance to vancomycin in the United States among patients infected with *Enterococcus faecium* amounts to approximately 20 to 30%; such resistance was almost unknown a decade ago. Many other microbes and medicaments could be cited as well. An understanding of these phenomena and the devising of appropriate practical response measures are important contemporary priorities.

General Therapeutic Approach

Drug Nomenclature

The names given to antimicrobials and antibiotics are as varied as their inventor's taste; however, some helpful unifying conventions are followed. For example, the penicillins are derived from fungi and have names ending in the suffix -cillin, as in ampicillin. The cephalosporins likewise are fungal products, although their names mostly begin with the prefix cef- (or, sometimes, following the English practice, ceph-). The synthetic fluoroquinolones mostly end in the suffix -floxacin. Although helpful in many respects, this nomenclature does result in many related substances possessing quite similar names. This can make remembering them a burden. Most of the remaining antibiotics are produced by fermentation of soil microorganisms belonging to various *Streptomyces* species. By convention, these have names ending in the suffix -mycin, as in streptomycin. Some prominent antibiotics are produced by fermentation of various soil microbes known as *Micromonospora* sp.; these antibiotics have names ending in -micin, as in gentamicin. The student has to take considerable care to avoid confusing them.

In earlier times, the terms “broad spectrum” and “narrow spectrum” had specific clinical meaning. The widespread emergence of microbes resistant to single agents and to multiple agents, however, has made these terms much less meaningful. Nonetheless, it still is valuable to remember that some antimicrobial families have the potential of inhibiting a wide range of bacterial genera belonging to both Gram-positive and Gram-negative cultures and so are called broad spectrum (e.g., the tetracyclines). Others inhibit only a few bacterial genera and are called narrow spectrum (e.g., the glycopeptides, typified by vancomycin, which are used almost exclusively for a few Gram-positive and anaerobic microorganisms).

The Importance of Pathogen Identification

Empiric-Based Therapy

Fundamental to appropriate antimicrobial therapy is an appreciation that individual species of bacteria are associated with particular infective diseases and that specific antibiotics are more likely to be useful than others for killing them. Sometimes, this can be used as the basis for successful empiric therapy. For example, first-course, community-acquired urinary tract infections in otherwise healthy individuals are most commonly caused by Gram-negative *Escherichia coli* of fecal origin. Even just knowing this much can give the physician several convenient choices for useful therapy. Likewise, skin infections, such as boils, are commonly the result of infection with Gram-positive *Staphylococcus aureus*. In most other cases, however, the cause of the disease is less obvious, and so, likewise, is the agent that might be useful against it. It is important to determine the specific disease that one is dealing with in these cases and what susceptibility patterns are exhibited by the causative microorganism. Knowing these factors

enables the clinician to narrow the range of therapeutic choices. The only certainty, however, is that inability of a given antibiotic to kill or inhibit a given pathogen in vitro is a virtual guarantee that the drug will fail in vivo. Unfortunately, activity in vitro all too often also results in failure to cure in vivo, but here, at least, there is a significant possibility of success. Before the emergence of widespread bacterial resistance, identification of the causative microorganism often was sufficient for selecting a useful antibiotic. Today, however, this is only a useful first step, and much more detailed laboratory studies are needed to make a successful choice.

Gram Stain

Hans C.J. Gram, a Danish microbiologist, developed the Gram method for staining bacteria so that they were more readily visible under the microscope. The term has proven to be particularly useful in describing antibiotics as well, because antibiotics are conveniently classified by their activity against microorganisms depending on their reaction to this method. Gram-positive microorganisms are stained blue by contact with a methyl violet–iodine process. This is largely a consequence of their lack of an outer membrane and the nature of the thick cell wall surrounding them. Gram-negative microorganisms do not retain the methyl violet–iodine stain when washed with alcohol but, rather, are colored pink when subsequently treated with the red dye safranin. The lipopolysaccharides on their outer membrane apparently are responsible for the staining behavior of Gram-negative cells.

Because the Gram stain is dependent on the outer layers of bacterial cells and this also strongly influences the ability of antimicrobial agents to reach their cellular targets, knowing the Gram-staining behavior of infectious bacteria helps one to decide which antimicrobial might be effective in therapy.

Not all bacteria can be stained by the Gram procedure, however, and these often require special staining processes for visualization. Among the more prominent of these for our purposes are the mycobacteria (the causative agents of tuberculosis, for example). These very waxy cells are called acid-fast and are stained by carbol fuchsin instead.

Experimentally Based Therapy

The modern clinical application of Koch's discoveries to the selection of an appropriate antibiotic involves sampling infectious material from a patient before instituting anti-infective chemotherapy, culturing the microorganism on suitable growth media, and identifying its genus and species. The bacterium in question is then grown in the presence of a variety of antibiotics to see which of them will inhibit its growth or survival and what concentrations will be needed to achieve this result. This is expressed in units of minimum inhibitory concentration (MIC). This term refers to that concentration that will inhibit 99% or more of the microbe in question, and it represents the minimum quantity that must reach the site of the infection to be useful. These concepts are illustrated in Figure 38.1.

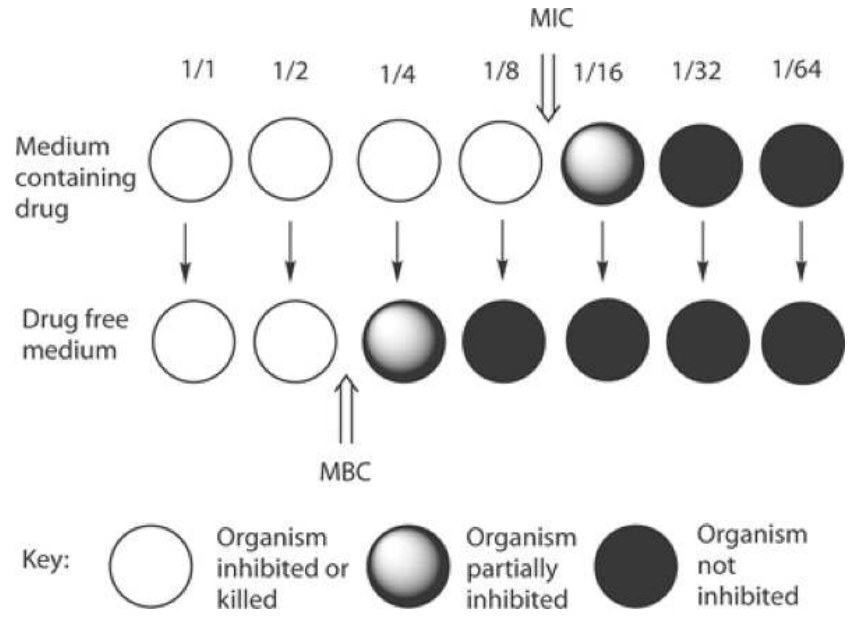

Fig. 38.1. In the top tubes (viewed from the top), a serially decreasing amount of antimicrobial agent is added to a suitable growth medium inoculated with a

microorganism. Following incubation, microbial growth is detected by turbidity. The last concentration which produces no visible growth is scored as the minimum inhibitory concentration (MIC) (1/8). Next, a loopful is taken from each tube and placed in fresh medium not containing antibiotic (bottom row). In tubes where the organisms were killed by the drugs, there is no resumption of growth. Where the organisms were inhibited but not killed, removal of drug allows resumption growth. The last concentration that produces no visible growth under these conditions is scored as the minimum bactericidal concentration (MBC) (1⁄2).

To “cure” the infection, it usually is desirable to have several multiples of the MIC at the site of infection. This requires not only an understanding of the MIC but also an understanding of pharmacokinetic and pharmacodynamic considerations as well as the results of accumulated clinical experience. The choice of anti-infective agent is made from among those that are active. One of the most convenient experimental procedures is that of Kirby and Bauer. With their technique, sterile disks of filter paper impregnated with fixed doses of commercially available antibiotics are placed on the seeded Petri dish. The dish is then incubated at 37°C for 12 to 24 hours. If the antibiotic is active against the particular strain of bacterium isolated from the particular patient, a clear zone of inhibition will be seen around the disk. If a given antimicrobial agent is ineffective, the bacterium may even grow right up to the edge of the disk. The diameter of the inhibition zone is directly proportional to the degree of sensitivity of the bacterial strain and the concentration of the antibiotic in question. Currently, a given zone size in millimeters is dictated above which the bacterium is sensitive and below which it is resistant. When the zone size obtained is near this breakpoint (the breakpoint represents the maximum clinically achievable concentration of an anti-infective agent), the drug is regarded as being intermediate in sensitivity, and clinical failure can occur. This powerful methodology gives the clinician a choice of possible antibiotics to use in the particular patient and is illustrated in Figure 38.2. The widespread occurrence of resistance of individual strains of bacteria to given antibiotics reinforces the need to perform Kirby-Bauer susceptibility disk testing, but other laboratory methods can be employed for similar purposes. Of particular note are the E test strips, which utilize the

same idea but employ a gradient of drug concentrations on a filter-paper strip.

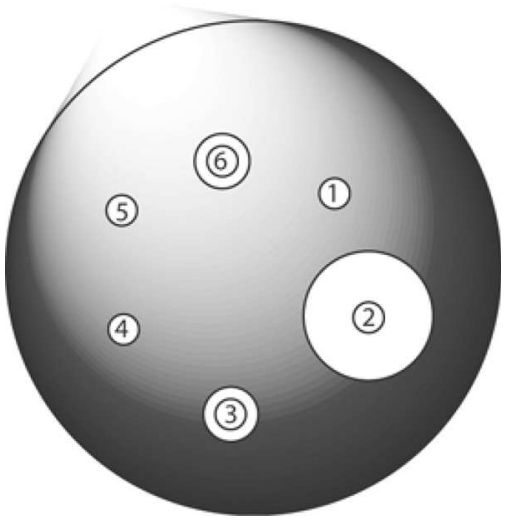

Fig. 38.2. Looking down on a Petri dish containing solidified nutrient agar to which had been added a suspension of a bacterial species. Next, six filter-paper disks containing six different antimicrobials was added followed by overnight incubation. The antimicrobials in disks 1, 4, and 5 were inactive. Of

the active agents in disks 2, 3, and 6, antibiotic 2 was much more active, because the microorganism was not able to grow as near this impregnated disk.

This high level of scientific medicine requires significant expertise and equipment, so it is practiced mainly in urban medical centers. In office practice, the choice of medicinal agents is more commonly made empirically.

Bactericidal Versus Bacteriostatic

Almost all antibiotics have the capacity to be bactericidal in vitro; that is, they will kill bacteria if the concentration or dose is sufficiently high. In the laboratory, it is almost always possible to use such doses. Subsequent inoculation of fresh, antibiotic-free media with a culture that has been so treated will not produce growth of the culture, because the cells are dead. When such doses are achievable in live patients, such drugs are clinically bactericidal. At somewhat lower concentrations, bacterial multiplication is prevented even though the microorganism remains viable (bacteriostatic action).

The smallest concentration that will kill a bacterial colony is the minimum bactericidal concentration. The difference between a minimum bactericidal dose and a bacteriostatic dose is characteristic of given families of antibiotics. With gentamicin, for example, doubling or quadrupling the dose changes the effect on bacteria from bacteriostatic to bactericidal. Such bactericidal doses usually are achievable in the clinic. The difference between bactericidal and bacteriostatic doses with tetracycline is approximately 40-fold. It is not possible to achieve such doses safely in patients, so tetracycline is referred to as clinically bacteriostatic. If a bacteriostatic antibiotic is withdrawn prematurely from a patient, the microorganism can resume growth and the infection reestablish itself, because the culture is still alive. In this case, subsequent inoculation of fresh laboratory media not containing the antibiotic will result in colony development. Obviously, in immunocompromised patients who are unable to contribute natural body defenses to fight their own disease, having the drug kill the bacteria is essential for recovery. On the other hand, when a patient is immunocompetent or the infection is not severe, a bacteriostatic concentration will break the fulminating stage of the infection (when bacterial cell numbers are increasing at a logarithmic rate). With *Escherichia coli*, for example, the number of cells doubles every 2 hours. A bacteriostatic agent will interrupt this rapid growth and give the immune system a chance to deal with the disease. Cure usually follows if the numbers of live bacteria are not excessive at this time. Thus, whereas it is preferred that an antibiotic be bactericidal, bacteriostatic antibiotics are widely used and usually satisfactory. Obviously, however, patients should not skip doses or prematurely stop treatment.

Microbial Susceptibility

Resistance

Resistance is the failure of microorganisms to be killed or inhibited by antimicrobial treatment. Resistance can either be intrinsic (exist before exposure to drug) or acquired (develop subsequent to exposure to a drug). Resistance of bacteria to the toxic effects of antimicrobial agents and to antibiotics develops fairly easily both in the laboratory and in the clinic and is an ever-increasing public health hazard. Challenging a culture in the laboratory with sublethal quantities of an antibiotic kills the most intrinsically sensitive percentage of the strains in the colony. Those not killed or seriously inhibited continue to grow and have access to the remainder of the nutrients. A mutation to lower sensitivity also enables individual bacteria to survive against the selecting pressure of the antimicrobial agent. If the culture is treated several times in succession with sublethal doses in this manner, the concentration of antibiotic required to prevent growth becomes ever higher. When the origin of this form of resistance is explored, it almost always is found to result from an alteration in the biochemistry of the colony so that the molecular target of the antibiotic becomes less sensitive, or it can result from decreased uptake of antibiotic into the cells. This is genomically preserved and passes to the next generation by reproductive fission. The altered progeny may be weaker than the wild strain so that they die out if the antibiotic is not present to give them a competitive advantage. In some cases, additional compensatory mutations can occur that restore the vigor of the resistant organisms. Resistance of this type usually is expressed toward other antibiotics with the same mode of action and, therefore, is a familial characteristic—most tetracyclines, for example, show extensive

cross-resistance with other agents in the tetracycline family. This is very enlightening with respect to discovery of the molecular mode of action, but it is not very relevant to the clinical situation.

In the clinic, resistance more commonly takes place by Resistance (R) factor mechanisms. In the more lurid examples, enzymes are elaborated that attack the antibiotic and inactivate it. Mutations leading to resistance occur by many mechanisms. They can result from point mutations, insertions, deletions, inversions, duplications, and transpositions of segments of genes or by acquisition of foreign DNA from plasmids, bacteriophages, and transposable genetic elements. The genetic material coding for this form of resistance very often is carried on extrachromosomic elements consisting of small, circular DNA molecules known as plasmids. A bacterial cell may have many plasmids or none. The plasmid may carry DNA for several different enzymes capable of destroying structurally dissimilar antibiotics. Such plasmid DNA may migrate within the cell from plasmid to plasmid or from plasmid to chromosome by a process known as transposition. Such plasmids may migrate from cell to cell by conjugation (passage through a sexual pilus), transduction (carriage by a virus vector), or transformation (excretion of DNA from cell A and its subsequent uptake by cell B). These mechanisms can convert an antibiotic-sensitive cell to an antibiotic-resistant cell. This can take place many times in a bacterium's already short generation time. The positive selecting pressure of inadequate levels

of an antibiotic favors explosive spread of R-factor resistance. This provides a rationale for conservative but aggressive application of appropriate antimicrobial chemotherapy. Bacterial resistance generally is mediated through one of three mechanisms: 1) failure of the drug to penetrate into or stay in the cell, 2) destruction of the drug by defensive enzymes, or 3) alterations in the cellular target of the enzymes. It rarely is an all-or-nothing effect. In many cases, a resistant microorganism can still be controlled by achievable, though higher, doses than are required to control sensitive populations.

Persistence

Sensitive bacteria may not all be killed. Survivors are thought to have been resting (not metabolizing) during the drug treatment time and, therefore, to remain viable when tested subsequently. These bacteria are still sensitive to the drug even though they survived an otherwise toxic dose. Some bacteria also can aggregate in films. A poorly penetrating antibiotic may not reach the cells lying deep within such a film. Such cells, although intrinsically sensitive, may survive antibiotic treatment. Bacteria living in host cells or in cysts also are harder to reach by drugs and so are more difficult to control.

Postantibiotic Effect

Some antibiotics exert a significant toxicity to certain microorganisms that persists for a time after the drug is withdrawn and the concentration of drug in the blood falls below the MIC. A constant multiple of the MIC of a drug may not be essential for therapeutic success when a postantibiotic effect (PAE) is operating, because the microbe is still affected for a time after the drug is withdrawn. The PAE is defined by the time required for a 10-fold increase in viable bacterial colonies to occur after exposure to a single dose of the antimicrobial agent. The pharmacological basis for this effect is not clear. It is speculated that adherence to the intercellular target prevents some significant quantity of the antimicrobial agent from being washed away for a time. Others believe that there are other drug-related effects that injure the bacterium and that it is only slowly able to repair. Some as-yet-undiscovered cause might be at play. Under some conditions, a PAE can be detected for days in the chemotherapy of mycobacterial infections. The PAE has been observed for a variety of antibiotics, and its duration varies with the drug, the organism, the concentration of drug, and the duration of treatment. This phenomenon can be used to assist in patient compliance by decreasing the frequency and the length of chemotherapy; however, it also may lead to drug resistance and should be employed conservatively.

Biphasic (“Eagle”) Effect

The biphasic effect is associated primarily with β-lactam antibiotics. It is a curious phenomenon in which low doses in vitro against certain bacteria (staphylococci and streptococci) produce lysis, whereas higher doses do not. This is believed to result from the differential sensitivity of the penicillin binding proteins (see below for an explanation of this term) in that higher doses of β-lactams inhibit the autolysins (this term also will be defined later). These are enzymes that also contribute to bacterial lysis.

Inoculum Effect

In a number of cases, microbial resistance is mediated by the production of bacterial enzymes that attack the antibiotic molecule, changing its structure to an inactive form. This can lead to a so-called inoculum effect, in which a susceptible antibiotic is apparently less potent when larger numbers of bacteria are present in the medium than when fewer cells are employed. The more bacteria that are present, the more antibiotic-destroying enzyme that is present, and the more antibiotic that is required to overcome this to achieve the desired response. An antibiotic that is not enzyme modified is comparatively free of inoculum effects.

Antimicrobial Dosing

Combination Therapy

The student may suppose that use of combinations of antibiotics would be superior to the use of individual antibiotics, because this would broaden the antimicrobial spectrum and make the accurate identification of the pathogen less critical. It has been found, however, by experiment that all too often, such combinations are antagonistic. A useful generalization, but one that is not always correct, is that one often may successfully combine two bactericidal antibiotics, particularly if their molecular mode of action is different. A common example is the use of a β-lactam antibiotic and an aminoglycoside for first-day empiric therapy of overwhelming sepsis of unknown etiology. Therapy must be instituted as soon after a specimen is obtained, or the patient may die. This often does not allow the microbiological laboratory sufficient time to identify the offending microorganism or to determine its antibiotic susceptibility. An emergency resort therefore is made to what is termed “shotgun therapy.” Both of the antibiotic families applied in this example are bactericidal in readily achievable parenteral doses. As will be detailed later in this chapter, the β-lactams inhibit bacterial cell wall formation, and the aminoglycosides interfere with protein biosynthesis and membrane function. Their modes of action are supplementary. Because of toxicity considerations and the potential for untoward side effects, this empiric therapy is replaced by suitable specific monotherapy at the first opportunity after the sensitivity of the offending bacterium is experimentally established.

One also often may successfully combine two bacteriostatic antibiotics for special purposes, such as a macrolide and a sulfonamide. Occasionally, these are used in combination for the treatment of an upper respiratory tract infection caused by *Haemophilus influenzae*, because the combination of a protein biosynthesis inhibitor and an

inhibitor of DNA biosynthesis gives fewer relapses than the use of either agent alone. The use of a bacteriostatic agent, such as tetracycline, in combination with a bactericidal agent, such as a β-lactam, usually is discouraged. The β-lactam antibiotics are much more effective when used against growing cultures, and a bacteriostatic agent interferes with bacterial growth, often giving an indifferent or antagonistic response when such agents are combined. Additional possible disadvantages of combination chemotherapy are higher cost, greater likelihood of side effects, and difficulties in demonstrating synergism in humans. The rising tide of antibiotic resistance is overcoming these reservations, however, and combination therapy is becoming more common.

Serum Protein Binding

The influence of serum protein binding on antibiotic effectiveness is fairly straightforward. It is considered in most instances that the percentage of antibiotic that is protein bound is not available at that moment for the treatment of infections and, therefore, must be subtracted from the total blood level to get the effective blood level. The tightness of the binding also is a consideration. Thus, a heavily and firmly serum protein-bound antibiotic would not generally be a good choice for the treatment of septicemias or infections in deep tissue, even though the microorganism involved is susceptible during in vitro tests. If the antibiotic is rapidly released from protein bondage, however, this factor decreases in importance, and the binding becomes a depot source. Distinguishing between these two types of protein binding is accomplished by comparing the percentages of binding to the excretion half-life. A highly bound but readily released antibiotic will have a comparatively short half-life and work well for systemic infections. Normally, an antibiotic that is not significantly protein bound will be rapidly excreted and have a short half-life. Thus, some protein binding of poorly water-soluble agents generally is regarded as being helpful. The student will recall that under most circumstances, the urine is a protein-free filtrate, so the proportion of an antibiotic that is firmly bound to

serum proteins will be retained in the blood. Thus, a highly and firmly protein-bound antibiotic could be satisfactory for mild urinary tract infections.

Preferred Means of Dosing

Under ideal circumstances, it is desirable for an antibiotic to be available in both parenteral and oral forms. Whereas there is no question that the convenience of oral medication makes this ideal for outpatient and community use, very ill patients often require parenteral therapy. It would be consistent with today's practice of discharging patients “quicker and sicker” to send them home from the hospital with an efficacious oral version of the same antibiotic that led to the possibility of discharge in the first place. In that way, the patient would not have to come back to the hospital at intervals for drug administration, nor would one have to risk treatment failure by starting therapy with a new drug. For drugs with significant toxicities, the physician will prefer the injection form; the physician using this method is certain that the whole dose has been taken at the appropriate time. If the local pharmacist is adept at administration of parenteral medication, these considerations become less important. Employing directly observed therapy also avoids many aspects of noncompliance. For patients with highly contagious and dangerous infections, such as tuberculosis and HIV, directly observed therapy is increasingly the treatment mode of choice.

Initiation of Therapy

Because bacteria multiply rapidly—populations often double in 0.5 to 3.0 hours—it is important to institute antibiotic therapy as soon as possible. Thus, it often is desirable to initiate therapy with a double (loading) dose and then to follow this with smaller (maintenance) doses. To prevent relapse, the patient must be instructed not to skip doses and to take all of the medication provided, even though the presenting symptoms (e.g., diarrhea or fever) may resolve before the entire drug is taken. All too often, treatment failure and the emergence of resistance probably is caused by poor compliance or premature cessation of therapy by the patient.

Prophylactic Use of Antibiotics

Antibiotics often are used prophylactically, such as in preoperative bowel sanitization and orally for treatment of viral sore throats. These are not sound practices, because the patient is exposed to the possibility both of drug-associated side effects and a suprainfection by drug-resistant microorganisms. Moreover, the therapeutic gain from such practices often is marginal. As frustrating as this may be to the infectious diseases specialist, however, these are common medical practices and, hence, are difficult to stop.

Agricultural Use of Antibiotics

It is estimated that half of the antibiotics of commerce are used for agricultural purposes. Their use for treatment of infections of plants and animals is not to be discouraged so long as the drug residues from the treatment do not contaminate foods. In contamination, problems

such as penicillin allergy or subsequent infection higher up the food chain by drug-resistant microbes can occur. Several instances of death in humans have been recorded in the 1990s from such incidents. Animals grow demonstrably more rapidly to marketable size when antibiotics are added to their feed, even though the animals have no apparent infection. This is believed to result, in large part, from suppression of subclinical infections that, consequently, would divert protein biosynthesis from muscle and tissue growth into proteins needed to combat the infection. Under appropriate conditions, antibiotic feed supplementation is responsible, in part, for the comparative wholesomeness and cheapness of our food supplies. This practice has the potential, however, to contaminate the food that we consume or to provide reservoirs of drug-resistant enteric microorganisms. Occasionally, infections are traced to this cause, and resistance genes can originate in this manner and pass from strain to strain—and even to other species.

Cost

Antibiotics often are expensive, but so are morbidity and mortality. Nonetheless, for many patients, cost is a significant consideration. The pharmacist is in an ideal position to guide both the physician and the patient on the question of possible alternative, equivalent treatments that might be more affordable. The most frequent comparisons are based on the cost of the usual dose of a given

agent for a single course of therapy (usually the wholesale cost to the pharmacist for 10 days worth of drug).

Therapeutic Classes

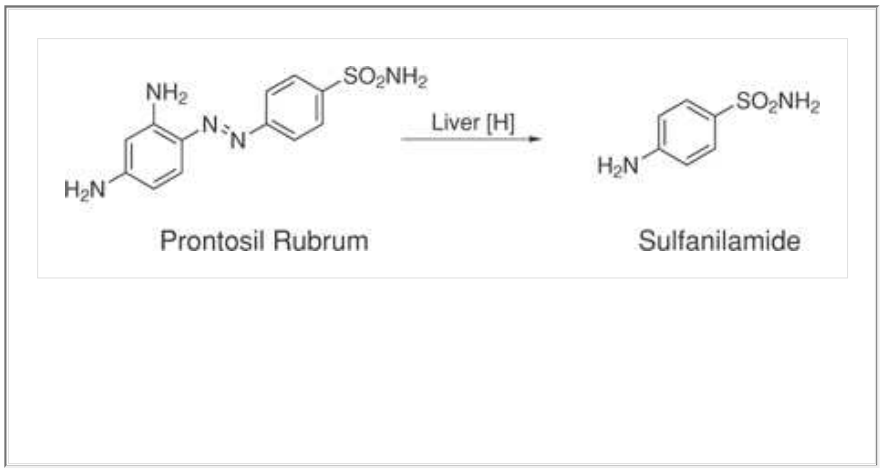
Synthetic Antimicrobial Agents

Synthetic antimicrobial agents have not been modeled after any natural product, so they may not properly be termed "antibiotics." Some synthetics are extremely effective for treatment of infections and are widely used. Very few antibiotics are known to work in precisely the same way as these agents in killing bacteria. Also curious is the fact that those agents, for which the molecular mode of action is known, are at present nearly all effective against key enzymes needed for the biosynthesis or functioning of nucleic acids. Because they interrupt the biosynthesis or functions of nucleic acids rather than attack the finished products or substitute for them in nucleic acids, they are not genotoxic but are comparatively safe to use.

Sulfonamides

Introduction

The antibacterial properties of the sulfonamides were discovered in the mid-1930s following an incorrect hypothesis but after observing the results carefully and drawing correct conclusions. Prontosil rubrum, a red dye, was one of a series of dyes examined by Gerhard Domagk of Bayer of Germany in the belief that it might be taken up selectively by certain pathogenic bacteria and not by human cells, in a manner analogous to the way in which the Gram stain works, and, therefore, serve as a selective poison to kill these cells. The dye, indeed, proved to be active in vivo against streptococcal infections in mice. Curiously, it was not active in vitro. Trefouel and Bovet in France soon showed that the urine of prontosil rubrum–treated animals was bioactive in vitro. Fractionation led to identification of the active substance as *p*-aminobenzenesulfonic acid amide (sulfanilamide), a colorless cleavage product formed by reductive liver metabolism of the administered dye. Today, we would call prontosil rubrum a pro-drug. The discovery of the in vivo antibacterial properties of sulfanilamide ushered in the modern anti-infective era, and these investigators shared a Nobel Prize for medicine in 1938. For the first time in the long and weary chronicle of human struggle against infectious disease, physicians now had a comparatively safe and responsive oral drug to use. Considered along with the use of penicillin only 5 years later, the era of the so-called "wonder drugs" had dawned.



Once mainstays of antimicrobial chemotherapy, the sulfonamides have decreased enormously in popularity and now are comparatively minor drugs. The relative cheapness of the sulfonamides is one of their most attractive features and accounts for much of their persistence in the market.

Mechanism of action

The sulfonamides are bacteriostatic when administered to humans in achievable doses. They inhibit the enzyme dihydropteroate synthase, an important enzyme needed for the biosynthesis of folic acid derivatives and, ultimately, the thymidine required for DNA. They do this by competing at the active site with

p-aminobenzoic acid (PABA), a normal structural component of folic acid derivatives. PABA is otherwise incorporated into the developing tetrahydrofolic acid molecule by enzyme-catalyzed condensation with 6-hydroxymethyl-7,8-dihydropterin-pyrophosphate to form 7,8-dihydropteroate and pyrophosphate. Thus, sulfonamides also may be classified as antimetabolites (Fig. 38.3). Indeed, the antimicrobial efficacy of sulfonamides can be reversed by adding significant quantities of PABA into the diet (in some multivitamin preparations and as metabolites of certain local anesthetics) or into the culture medium. Most susceptible bacteria are unable to take up preformed folic acid from their environment and convert it to a tetrahydrofolic acid but, instead, synthesize their own folates de novo. Folates are essential intermediates for the biosynthesis of thymidine, without which bacteria cannot multiply. This inhibition is strongly bacteriostatic and, ultimately, bactericidal. Humans are unable to synthesize folates from component parts, because we lack the necessary enzymes, including dihydropteroate synthase, and folic acid is supplied to us in our diet. Consequently, sulfonamides have no similarly lethal effect on human cell growth. The basis for the selective toxicity of sulfonamides thus is clear.

In a few strains of bacteria, however, the picture is somewhat more complex. Here, sulfonamides are attached to the dihydropteroate diphosphate in the place of the normal PABA. The resulting unnatural product, however, is not capable of undergoing the next necessary reaction (condensation with glutamic acid). This false metabolite

also is an enzyme inhibitor, and the net result is inability of the bacteria to multiply as soon as the preformed folic acid in their cells is used up and further nucleic acid biosynthesis becomes impossible. For these strains the result is the same, but the molecular basis of the effect is somewhat different (Fig. 38.3). Bacteria that are able to take up preformed folic acid into their cells are intrinsically resistant to sulfonamides.

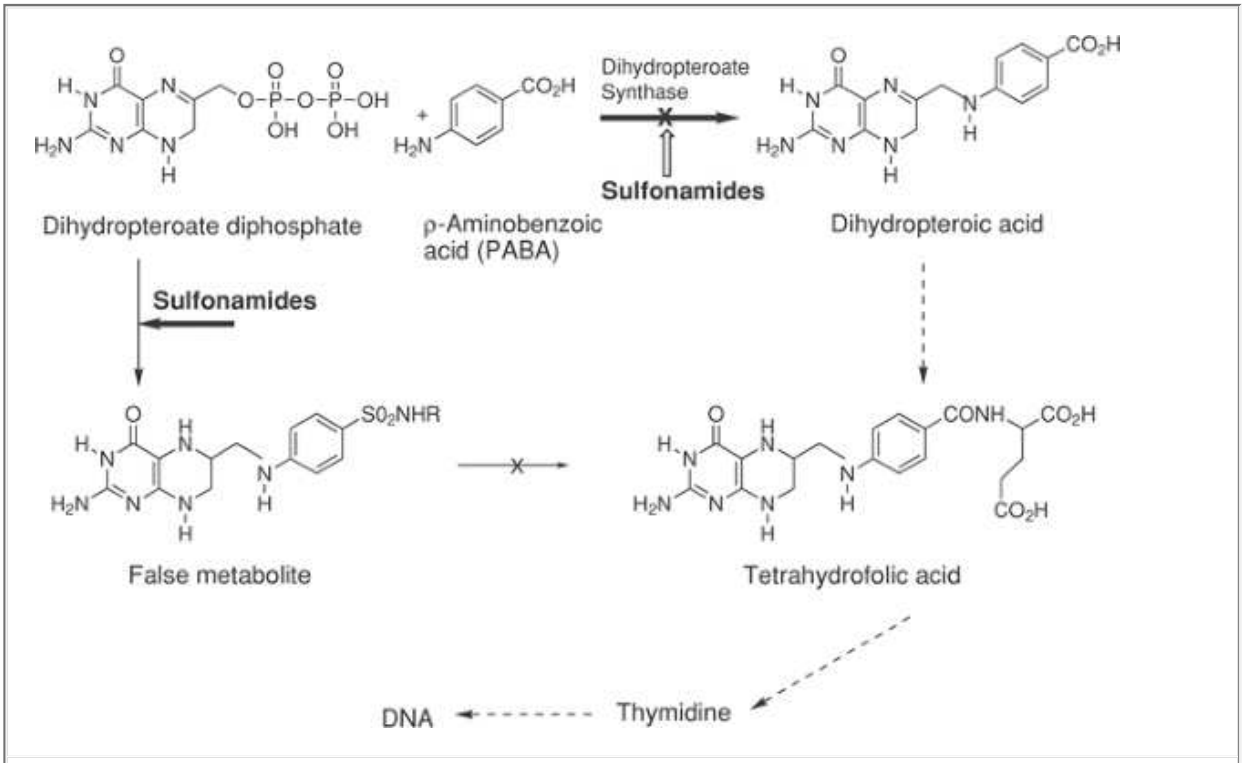


Fig. 38.3. Microbial biosynthetic pathway leading to tetrahydrofolic acid synthesis and major site of action (⇒) of sulfonamides as well as site of action seen in some bacteria (←) resulting in incorporation of sulfonamide as a false metabolite.

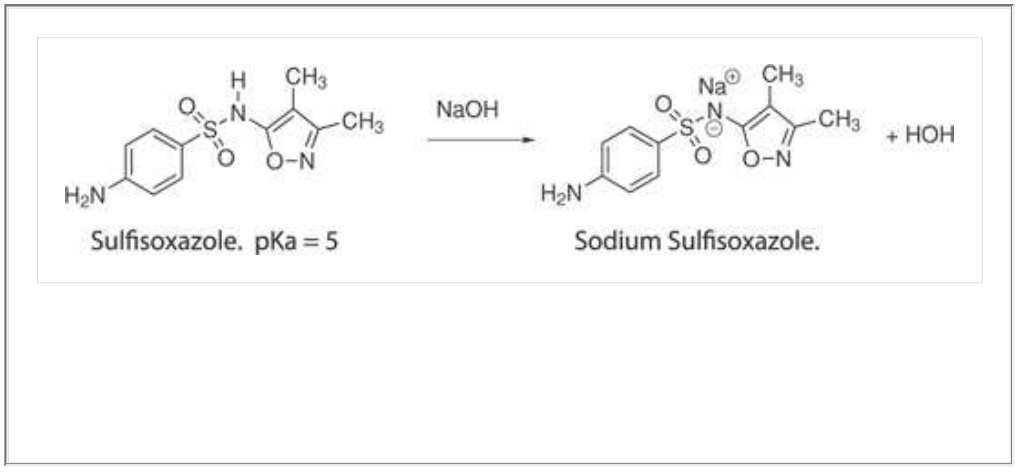
Structure–activity relationships

The basis of the structural resemblance of sulfonamides to PABA that is so devastating to these bacteria is clear. The functional group that differs in the two molecules is the carboxyl of PABA and the sulfonamide moiety of sulfanilamide. The strongly electron-withdrawing character of the aromatic SO_2 group makes the nitrogen atom to which it is directly attached partially electropositive. This, in turn, increases the acidity of the hydrogen atoms attached to the nitrogen so that this functional group is slightly acidic (pK_a = 10.4). The pK_a of the carboxyl group of PABA is approximately 6.5. It was soon found, following a crash synthetic program, that replacement of one of the NH_2 hydrogens by an electron-withdrawing heteroaromatic ring was not only consistent with antimicrobial activity but also greatly acidified the remaining hydrogen and dramatically enhanced potency. With suitable groups in place, the pK_a is reduced to the same range as that of PABA itself. Not only did this markedly increase the antibacterial potency of the product, it also dramatically increased the water solubility under physiologic conditions. The pK_a of sulfisoxazole, one of the most popular of the sulfonamides in present use, is approximately 5.0. The poor water solubility of the earliest sulfonamides led to occasional crystallization in the urine (crystalluria) and resulted in kidney damage, because the molecules were un-ionized at urinary pH values. It is still recommended to drink increased quantities of water to avoid crystalluria when taking certain sulfonamides. This form of toxicity is now comparatively uncommon with the more important agents used today, however, because these agents form sodium salts that are at least partly ionized and, hence, reasonably water soluble at urinary pH values. They are poorly tolerated on injection, however, because these salts are corrosive to tissues.

Structural variation among the clinically useful sulfonamides is restricted primarily to installation of various heterocyclic aromatic substituents on the sulfonamide nitrogen.



Pharmacokinetics

The orally administered sulfonamides are well absorbed from the gastrointestinal (GI) tract, distributed fairly widely, and excreted by the kidney. The drugs are bound to plasma protein (sulfisoxazole, 30–70%, sulfamethoxazole, 70%) and, as such, may displace other protein-bound drugs as well as bilirubin. The latter phenomenon disqualifies them for use in late term pregnancy as they can cause neonatal jaundice. Sulfonamides are partly deactivated by acetylation at N-4 and glucuronidation of the anilino nitrogen in the liver.

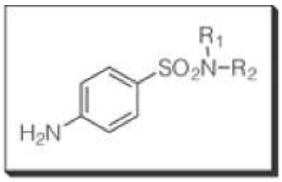
Plasmid-mediated resistance development is common, particularly among Gram-negative microorganisms and usually takes the form of decreased sensitivity of dihydropteroate synthase or increased production of PABA.

Therapeutic Applications

Of the thousands of sulfonamides that have been evaluated, sulfisoxazole acetyl in combination with erythromycin ethylsuccinate is currently the most popular. Sulfisoxazole acetyl is tasteless, which accounts for its use in pediatric preparations and is a pro-drug. The acetyl moiety is removed in the GI tract, giving rise to the active sulfisoxazole. Along with the surviving sulfonamides (Table 38.1), it has a comparatively broad antimicrobial spectrum in vitro, especially against Gram-negative organisms, but its clinical use generally is restricted because of the development of bacterial resistance. Susceptible organisms may include Enterobacteriaceae (*Escherichia coli, Klebsiella* sp., and *Proteus* sp.) and *Streptococcus pyogenes,*

Streptococcus pneumoniae, and *Haemophilus* sp. *Sulfamethoxazole, in combination with trimethoprim, is used for treatment of primary uncomplicated urinary tract infections and, occasionally, as a backup to other, normally more preferred agents in special situations.*

The remaining sulfonamides are not used systemically. Sulfadiazine in the form of its silver salt is used topically for treatment of burns and is effective against a range of bacteria and fungus. Sulfacetamide is used ophthalmically for treatment of eye infections caused by susceptible organisms, and sulfasalazine is a pro-drug used in the treatment of ulcerative colitis and Crohn's disease.



Generic name	R_1	R_2	pKa
Sulfamethoxazole	H		5.6
Sulfadiazine	H		6.5
Silver Sulfadiazine	$Ag^{\oplus}$		
Sulfisoxazole	H		5.0
Acetyl Sulfisoxazole			
Sulfacetamide	H	$COCH_3$	5.4

Table 38.1. Clinically Relevent Sulfonamides

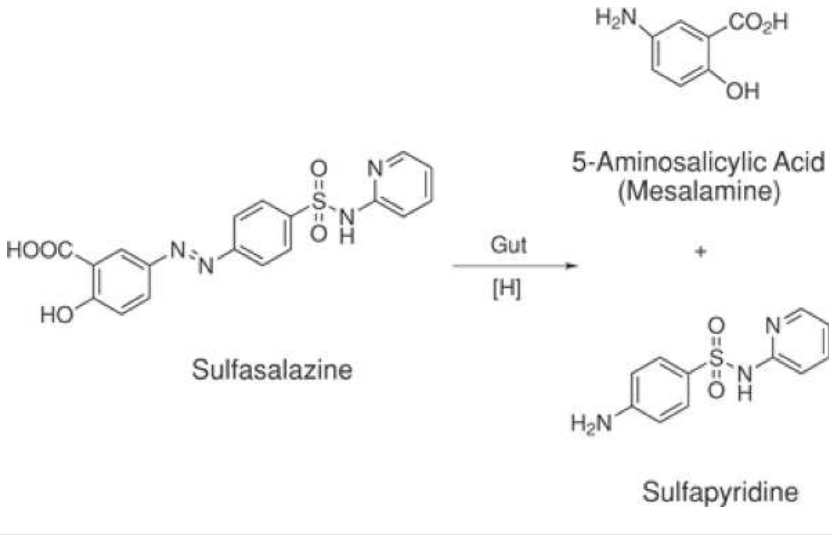


Fig. 38.4. Activation of sulfasalazine to 5-aminosalicylic acid.

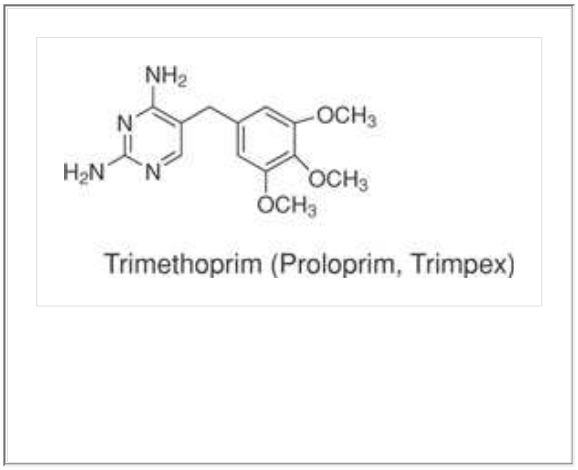
Adverse effects

Allergic reactions are the most common adverse effect and take the form of rash, photosensitivity, and drug fever. Less common problems are kidney and liver damage, hemolytic anemia, and other blood problems. The most serious adverse effect is the Stevens-Johnson syndrome characterized by sometimes-fatal erythema multiforme and ulceration of mucous membranes of the eye, mouth, and urethra. Fortunately, these effects are comparatively rare.

Sulfasalazine

Sulfasalazine stands out from the typical sulfonamide by the fact that although administered orally, the drug is not absorbed in the gut, so the majority of the dose is delivered to the distal bowel. In addition, the drug is a pro-drug, which undergoes reductive metabolism by gut bacteria, converting the drug into sulfapyridine and 5-aminosalicyclic acid the active component (Fig. 38.4). The liberation of 5-aminosalicylic acid (mesalamine), an anti-inflammatory agent, is the purpose for administering this drug. This agent is used to treat ulcerative colitis and Crohn's disease. Direct administration of salicylates is otherwise irritating to the gastric mucosa.

Trimethoprim



Mechanism of action

A further step in the pathway leading from the pteroates to folic acid and on to DNA bases requires the enzyme dihydrofolate reductase. Exogenous folic acid must be reduced stepwise to dihydrofolic acid and then to tetrahydrofolic acid, an important cofactor essential for supplying a 1-carbon unit in thymidine biosynthesis and, ultimately, for DNA synthesis (Fig. 38.5). The same enzyme also must reduce endogenously produced dihydrofolate. Inhibition of this key

enzyme had been widely studied in attempts to find anticancer agents by starving rapidly dividing cancer cells of needed DNA precursors. The student will recall that methotrexate and its analogues came from such studies. Methotrexate is, however, much too toxic to be used as an antibiotic. Subsequently, however, trimethoprim was developed in 1969 by George Hitchings and Gertrude Elion (who shared a Nobel Prize for this and other contributions to chemotherapy in the 1980s). This inhibitor prevents tetrahydrofolic acid biosynthesis and results in bacteriostasis. Trimethoprim selectivity between bacterial and mammalian dihydrofolate reductases results from the subtle but significant architectural differences between these enzyme systems. Whereas the bacterial enzyme and the mammalian enzyme both efficiently catalyze the conversion of dihydrofolic acid to tetrahydrofolic acid, the bacterial enzyme is sensitive to inhibition by trimethoprim by up to 40,000-fold lower concentrations than the mouse enzyme is. This difference explains the useful selective toxicity of trimethoprim.

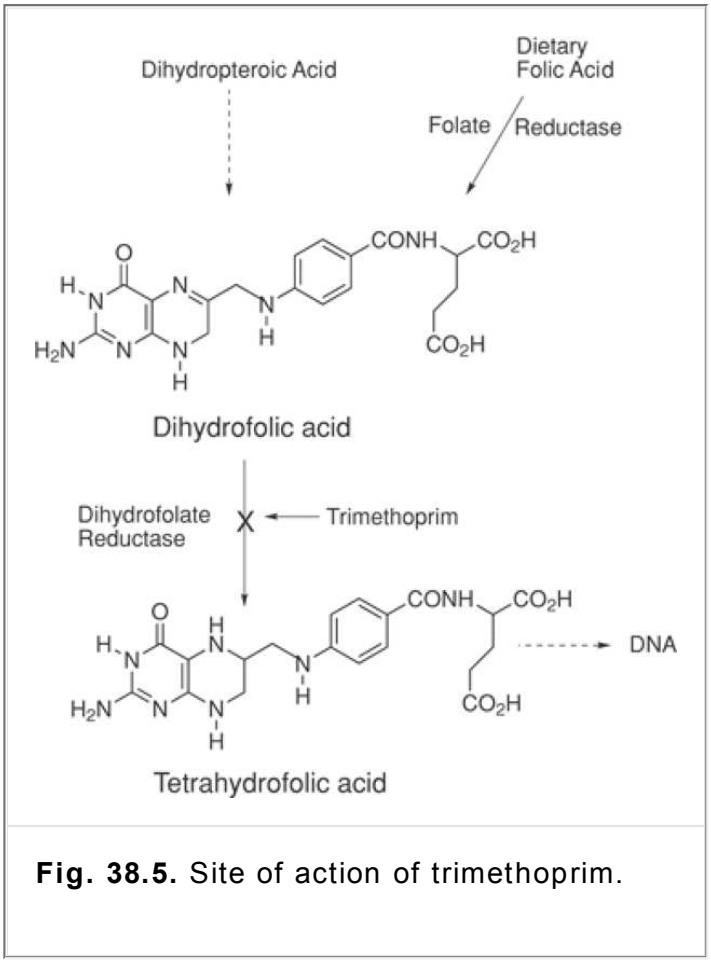


Fig. 38.5. Site of action of trimethoprim.

Therapeutic application

Trimethoprim frequently is used as a single agent clinically for the oral treatment of uncomplicated urinary tract infections caused by susceptible bacteria (predominantly community acquired *Escherichia coli* and other Gram-negative rods). It is, however, most commonly used in a 1:5 fixed concentration ratio with the sulfonamide sulfamethoxazole (Bactrim, Septra). This combination is not only synergistic in vitro but also is less likely to induce bacterial resistance than either agent alone. It is rationalized that microorganisms not

completely inhibited by sulfamethoxazole at the pteroate condensation step will not likely be able to push the lessened amount of substrates that leak past a subsequent blockade of dihydrofolate reductase. Thus, these agents block sequentially at two different steps in the same essential pathway, and this combination is extremely difficult for a naive microorganism to survive. It also is comparatively uncommon that a microorganism will successfully mutate to resistance at both enzymes during the course of therapy. Of course, if the organism is already resistant to either drug at the outset of therapy, which happens more and more often, much of the advantage of the combination is lost.

Pairing these two particular antibacterial agents was based on pharmacokinetic factors and convenient availability. For such a combination to be useful in vivo, the two agents must arrive at the necessary tissue compartment where the infection is at the correct time and in the correct ratio. In this context, the optimum ratio of these two agents in vitro is 1:20. Of all the combinations tried, sulfamethoxazole came closest to being optimal for trimethoprim. Administration of a 1:5 combination of the two drugs orally produces the desired 1:20 ratio in the body once steady state is reached. Conveniently, sulfamethoxazole was already on the market, so it did not have to be approved specially by the U.S. Food and Drug Administration (FDA) for this purpose.

It is easier to demonstrate synergy in vitro than in vivo, and concerns about the toxic contribution of the sulfonamide (and, doubtless, commercial considerations as well) have led to a recent vogue for the use of trimethoprim alone. Trimethoprim has a broad spectrum in vitro, so it is potentially useful against many microorganisms. Combined with sulfamethoxazole, it is used for oral treatment of urinary tract infections, shigellosis, otitis media, traveler's diarrhea, methicillin-resistant *Staphylococcus aureus* (MRSA), *Legionella* infection, and bronchitis.

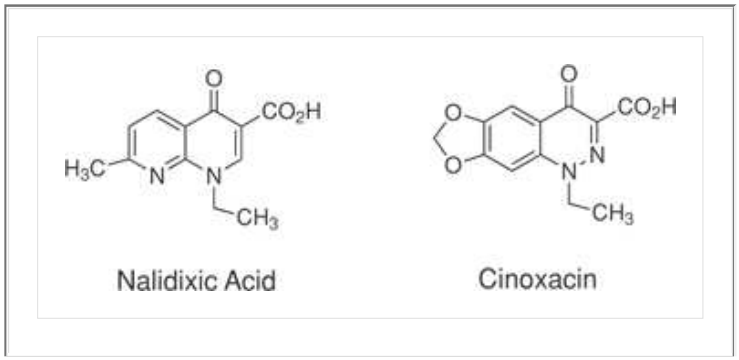
Among the opportunistic pathogens that afflict patients with AIDS is the pneumonia-causing fungus *Pneumocystis jiroveci* (previously classified as *Pneumocystis carinii*). Immunocompetent individuals rarely become infected with *P. jiroveci*, but it is a frequent pathogen in patients with AIDS and is nearly 100% fatal in such immunocompromised individuals. The combination of sulfamethoxazole–trimethoprim has proven to be useful and comparatively nontoxic for these patients. A form for injection is available for use in severe infections and is particularly useful in patients with AIDS. This treatment form leads to more frequent toxic reactions, however. The most frequent side effects of trimethoprim–sulfamethoxazole are rash, nausea, and vomiting. Blood dyscrasias are less common, as is pseudomembranous colitis (caused by nonantibiotic-sensitive opportunistic gut anaerobes, often *Clostridium difficile*). Many broad-spectrum antimicrobials can lead to such severe drug related diarrhea, and this side effect must be monitored carefully. Severe, nonresolving diarrhea can be fatal; therefore, it is a justification for withdrawing existing therapy in favor of antianaerobic antibiotic. Despite a significant effort, no structurally related analogue has emerged to compete with trimethoprim.

Resistance

Bacterial resistance to trimethoprim is increasingly common. In pneumococcal infections, it can result from a single amino acid mutation (Ile-100 to Leu) in the dihydrofolate reductase enzyme. Overexpression of dihydrofolate reductase by *Staphylococcus aureus* has been reported in resistant strains as well.

Quinolones

Introduction



The quinolone antimicrobials comprise a group of synthetic substances possessing in common an N-1-alkylated 3-carboxypyrid-4-one ring fused to another aromatic ring, which itself carries other substituents. The first quinolone to be marketed (in 1965) was nalidixic acid. Nalidixic acid and cinoxacin are classified as first-generation quinolones based on their spectrum of activity and pharmacokinetic properties. While still available, they are considered to be minor urinary tract disinfectants that are effective primarily against certain susceptible Gram-negative bacteria. Thus, the quinolones were of little clinical significance until the discovery that the addition of a fluoro group to the 6-position of the basic nucleus greatly increased the biological activity. Brought to the market in 1986, norfloxacin, the first of the second-generation quinolones, has a broad spectrum and equivalent in potency to many of the fermentation derived antibiotics. Following its introduction, intense competition ensued, more than a thousand second-, third-, and fourth-generation analogues have now been made. Alatrofloxacin, ciprofloxacin, enoxacin, gatifloxacin, gemifloxacin, lomefloxacin, norfloxacin, ofloxacin, levofloxacin, moxifloxacin, sparfloxacin, and trovafloxacin are currently marketed in the United States (Fig. 38.6). Ciprofloxacin and levofloxacin dominate the worldwide fluoroquinolone market, accounting between them for over $3 billion in 2002.

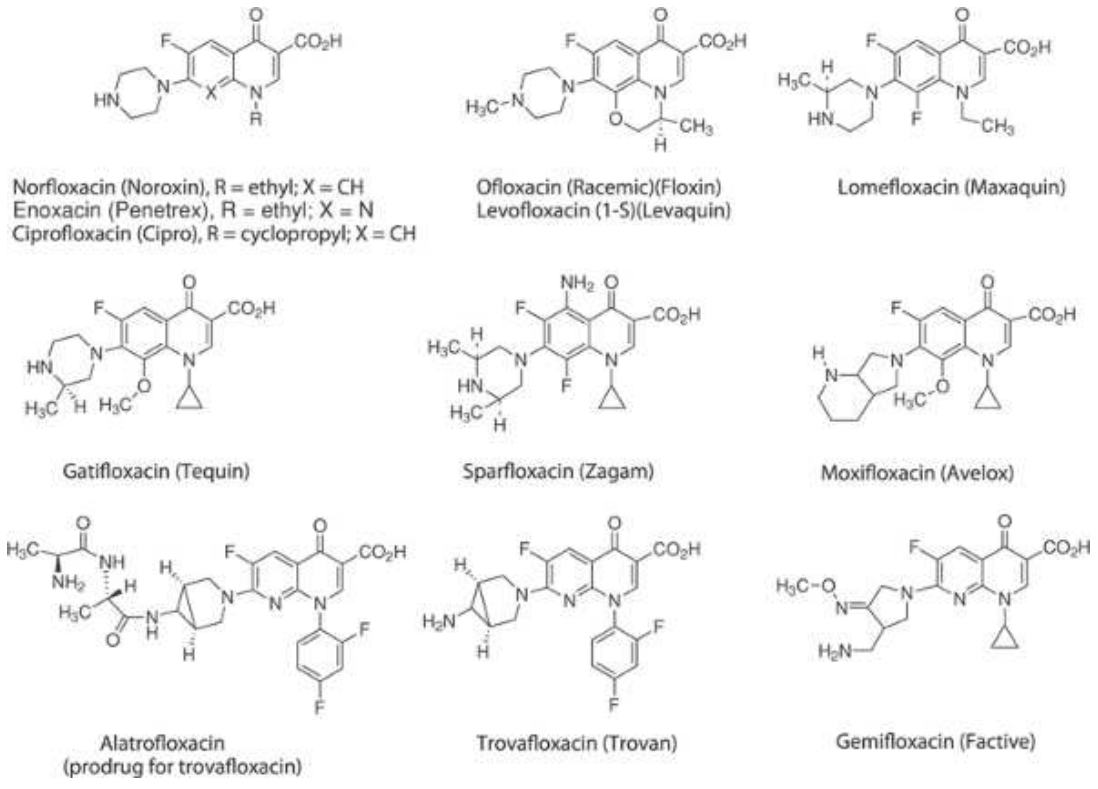


Fig. 38.6. Second-, third-, and fourth-generation quinolones.

It should be noted that the more recent quinolones also are referred to as the fluoroquinolones and that these agents are now an important class of antimicrobial agents.

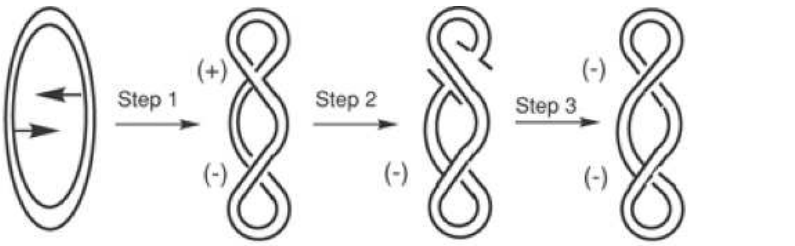
Mechanism of action

The quinolones are rapidly bactericidal, largely as a consequence of inhibition of DNA gyrase and topoisomerase IV, key bacterial enzymes that dictate the conformation of DNA. The *Escherichia coli* chromosome is a single, circular molecule of approximately 1 mm in length, whereas the cell is only 1 to 3 μm long. Thus, the DNA molecule must be dramatically compacted in a conformationally stable way so that it

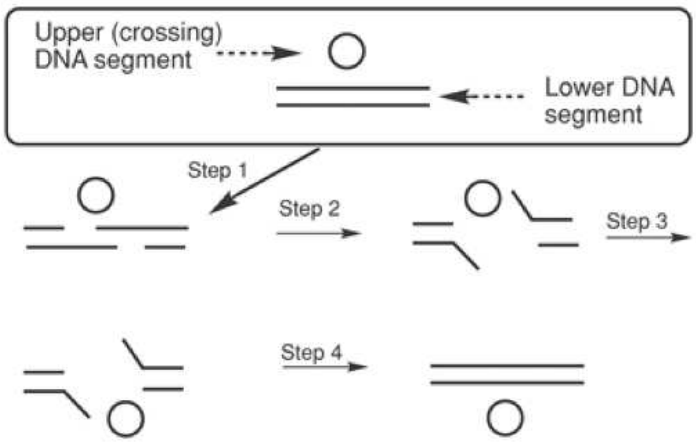
can fit. Using the energy generated by adenosine triphosphate (ATP) hydrolysis, the molecule is progressively wound about itself in a positive super coil. In the absence

of ATP, the process is reversed, relaxing the molecule. It also must be partially unwound so that the cell has access to the genetic information that it contains. This requires reversible conformational changes so that it can be stored properly, unwound, replicated, repaired, and transcribed on demand. These enzymes alter the conformation of DNA by catalyzing transient double-strand cuts staggered by four base pairs, passing the uncut portion of the molecule through the gap, and resealing the molecule back together. In this way, DNA gyrase alters the degree of DNA twisting by introducing negative DNA super coils, releasing tensional stress in the molecule. On the other hand, DNA topoisomerase IV decatenates (unties) enchained daughter DNA molecules produced through replication of circular DNA. Inhibition of DNA gyrase and topoisomerase IV makes a cell's DNA inaccessible and leads to cell death, particularly if the cell must deal with other toxic effects at the same time. These processes are shown schematically in Fig. 38.7. Different quinolones inhibit these essential enzymes to different extents. Topoisomerase IV seems to be more important to some Gram-positive organisms and DNA gyrase to some Gram-negative organisms.

The coumermycins, of which novobiocin (now archaic) was the most clinically relevant, bind to a different site in these topoisomerases (i.e., where the ATP binds). Resistance to the coumermycins develops rather easily, and they find little use today.



A. View from the top: Step 1. Stabilize positive node. Step 2. Break both strands of the back segment. Step 3. Pass unbroken segment through the break and reseal on the front side.



B. View from the side: Step 1. Staggered cuts in each strand. Step 2. Gate opens. Step 3. Transverse segment passed through the break. Step 4. Reseal cut segment.

Fig. 38.7. Schematic depicting supercoiling of circular DNA catalyzed by DNA gyrase.

Humans shape their DNA with a topoisomerase II, an analogous enzyme that does not bind quinolones at

normally achievable doses, so the quinolones of commerce do not kill host cells.

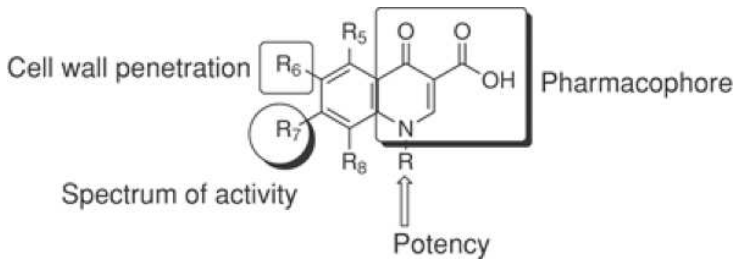


Fig. 38.8. Major structure–activity relationship features.

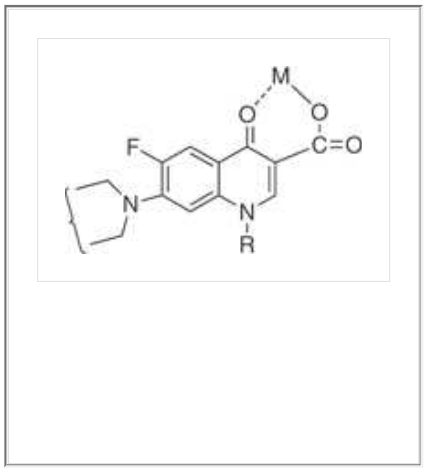
Structure–activity relationship

The structural features of the quinolones strongly influence the antimicrobial and pharmacokinetic properties of this class of drugs. The essential pharmacophore for activity is the carboxy-4-pyridone nucleus (Fig. 38.8). Apparently, the carboxylic acid and the ketone are involved in binding to the DNA/DNA-gyrase enzyme system. Reduction of the 2,3-double bond or the 4-keto group inactivates the molecule, and substitution at C-2 interferes with enzyme–substrate complexation. Fluoro substitution at the C-6 position greatly improves antimicrobial activity by increasing the lipophilicity of the molecule, which in turn improves the drugs penetration through the bacterial cell wall. Additionally, C-6 fluoro increases the DNA gyrase inhibitory action. An additional fluoro group at C-8 further improves drug absorption and half-life but also may increase drug-induced photosensitivity. Heterocyclic substitution at C-7 improves the spectrum of activity especially against Gram-negative organisms. The piperazinyl (as in ciprofloxacin) and pyrrolidinyl (as in moxifloxacin) represent the most significant antimicrobial improvement. Unfortunately, the piperazinyl group at C-7 also increases binding to central nervous system (CNS) γ-aminobutyric acid (GABA) receptors, which accounts for CNS side effects. Alkyl substitution on the piperazine (lomefloxacin and ofloxacin) is reported to decrease binding to GABA, as does the addition of bulky groups at the N-1 position (sparfloxacin). The cyclopropyl substitution at N-1 appears to broaden activity of the quinolones to include activity against atypical bacteria, including *Mycoplasma, Chlamydia*, and *Legionella* species.

The introduction of a third ring to the nucleus of the quinolones gives rise to ofloxacin. Additionally, ofloxaxin has an asymmetric carbon at the C-3' position. The *S*-(–)-isomer (levofloxacin) is twice as active as ofloxacin and 8- to 128-fold more potent than the *R*-(+)-isomer resulting from increased binding to the DNA-gyrase.

Several of the quinolones produce mild to severe photosensitivity. A C-8 halogen appears to produce the highest incidence of photosensitivity via singlet oxygen and radical induction. Lomefloxacin has been reported to have the highest potential for producing phototoxicity. Substitution of a methoxy group at C-8 has been reported to reduce the photosensitivity (gatifloxacin).

Finally, a chemical incompatibility common to all the quinolones involves the ability of these drugs to chelate polyvalent metal ions (Ca^{2+}, Mg^{2+}, Zn^{2+}, Fe^{2+}, and Al^{3+}), resulting in decreased solubility and reduced drug absorption. Chelation occurs between the metal and the 3-carboxylic acid and 4-keto groups. Agents containing polyvalent metals should be administered at least 4 hours before or 2 hours after the quinolones.



Pharmacokinetics

The fluoroquinolones are well absorbed following oral administration, with excellent bioavailability. The maximum plasma concentration usually is reached within a few hours, and the drugs are moderately bound to plasma protein, leading to comparatively long half-lives (Table 38.2). Earlier quinolones were rapidly excreted into the urine, which limited their therapeutic application to urinary tract infections, whereas the newer drugs are distributed to alveolar macrophages, bronchial mucosa, epithelial lining fluid, and saliva, improving the use in various systemic infections. Several studies have suggested that the ratio of mean peak plasma concentration to MIC and the 24-hour area under the curve to MIC may correlate with therapeutic outcomes. If this proves to be true, it could greatly help the clinician in choosing the appropriate drug and dosing schedule.

Therapeutic applications

The quinolones therapeutically fall into one of four classifications (Table 38.3). The specific drugs within each classification include nalidixic acid and cinoxin as first-generation agents, with utility limited to uncomplicated urinary tract infections. The second-generation quinolones include norfloxacin, lomefloxacin, enoxacin, ofloxacin, and ciprofloxacin. Whereas norfloxacin is used mainly for urinary tract infections (*Enterobacter* sp., *Enterococcus* sp., or *Pseudomonas aeruginosa*), ciprofloxacin also is used for prostatitis, upper respiratory tract infections, bone infections, septicemia, staphylococcal and pseudomonal endocarditis, meningitis, sexually transmitted diseases (gonorrhea and chlamydia), chronic ear infections, and purulent osteoarthritis. The third-generation quinolones, which include levofloxacin, sparfloxacin, gatifloxacin, and gemifloxacin, are used to treat infections caused by *Legionella* sp., *Chlamydia* sp., and *Mycoplasma* sp., as well as *Streptococcus pneumoniae*. These agents may find use in the treatment of acute bacterial exacerbation of chronic bronchitis and community-acquired pneumonia. Gemifloxacin has been approved for use against multidrug-resistant *S. pneumoniae*. Additional indications may include skin and skin structure infections and acute sinusitis caused by *S. pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. The fourth-generation quinolines include trovafloxacin and moxifloxacin, which have a spectrum of activity that includes anaerobes, such as *Bacteroides fragilis*.

Table 38.2. Pharmacokinetic Properties for Selective Quinolones

Drug	Bioavailability (%)	Protein Binding (%)	Half-life (hours)
Ciprofloxacin	70	30	3.5
Enoxacin	90	40	3–6
Gatifloxacin	96	20	8.0

Gemifloxacin	71	60–70	8.0
Levofloxacin	99	31	6.9
Lomefloxacin	95	10	8
Moxifloxacin	86	47	12.1
Norfloxacin	30–40	10–15	3–4
Ofloxacin	98	32	9
Sparfloxacin	90	56	18.7
Trovafloxacin	88	73	11.0

Table 38.3. Therapeutic Classification of Quinolones

Generation	Characteristics
First generation	Poor serum and tissue concentration Not valuable for systemic infections Lack activity against *Pseudomonas aeruginosa*, Gram-positive organisms, and anaerobes
Second generation	Adequate serum and tissue concentration Good for systemic infections Active against Gram-negative organisms, including *P. aeruginosa*; weak activity against *Streptococcus pneumoniae*; no activity against anaerobes
Third generation	Once-daily dosing Active against *S. pneumoniae* and atypical bacteria; less active against *P. aeruginosa*
Fourth generation	Active against anaerobes and aerobic Gram-positive and Gram-negative organisms

Resistance

Resistance to the quinolones is becoming more frequent and is associated with spontaneous mutations in two genes (*gyrA* and *gyrB*) that encode for the quinolone target protein, DNA gyrase. A single step mutation can lead to low-level resistance, whereas mutations in both genes lead to high-level resistance. This mechanism of resistance would be expected to produce cross-resistance within the class of quinolones. In

addition, there are suggestions that resistance may be associated with an increase in drug efflux or a decrease in outer membrane permeability affecting drug influx. Such a mechanism of resistance would be expected to be more common in Gram-negative organisms with a more complex cell wall than in Gram-positive organisms with its cell envelope.

Adverse effects

The quinolone class is associated with more side effects than the β-lactam and macrolide classes but, nonetheless, see very widespread medicinal use.

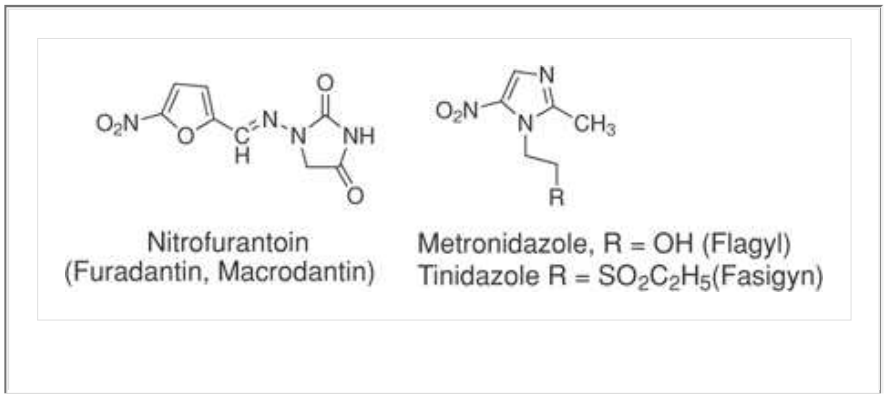
Among the side effects associated with quinolones is a proconvulsant action, especially in epileptics, but this is mainly associated with the first-generation agents. Other CNS problems include hallucinations, insomnia, and visual disturbances. Some patients also experience diarrhea, vomiting, abdominal pain, and anorexia. These effects are most common with trovafloxacin. The quinolones are associated with erosion of the load-bearing joints of young animals. As a precaution, these drugs are not used casually in children younger than 18 years or in sexually active females of childbearing age. Ciprofloxacin is the fluoroquinolone of choice for children when use of a quinolone is required, because it has been extensively studied for this purpose. They also are potentially damaging in the first trimester of pregnancy because of a risk of severe metabolic acidosis and of hemolytic anemia. Coadministration with theophylline potentiates the action of the latter and should be monitored closely. Although it takes much higher concentrations of fluoroquinolones to inhibit human topoisomerase II than concentrations of either DNA gyrase or bacterial topoisomerase IV, some agents have a narrower margin of safety. With gemifloxacin, a mild to severe rash may develop.

Severe toxicities

Certain members of the fluoroquinolone family were marketed for a time but were subsequently severely limited in use or withdrawn because of the unacceptable toxicities experienced by some patients. These agents had been introduced with great hopes because of their breadth of spectrum and potency against resistant microorganisms. Temafloxacin, for example, was removed from the market because of hemolysis, renal failure, and thrombocytopenia (the hemolytic uremic syndrome). These effects only became apparent when large numbers of patients received the drug. Severe liver toxicity led to the removal from the market in Europe and restrictions on the use of trovafloxacin in the United States only for severe infections involving institutional care, where the patient can be closely monitored. Grepafloxacin was introduced to the market in late 1997 as a broad-spectrum fluoroqinolone and was withdrawn from the market in 1999 based on cardiovascular toxicity. Gatifloxacin, gemifloxacin, and moxifloxacin carry warnings about QT-interval prolongation but are still in use. Sparfloxacin also has been reported to produce cardio- and phototoxicity and should be used with great care. The drugs were reported to cause a prolonged QTc interval. Analogues with a C-8 chloro substituent, such as clinafloxacin and sitafloxacin, also were very potent but have largely fallen from favor because of excessive phototoxicity. All these drugs were well on the way to great popularity when these untoward events were detected. These phenomena were not apparently revealed during extensive previous animal and clinical studies. No consistent structural pattern is associated with these problems, with the exception that one would not use an N-1 2,4-difluorophenyl moiety except with great care.

Miscellaneous Agents

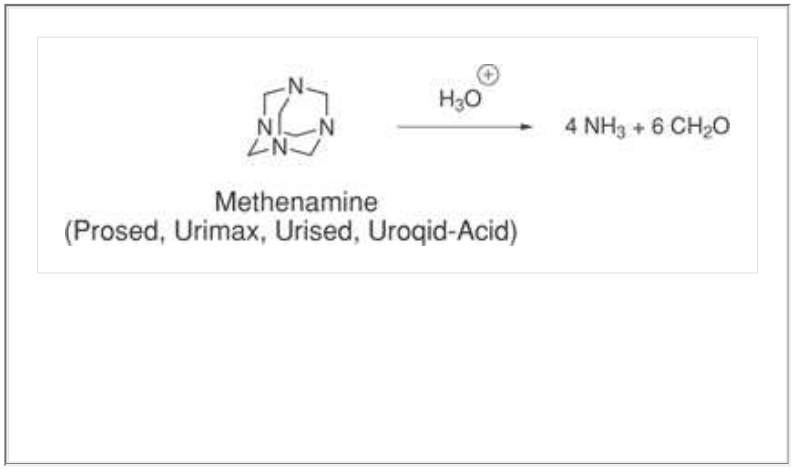
Nitroheteroaromatic compounds



Nitrofurantoin, a widely used oral antibacterial nitrofuran, has been available since World War II. It is used for prophylaxis or treatment of acute urinary tract infections when kidney function is not impaired, and it inhibits kidney stone growth. Nausea and vomiting are common side effects. This is avoided, in part, by slowing the rate of absorption of the drug through use of wax-coated, large particles (Macrodantin). Nitrofurantoin inhibits DNA and RNA functions through mechanisms that are not well understood, although bioreductive activation is suspected to be an important component of this. Resistance is not commonly encountered. Rather severe side effects can be experienced when using this drug (e.g., acute pulmonary reactions, peripheral neuropathy, hemolytic anemia, liver toxicity, and fertility impairment), so caution is in order.

Metronidazole was initially introduced for the treatment of vaginal infections caused by amoeba. This nitroimidazole also is useful orally, however, for the treatment of trichomoniasis, giardiasis, and *Gardnerella vaginalis* infections. It has found increasing use of late in the parenteral treatment of anaerobic infections and in the treatment of pseudomembranous enterocolitis resulting from *Clostridium difficile*, an opportunistic pathogen that occasionally flourishes as a consequence of broad-spectrum antibiotic therapy. Infections with *C. difficile* can be life-threatening. The drug is believed to be metabolically activated by reduction of its nitro group to produce reactive oxygen species. Metronidazole also is a component of a multidrug cocktail used to treat *Helicobacter pylori* infections associated with gastric ulcers. Both drugs can cause disulfuram-like adverse reactions when alcohol is consumed. For many years, it had little competition from other therapies for its indications. Recently, tinidazole, another nitroimidazole, has been introduced in the United States as just such a competitor. It is too early to judge how competitive this agent will be, but it has a longer duration of action. Metronidazole use is associated with allergic rashes and CNS disturbances, including convulsions in some patients. It is carcinogenic in rodents. Thus, some caution is associated with its use.

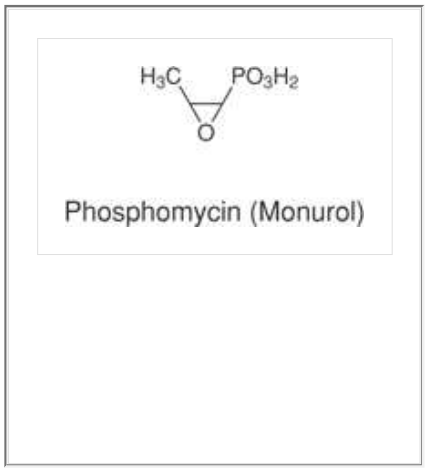
Methenamine



P.1044

A venerable drug used for the disinfection of acidic urine, methenamine is a low-molecular-weight polymer of ammonia and formaldehyde that reverts to its components under mildly acidic conditions. Formaldehyde is the active antimicrobial component. Methenamine is used for recurrent urinary tract infections. The drug is available in various dosage forms as well as various salts, including the hippurate and mandelate.

Phosphomycin



Phosphomycin, introduced in 1972, inhibits enolpyruvial transferase, an enzyme catalyzing an early step in bacterial cell wall biosynthesis. Inhibition results in reduced synthesis of peptidoglycan, an important component in the bacterial cell wall. Phosphomycin is bactericidal against *Escherichia coli* and *Enterobacter faecalis* infections.

Antibiotics: Inhibitors of Bacterial Cell Wall Biosynthesis

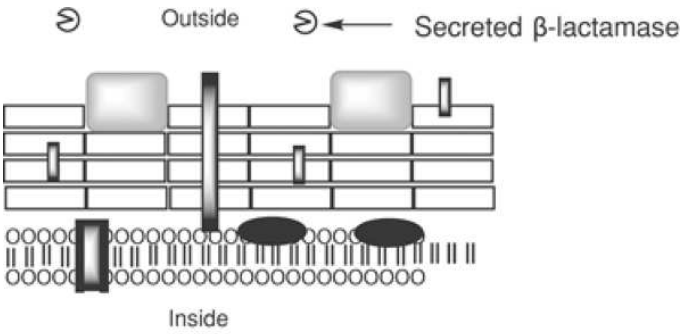
Bacterial cell wall

Bacterial cells are enclosed within a complex and largely rigid cell wall. This differs dramatically from mammalian cells, which are surrounded by a flexible membrane, the chemical composition of which is dramatically different. This provides a number of potentially attractive targets for selective chemotherapy of bacterial infections. For one thing, enzymes that have no direct counterpart in mammalian cells construct the bacterial cell wall. Three of the main functions of the bacterial cell wall are 1) to provide a semipermeable barrier interfacing with the environment through which only desirable substances may pass, 2) to provide a sufficiently strong barrier so that the bacterial cell is protected from changes in the osmotic pressure of its environment, and 3) to prevent digestion by host enzymes. The initial units of the cell wall are constructed within the cell, but soon, the growing and increasingly complex structure must be extruded; final assembly takes place outside of the inner membrane. This circumstance makes the enzymes involved in the late steps more vulnerable to inhibition, because they are at or near the cell surface. Whereas individual bacterial species differ in specific details, the following generalized picture of the process is sufficiently accurate to illustrate the process.

Gram-Positive Bacteria

The cell wall of Gram-positive bacteria, although complex enough, is simpler than that of Gram-negative organisms. A schematic representation is shown in Figure 38.9. On the very outside of the cell is a set of characteristic carbohydrates and proteins that, together, make up the antigenic determinants that differ from species to species and that also cause adherence to particular target cells. There also may be a lipid-rich capsule surrounding the cell (not shown in Fig. 38.9). The next barrier that the wall presents is the peptidoglycan layer. This is a spongy, gel-forming layer consisting of a series of alternating sugars (N-acetylglucosamine and N-acetylmuramic acid) linked (1,4)-β in a long chain (Fig. 38.10). To the lactic acid carboxyl moieties of the N-acetylmuramic acid units is attached, through an amide linkage, a series of amino acids, of which L-alanyl-D-glutamyl-L-lysyl-D-alanine is

typical of *Staphylococcus aureus*. One notes the D-stereochemistry of the glutamate and the terminal alanine. This feature is presumably important in protecting the peptidoglycan from hydrolysis by host peptidases, particularly in the GI tract. This unusual structural feature facilitates successful parasitism.



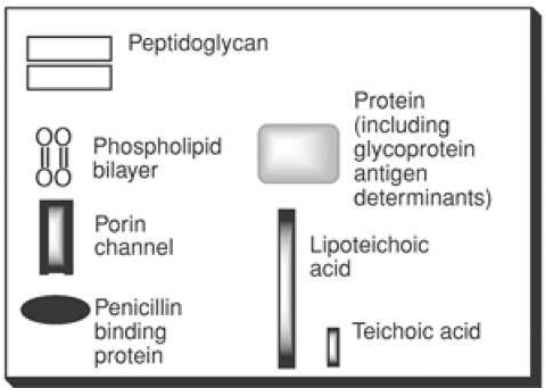


Fig. 38.9. Schematic of some features of the Gram-positive bacterial cell wall.

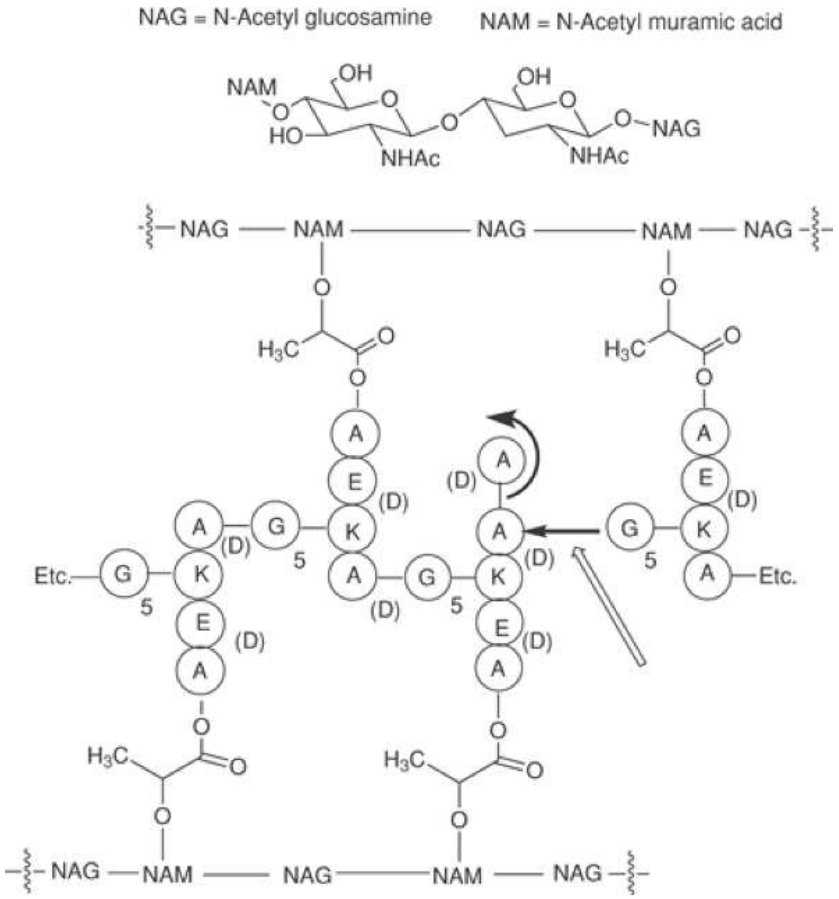

Fig. 38.10. Schematic of cell wall cross-linking. Pentaglycyl group replaces terminal D-alanine.

Table 38.4. Pencillins Binding Proteins (PBP) of E. coli

PBP	Function	Lethality?
1A	Cell elongation (peripheral wall extension)	Yes
1B	Cell elongation (peripheral wall extension)	Yes
2	Maintenance of rod shape	Yes
3	Septum formation	No
4	Limit the amount of cross linking of the peptidoglycan	No
5	Limit the amount of cross linking of the peptidoglycan	No

6	Limit the amount of cross linking of the peptidoglycan	No

V. Lorian, Ed., Antibiotics in Laboratory Medicine, Williams & Wilkins, Baltimore (1986).

The early steps in the biosynthesis of the peptidoglycan unit result in formation of a complex polymeric sheet. This is then cross-linked to form a thickened wall. This bonds the terminal D-alanyl unit to the lysyl unit of an adjacent tetrapeptide strand through a pentaglycyl unit. This last step is an enzyme-catalyzed transamidation by which the terminal amino moiety on the last glycine unit of the A strand displaces the terminal D-Ala unit on the nearby B strand. The cell wall transamidase (one of the penicillin binding proteins [PBPs]) forms a transient, covalent bond during the synthesis phase with a particular serine hydroxyl on the enzyme. Completion of the catalytic cycle involves displacement of the enzyme by a glycine residue, which regenerates the enzyme. This process gives the wall additional rigidity, much as would be achieved by gluing the pages of a book together. This strong barrier protects against osmotic stress and accounts for the retention of characteristic morphological shape of Gram-positive bacteria (e.g., globes and rods). This step is highly sensitive to inhibition of β-lactam antibiotics. It also is the target of the glycopeptide antibiotics (e.g., vancomycin), as will be discussed later.

The peptidoglycan layer is traversed by complex glycophospholipids called teichoic and teichuronic acids. These are largely responsible for the acid mantle of Gram-positive bacteria. Beneath the peptidoglycan layer is the lipoidal cytoplasmic cell membrane in which a number of important protein molecules float in a lipid bilayer. Among these proteins are the β-lactam targets, known as the PBPs. These enzymes are important in cell wall formation and remodeling. In Gram-positive bacteria, the outer layers are relatively ineffective in keeping out antibiotics. It is the inner membrane and its protein components that provide the principal barrier to uptake of antibiotics. There are at least seven types of PBPs. Those of *Escherichia coli* are classified in Table 38.4. The functions of all of these are not entirely understood, but they are important in construction and repair of the cell wall. β-Lactam antibiotics bind to these proteins and kill bacteria by preventing the biosynthesis of a functional cell wall. Various β-lactam antibiotics display different patterns of binding to these proteins. The action of these proteins must alternate in a controlled and systematic way between their active and inert states so that bacterial cells can grow and multiply in an orderly manner. Selective interference by β-lactam antibiotics with the functioning of these proteins prevents normal growth and repair and creates serious problems for bacteria, particularly young cells needing to grow and mature cells needing to repair damage or to divide. The rapid bactericidal effect of penicillins on such cells can readily be imagined.

Gram-Negative Bacteria

With the Gram-negative bacteria, the cell wall is more complex and more lipoidal (Fig. 38.11). These cells usually contain an additional, outer lipid membrane that differs considerably from the inner membrane. The outer layer contains complex lipopolysaccharides that encode antigenic responses, cause septic shock, provide the serotype, and influence morphology. This exterior layer also contains a number of enzymes and exclusionary proteins. Important among these are the porins. These are transmembranal supermolecules made

up of two or three monomeric proteins. The center of this array is a transmembranal pore of various dimensions. Some allow many kinds of small molecules to pass, and others contain specific receptors that allow only certain molecules to come in. The size, shape, and lipophilicity of drugs are important considerations controlling porin passage. Antibiotics have greater difficulty in penetrating into Gram-negative bacterial cells as a consequence. Next comes a periplasmic space containing a somewhat less impressive and thinner, as compared to the Gram-positive organisms, layer of peptidoglycan. Also present is a phospholipid-rich cytoplasmic membrane in which floats a series of characteristic proteins with various functions. The β-lactam targets (i.e., the PBPs) are found here.

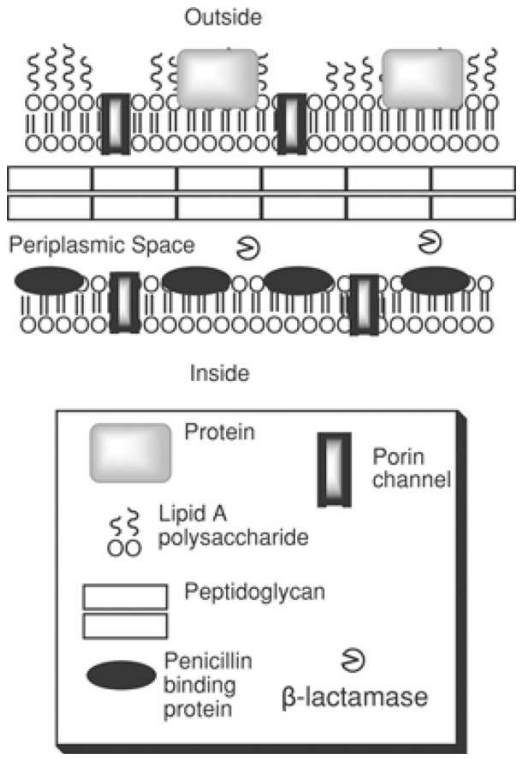

Fig. 38.11. Schematic of some features of the Gram-negative bacterial cell wall.

Other inner membrane proteins are involved in transport, energy, and biosynthesis. In many such cells are proteins that actively pump out antibiotics and other substances at the expense of energy and that may require the simultaneous entrance of oppositely charged materials to maintain an electrostatic balance.

β-Lactam antibiotics

The name “lactam” is given to cyclic amides and is analogous to the name “lactone,” which is given to cyclic esters. In an older nomenclature, the second carbon in an aliphatic carboxylic acid was designated α, the third β, and so on. Thus, a β-lactam is a cyclic amide with four atoms in its ring. The contemporary name for this ring system is azetidinone. This structural feature was very rare when it was found to be a feature of the structure of the penicillins, so the name “β-lactam” came to be a generic descriptor for the whole family. It is fortunate that this ring ultimately proved to be the main component of the pharmacophore, so the term

possesses medicinal as well as chemical significance. The penicillin subclass of β-lactam antibiotics is characterized by the presence of a substituted 5-membered thiazoldine ring fused to the β-lactam ring. This fusion and the chirality of the β-lactam ring results in the molecule roughly possessing a "V"-shape. This drastically interferes with the planarity of the lactam bond and inhibits resonance of the lactam nitrogen with its carbonyl group. Consequently, the β-lactam ring is much more reactive and, therefore, more sensitive to nucleophilic attack when compared with normal planar amides.

History

The story of the discovery of the penicillins are widely known. In 1929, Alexander Fleming, a physician and a clinical microbiologist, was preserving a culture of a pathogen, and the plate became contaminated with an airborne fungus, *Penicillium notatum* (now named *Penicillium chrysogenum*), which not only grew on the plate but also produced a clear zone of inhibition around its colony. On returning from a vacation and finding this, he recognized the potential significance of this antibiotic effect, so he preserved the fungus and tried to identify its active constituent. The state of development of the art as well as his background and training were insufficient for the task at that time. It was not until a decade later that a group of English chemists, including Abraham, Chain, Florey, and Heatley, succeeded in purifying the unstable antibiotic. Finally, on February 12, 1941, following heroic efforts necessitated by wartime conditions, enough material was available for clinical examination and the demonstration that penicillin actually worked in humans. Much new technology had to be developed before large-scale use of penicillin could take place. The efforts of an international team solved, for example, the problems of large-scale sterile aerobic submerged fermentation, directed fermentation, strain improvement, and many other vexing problems. By 1943, penicillin was being produced in very large quantities for use by the armed forces. When peace came in 1945, production was in tons, and the drug was available very cheaply.

The earliest penicillins were produced by fungi from media constituents. The bicyclic heterocyclic nucleus of 6-aminopenicillanic acid (6-APA) was constructed by an involved process catalyzed by enzymes. The side chain was added essentially intact from media constituents. It was discovered that certain arylacetic acids, when added to the medium, were used to form the side chain amide moiety and that this was very important for stability and breadth of spectrum. It was later discovered that exclusion of such materials from the medium allowed the production of 6-APA without a side chain. Chemists could then add a much wider variety of side chains without being limited by the specific requirements of the enzymes. With this breakthrough, the penicillin field expanded to include orally active, broad-spectrum, and enzymatically stable penicillins. The cephalosporins were discovered as secondary metabolites of a different fungal species. Because it was stable to many activity-destroying β-lactamases, its core nucleus, 7-aminocephalosporanic acid, was substituted with a wide variety of unnatural side chains, and three generations of clinically useful analogues resulted. Later work produced the monobactams, carbapenems, and β-lactamase inhibitors. In the year 2005, about half of the money spent worldwide on antibiotics was for β-lactams. More than 100,000 of these compounds have been prepared by partial or total chemical synthesis, and a significant number of these remain on the market more than 60 years after their discovery.

Penicillins

The medicinal classifications, chemical structures, and generic names of the penicillins currently available are presented in Table 38.5.

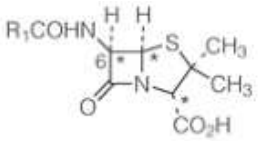
Preparation of Penicillins

The original fermentation derived penicillins were produced by growth of the fungus

Penicillium chrysogenum on complex solid media, with the result that they were mixtures differing from one another in the identity of the side-chain moiety. When a sufficient supply of phenylacetic acid is present in liquid media, this is preferentially incorporated into the molecule to produce mainly benzylpenicillin (penicillin G in the old nomenclature). Use of phenoxyacetic acid instead leads to phenoxymethyl penicillin (penicillin V). More than two dozen different penicillins have been made in this way, but these two are the only ones that remain in clinical use. The bicyclic penicillin nucleus itself is prepared biosynthetically via a complex process from an acylated cysteinyl valyl peptide. The complete exclusion of side chain precursor acids from the medium produces the fundamental penicillin nucleus, 6-APA, but in poor yield. By itself, 6-APA has only very weak antibiotic activity, but when substituted on its primary amino group with a suitable

amide side chain, its potency and antibacterial spectrum are profoundly enhanced. With this key precursor isolated, limitations caused by enzyme specificities in biosynthesis could be overcome by use of partial chemical synthesis. A more practical modern process for making 6-APA employs naturally occurring fungal enzymes that selectively hydrolyze away the side chain of natural penicillins without cleaving the β-lactam bond. These enzymes are found in certain Gram-negative bacteria but

appear to be of negligible importance with respect to bacterial resistance to β-lactam antibiotics. More recently, ingeniously selective chemical processes have been devised for accomplishing removal of less interesting side chains from biosynthetic penicillins. The operational chemical freedom resulting from the convenient availability of 6-APA has led to partial synthesis of many thousands of analogues.



Generic name	Trade name	R_1
Fermentation-Derived Penicillins		
6-Aminopenicillanic acid		H
Benzylpenicillin (Penicillin G)	Generic	C_6H_5-CH_2-
Phenoxymethylpenicillin (Penicillin V)	Generic	C_6H_5-OCH_2-
Semi-Synthetic Penicillinase-Resistant Parenteral Penicillins		
Methicillin		Nafcillin	Nallpen, Unipen	Semi-Synthetic Penicillinase-Resistant Oral Penicillins		
Oxacillin (X = Y = H)	Bactocill	Cloxacillin (X = Cl, Y = H)	Cloxapen	
Dicloxacillin (X = Y = Cl)	Dycill, Pathocil	
Semi-Synthetic Penicillinase-Sensitive, Broad Spectrum, Parenteral Penicillins		
Carbenicillin (R_2 = H)	Geocillin	Carbenicillin indanyl (R_2 = )		
Ticarcillin	Ticar	Mezlocillin	Mezlin	Piperacillin	Pipracil	Semi-Synthetic Penicillinase-Sensitive, Broad-Spectrum, Oral Penicillins		
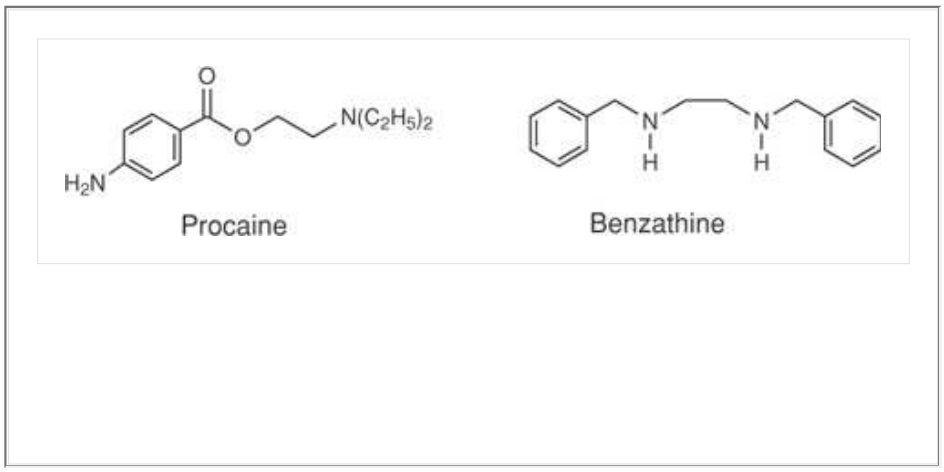
Ampicillin (X = H)	Principen, Omnipen	Amoxicillin (X = OH)	Amoxil, Trimox, Wymox	

Table 38.5. Commercially Significant Pencillins and Related Molecules

The sodium and potassium salts of penicillins are crystalline, hydroscopic, and water-soluble. They can be employed either orally or parentally. When dry, they are stable for long periods but hydrolyze rapidly when in solution. Their best stability is noted at pH values between 5.5 and 8.0 (especially at pH 6.0–7.2). The

procaine and benzathine salts of benzylpenicillin, on the other hand, are water insoluble. Because they dissolve slowly, they are used for repository purposes following injection when long-term blood levels are required.



Nomenclature

The nomenclature of the penicillins, as with most antibiotics, is complex. The Chemical Abstracts system is definitive and unambiguous, but it is too complex for ordinary use (Fig. 38.12). For example, the chemical name for benzylpenicillin sodium is monosodium (2*S*,5*R*,6*R*)-3,3-dimethyl-7-oxo-6-(2-phenylacetamido)-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylate.

Confusingly, the U.S. Pharmacopeia uses a different system that results in the atoms being numbered differently. The simplest system has stood the test of time and involves taking the repeating radical, carbonyl-6-APA, and using the chemical trivial name for the radical that completes the structure. Thus, use of the names benzylpenicillin and phenoxymethylpenicillin makes practical sense. There are three asymmetric centers in the benzylpenicillin molecule, as indicated by the asterisk in Table 38.5. This absolute stereochemistry must be preserved for useful antibiotic activity.

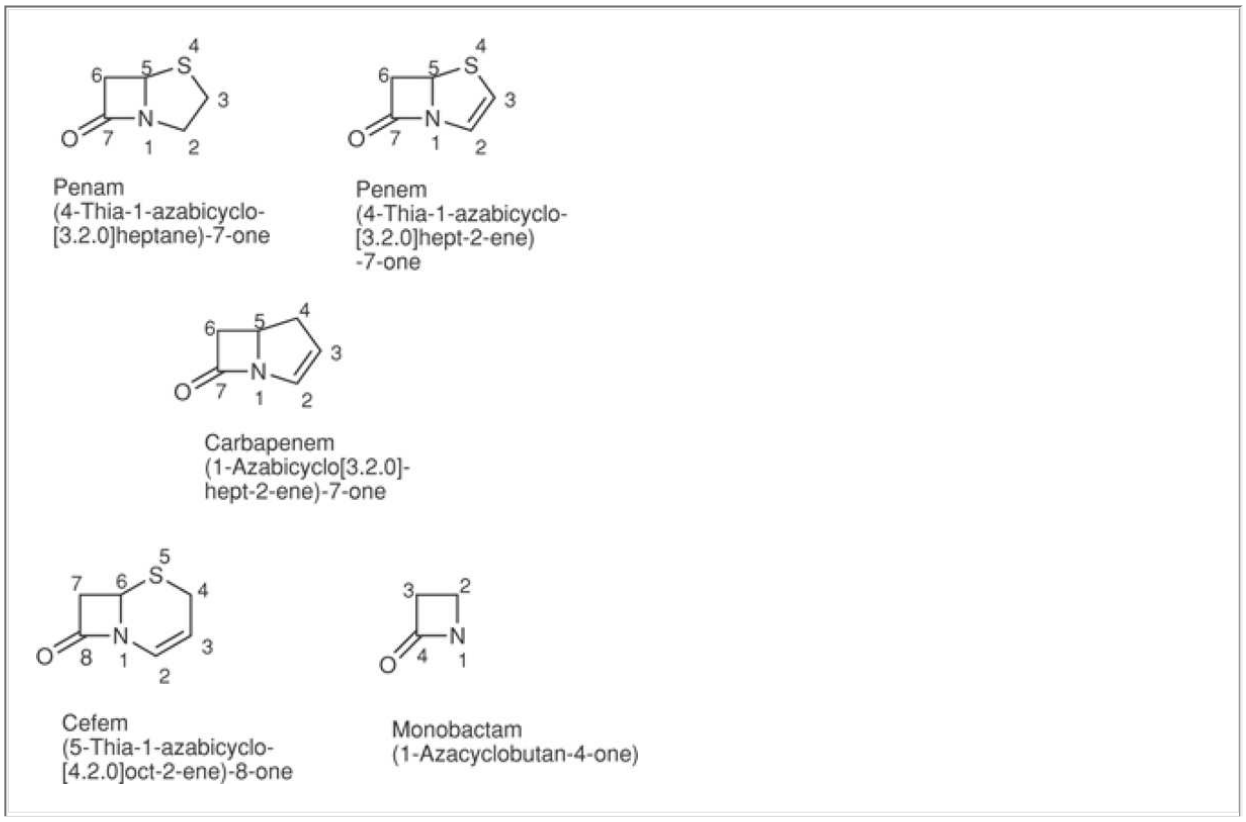


Fig. 38.12. Ring and numbering systems of clinically available β-lactam antibiotic types.

Clinically Relevant Chemical Instabilities

The most unstable bond in the penicillin molecule is the highly strained and reactive β-lactam amide bond. This bond cleaves moderately slowly in water unless heated, but it breaks down much more rapidly in alkaline solutions to produce penicilloic acid, which readily decarboxylates to produce penilloic acid (Fig. 38.13). Penicilloic acid has a negligible tendency to re-close to the corresponding penicillin, so this reaction is essentially irreversible under physiologic conditions. Because the β-lactam ring is an essential portion of the pharmacophore, its hydrolysis deactivates the antibiotic. A fairly significant degree of hydrolysis also takes place in the liver. The bacterial enzyme, β-lactamase, catalyzes this reaction as well and is a principal cause of bacterial resistance in the clinic. Alcohols and amines bring about the same cleavage reaction, but the products are the corresponding esters and amides. These products are inactive. A reaction with a specific primary amino group of aminoglycoside antibiotics is of clinical relevance, because it inactivates penicillins and cephalosporins (discussed later). When proteins serve as the nucleophiles in this reaction, the antigenic conjugates that cause many penicillin allergies are produced. Small molecules that are not inherently antigenic but that react with proteins to produce antigens in this manner are called haptens. Commercially

available penicillin salts may be contaminated with small amounts of these antigenic penicilloyl proteins derived from reaction with proteins encountered in their fermentative production or by high-molecular-weight, self-condensation–derived polymers resulting when penicillins are concentrated and react with themselves. Both of these classes of impurities are antigenic and may sensitize some patients.

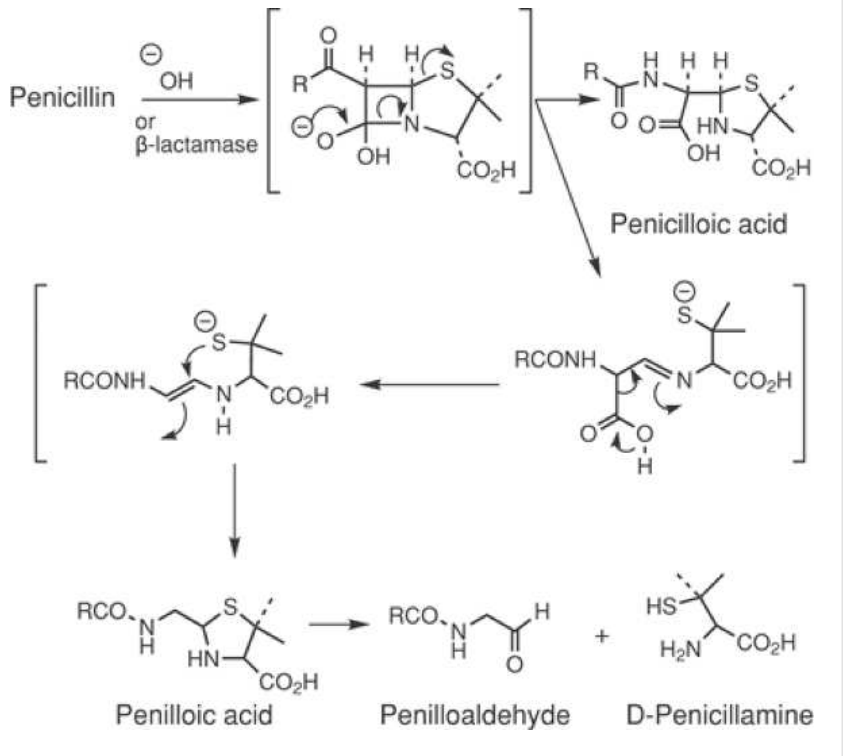

Fig. 38.13. Instability of β-lactams to nucleophiles.

Solutions of penicillins for parenteral use should be refrigerated, used promptly, and not stored. In acidic

solutions, the hydrolysis of penicillins is complex. Hydrolysis of the β-lactam bond can be shown through kinetic analysis to involve participation of the side-chain amide oxygen, because the rate of this reaction differs widely depending on the nature of the R group. The main end products of the acidic degradation are penicillamine, penilloic acid, and penilloaldehyde (Fig. 38.14). The intermediate penicillenic acid is highly unstable and undergoes subsequent hydrolysis to the corresponding penicilloic acid. An alternate pathway involves sulfur ejection to a product that, in turn, fragments to liberate penicilloic acid as well. Penicilloic acid readily decarboxylates to penilloic acid. The latter hydrolyzes to produce penilloaldehyde and penicillamine (itself used clinically as a chelating agent). Several related fragmentations to a variety of other products take place. None of these products has antibacterial activity. At gastric pH (~2.0) and temperature of 37°C, benzylpenicillin has a half-life measured in minutes. The less water-soluble amine salts are more stable.

Structure–Activity Relationship

The chemical substituents attached to the penicillin nucleus can greatly influence the stability of the penicillins as well as the spectrum of activity. It is important to recognize whether the structural changes affect drug stability on the shelf or in the GI tract (in vivo), improve stability toward bacterial metabolism, or enlarge the spectrum of activity.

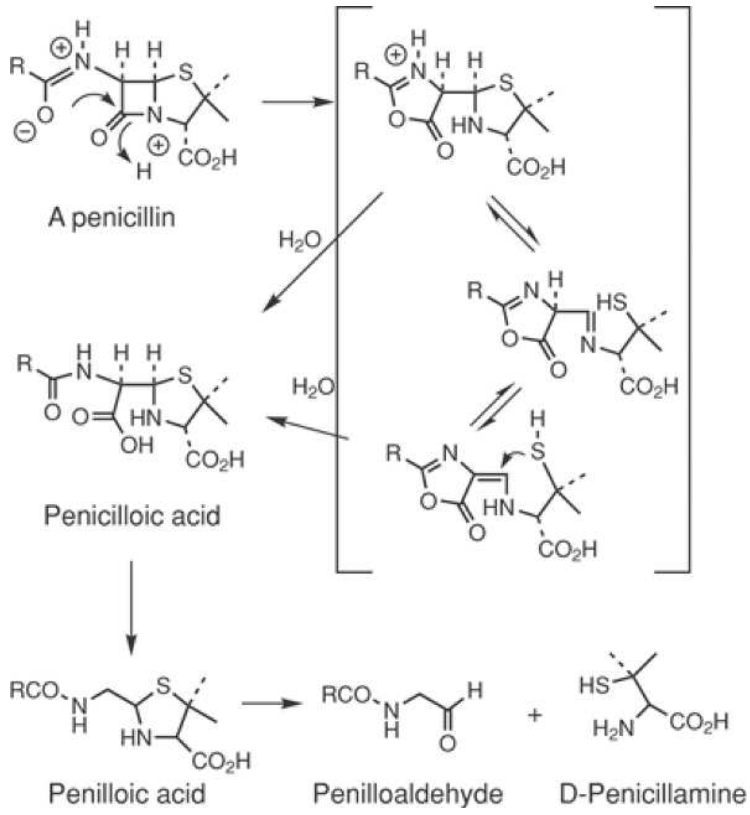

Fig. 38.14. Instability of penicillins in acid. Hydrolysis involves the C-6 side chain.

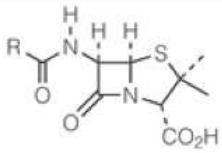

Drug	R	% Absorption intact drug
Benzylpenicillin		15–30
Pen V		60–73
Ampicillin		30–50
Amoxicillin		75–90

Table 38.6. Improved Acid Stability and Absorption of Substituted Penicillins

The substitution of a side-chain R group on the primary amine with an electron-withdrawing group decreases the electron density on the side-chain carbonyl and protects these penicillins, in part, from acid degradation. This property has clinical implications, because these compounds survive passage through the stomach better and many can be given orally for systemic purposes. The survival of passage and degree of absorption under fasting conditions is shown in Table 38.6.

In addition, in vitro degradation reactions of penicillins can be retarded by keeping the pH of solutions between 6.0 and 6.8 and by refrigerating them. Metal ions, such as mercury, zinc, and copper, catalyze the degradation of penicillins, so they should be kept from contact with penicillin solutions. The lids of containers used today are routinely made of inert plastics, in part, to minimize such problems.

The more lipophilic the side chain of a penicillin, the more serum protein bound is the antibiotic (Table 38.7).

This has some advantages in terms of protection from degradation, but it does reduce measurably the effective bactericidal concentration of the drug in whole blood. Contrary to popular assumption, the degree of serum protein binding of the penicillins has comparatively little influence on their half-lives. The penicillins are actively excreted into the urine via an active transport system for negatively charged ions, and the rate of release from their bound form is sufficiently rapid that the controlling rate is the kidney secretion rate. The serum half-life of penicillin G is approximately 0.4 to 0.9 hours and that of phenoxymethyl penicillin approximately 0.5 hours. Both are excreted into the urine by tubular excretion. Probenicid, when present, competes effectively for excretion and, as a consequence, prolongs the half-life.

Table 38.7. Protein Binding of Penicillins

Penicillin	% Protein binding
Benzyl penicillin	45 – 68%

Phenoxymethyl penicillin	75 – 89%
Methicillin	35 – 80%
Ampicillin	25 – 30%
Amoxicillin	25 – 30%
Carbenicillin	~50%
Oxacillin	>90%
	>90%
Cloxacillin	

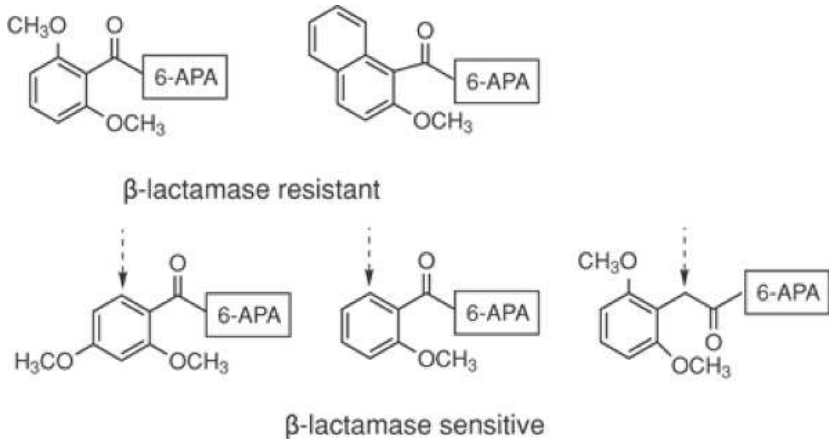

Fig. 38.15. β-Lactamase resistant/sensitive structural features.

Stability of the penicillins toward β-lactamase is influenced by the bulk in the acyl group attached to the primary amine. β-Lactamases are much less tolerant to the presence of steric hindrance near the side-chain amide bond than are the penicillin binding proteins. When the aromatic ring is attached directly to the side-chain carbonyl and both ortho positions are substituted by methoxy groups, β-lactamase stability results (Fig. 38.15). Movement of one of the methoxy groups to the para position, or replacing one of them by a hydrogen, resulted in an analogue sensitive to β-lactamases. Putting in a methylene between the aromatic ring and 6-APA likewise produced a β-lactamase–sensitive agent (see Fig. 38.15). These findings provide strong support for the hypothesis that its resistance to enzyme degradation is based on differential steric hindrance. Prime examples of this effect are seen in the drugs methicillin, nafcillin, oxacillin, cloxicillin, and dicloxicillin (Table 38.5).

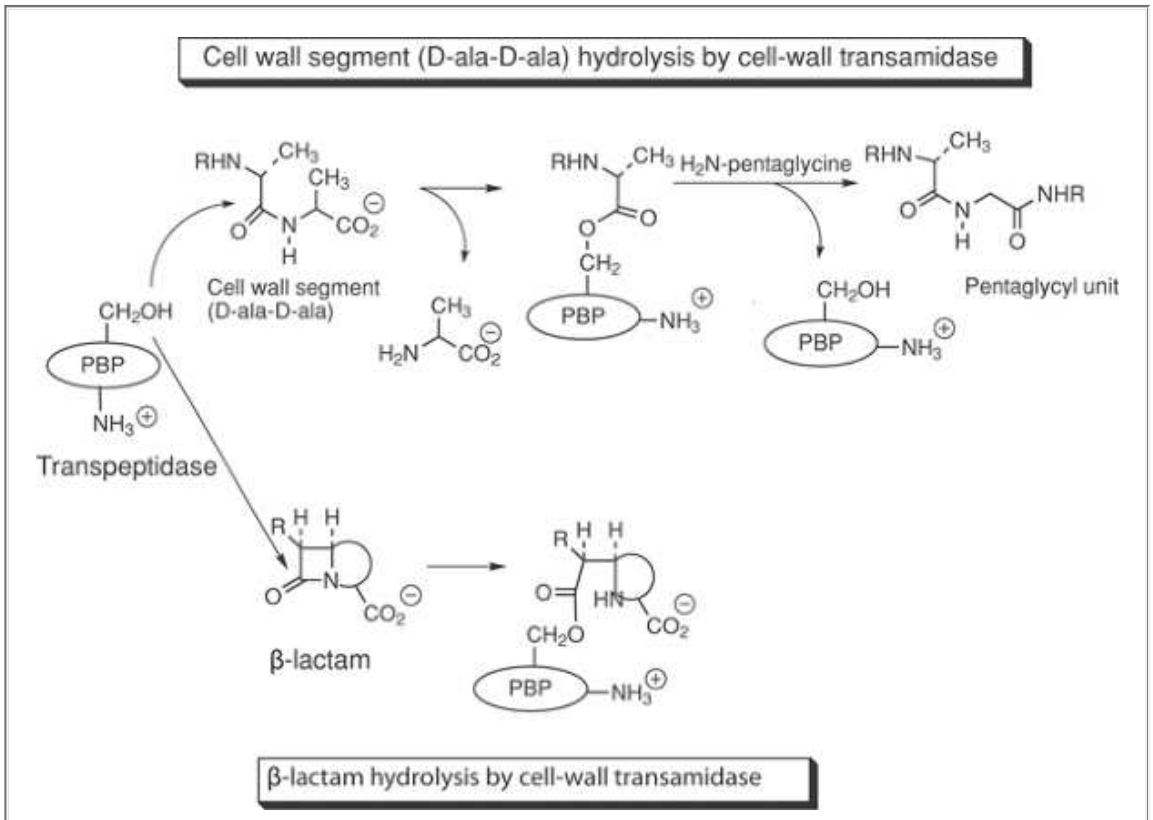

Fig. 38.16. Cell wall cross-linking and mechanism of action of β-lactams.

Mechanism of Action

The molecular mode of action of the β-lactam antibiotics is a selective and irreversible inhibition of the enzymes processing the developing peptidoglycan layer (Fig. 38.16). Just before cross-linking occurs, the peptide pendant from the lactate carboxyl of a muramic acid unit terminates in a D-alanyl-D-alanine unit. The terminal D-alanine unit is exchanged for a glycine unit on an adjacent strand in a reaction catalyzed by a cell wall transamidase. This enzyme is one of the penicillin biding proteins (carboxypeptidases, endopeptidases, and transpeptidases) that normally reside in the bacterial inner membrane and perform construction, repair, and housekeeping functions, maintaining cell wall integrity and playing a vital role in cell growth and division. They differ significantly from bacterium to bacterium, and this is used to rationalize different potency and morphologic outcomes following β-lactam attack on the different bacteria. The cell wall transamidase uses a serine hydroxyl group to attack the penultimate D-alanyl

unit, forming a covalent ester bond, and the terminal D-alanine, which is released by this action, diffuses away. The enzyme–peptidoglycan ester bond is attacked by the free amino end of a pentaglycyl unit of an adjacent strand, regenerating the active site of transpeptidase for further catalytic action and producing a new amide bond, which connects two adjacent strands together.

The three-dimensional geometry of the active site of the enzyme perfectly accommodates to the shape and separation of the amino acids of its substrate. Because the substrate has unnatural stereochemistry at the critical residues, this enzyme is not expected to attack host peptides or even other bacterial peptides composed of natural amino acids.

The penicillins and the other β-lactam antibiotics have a structure that closely resembles that of acylated D-alanyl-D-alanine. The enzyme mistakenly accepts the penicillin as though it were its normal substrate. The highly strained β-lactam ring is much more reactive than a normal amide moiety, particularly when fused into the appropriate bicyclic system. The intermediate acyl–enzyme complex, however, is rather different structurally from the normal intermediate in that the hydrolysis does not break penicillin into two pieces, as it

does with its normal substrate. In the penicillins, a heterocyclic residue is still covalently bonded and cannot diffuse away as the natural terminal D-alanine unit does. This presents a steric barrier to approach by the nearby pentaglycyl unit and, therefore, keeps the enzyme's active site from being regenerated and the cell wall precursors from being cross-linked. The resulting cell wall is structurally weak and is subject to osmotic stress. Cell lysis can result, and the cell rapidly dies, assisted by another class of bacterial enzymes, the autolysins. The result is a defective cell wall and an inactivated enzyme. The relief of strain that is obtained on enzymatic β-lactam bond cleavage is so pronounced that there is virtually no tendency for the reaction to reverse. Water also is an insufficiently effective nucleophile and cannot hydrolyze the complex either. Thus, the cell wall transamidase is stoichiometrically inactivated. The gaps in the cell wall produced by this covalent interruption are not filled in, because the enzyme is now inactivated. (More details of the putative drug–enzyme interaction will be discussed with the other classes of β-lactams.)

Binding of β-lactam antibiotics to PBP-1A and PBP-1B (transpeptidase) of *Escherichia coli* leads to cell lysis; to PBP-2 (transpeptidase) leads to oval cells deficient in rigidity and to inhibition of cell division; to PBP-3 (transpeptidase) leads to abnormally long, filamentous shapes by failure to produce a septum; and to PBP-4 through PBP-6 (carboxypeptidases) leads to no lethal effects. Approximately 8% of a dose of benzylpenicillin binds to PCP-1, 0.7% to PCP-2, 2% to PBP-3, 4% to PBP-4, 65% to PBP-5, and 21% to PBP-6. Thus, the majority of the penicillin dose bonds to PBPs for which the function remains obscure. Binding to PBP-1 is lethal. Other β-lactam antibiotics display different binding patterns. Amoxicillin and the cephalosporins bind more avidly to PBP-1, methicillin and cefotaxime to PBP-2, and mezlocillin and cefuroxime to PBP-3. All these drugs are lethal to susceptible bacteria.

Resistance

The first literature reports of a penicillinase were published in 1940 and 1944. This phenomenon was rare at the time and caused no particular alarm. Today, unfortunately, resistance to β-lactam antibiotics is increasingly common and is rather alarming. It can be intrinsic and involve decreased cellular uptake of drug, or it can involve lower binding affinity to the PBPs. This is particularly the case with MRSA, the PBP-2 of which has been mutated so that it no longer efficiently binds methicillin. Much more common, however, is the elaboration of a β-lactamase. β-Lactamases are enzymes (serine proteases) elaborated by microorganisms that catalyze hydrolysis of the β-lactam bond and inactivate β-lactam antibiotics to penicilloic acids before they can reach the PCPs (Fig. 38.17). In this, they somewhat resemble the cell wall transamidase from which they may have arisen. Hydrolytic regeneration of the active site is dramatically more facile with β-lactamases than is the case with cell wall transamidase so that the enzyme can turn over many times and a comparatively small amount of enzyme can destroy a large amount of drug. With Gram-positive bacteria, such as staphylococci, the β-lactamases usually are shed continuously into the medium and meet the drug outside the cell wall (Fig. 38.9). Thus, they are biosynthesized in significant quantities. With Gram-negative bacteria, a more conservative course is followed. Here, the β-lactamases are secreted into the periplasmic space between the inner and outer membrane, so although still distal to the PBPs, they do not readily escape into the medium and need not be resynthesized as often (Fig. 38.11). Numerous β-lactamases with various antibiotic substrate specificities are now known. Various classification systems are used for them, as illustrated in Tables 38.8 and 38.9. Elaboration of β-lactamases often is R factor–mediated and, in some cases, is even induced by the presence of β-lactam antibiotics. One now generally assumes that a *Staphylococcus aureus* strain will produce a

β-lactamase and that this will be less prevalent, but not uncommon, among *Haemophilus influenzae, Moraxella catarrhalis, Escherichia coli, and Klebsiella, Enterobacter, Serratia, Pseudomonas*, and *Bacteroides sp*. strains.

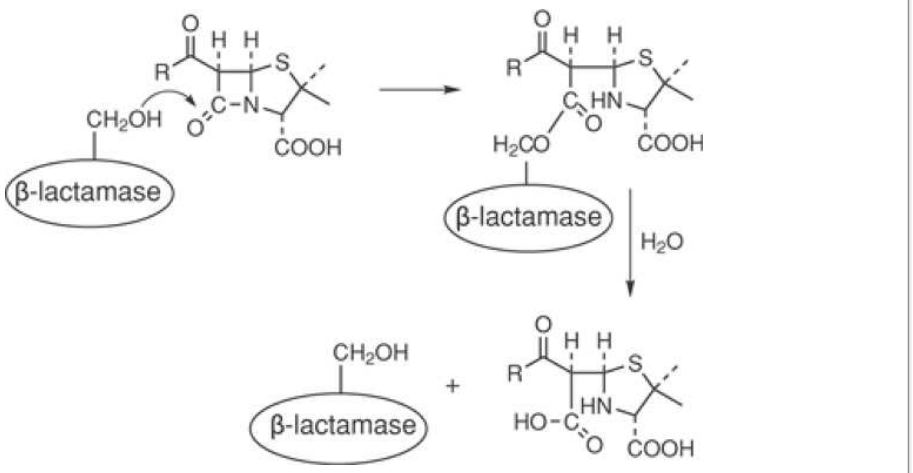

Fig. 38.17. β-Lactamase catalyzed hydrolysis of penicillins.

Table 38.8. β-lactamase Classifications According to Sykes and Matthew

Type	Substrate preferences	Gene location	Inducibility
Gram +/-	Penicillins mainly	r-Plasmid	Mostly
I	Cephalosponins mainly	Chromosome	Mainly
II	Penicillins mainly	Chromosome	Constituitive
III	Broad spectrum	r-Plasmid	Constituitive
IV	Broad spectrum	Chromosome	Constituitive
V	Methicillin, oxacillin, cloxacillin	r-Plasmid	Constituitive

Sykes RB, Matthew M. The beta-lactamases of gram-negative bacteria and their role in resistance to beta-lactam

antibiotics. J Antimicrob Chemother 1976; 2: 115–117.

Allergenicity

Approximately 6 to 8% of the U.S. population is allergic to β-lactam antibiotics. Most commonly, this is expressed as a mild drug rash or itching and is of delayed onset. Occasionally, the reaction is immediate and profound. It may include cardiovascular collapse and shock and can even result in death. Sometimes, penicillin allergy can be anticipated by taking a medication history, and often, the patients who are likely to be allergic are those with a history of hypersensitivity to a wide variety of allergens (e.g., foods and pollens). A previous history of allergy to penicillins is a contraindicating factor to their use. Topical wheal-and-flare tests are available when there is doubt. When an allergic reaction develops, the drug must be discontinued, and, because cross-sensitivity is common, other β-lactam drugs should generally be avoided. Considering all therapeutic categories, penicillins, especially the ones most commonly employed (benzylpenicillin and ampicillin/amoxicillin), are probably the drugs most associated with allergy. Erythromycin and clindamycin are useful alternate choices for therapy in many cases of penicillin allergy.

Table 38.9. β-Lactamase Classification According to Ambler[a] and Bush-Jacoby-Medeiros[b]

Classa	Characteristics
A	Penicillinases and TEM-type, broad-spectrum enzymes
B	Increased activity against cephalosporins
C	Chromosomal cephalosporinases of Gram-negative bacteria
D	Oxacillin-hydrolyzing enzymes
Groupb	**Characteristics**
1	Cephalosporinases that are not inhibited by clavulanic acid
2	β-Lactamases inhibited by β-lactamase inhibitors
3	Metallo-β-lactamases that are poorly inhibited by all classical β-lactamase inhibitors
4	Penicillinases that are not inhibited by clavulanic acid

[b]Bush K, Jacoby GA, Medeiros AA. A functional classification scheme for beta-lactamase and its correlation with molecular structure. Antimicrob Agents Chemother 1995;39:1211–1233.

In some cases, the patient may have become sensitized without knowing it because of previous passive exposure through contaminated foodstuffs or cross-contaminated medications. Penicillins are manufactured in facilities separate from those used to prepare other drugs to prevent cross-contamination and possible sensitization. Animals treated with penicillins are required to be drug-free for a significant time before products prepared from them can be consumed. The number of pharmacists who unknowingly override these protective measures by failing to cleanse their pill counters properly between prescriptions is unknown.

Because the origin of the allergy is a haptenic reaction with host proteins and the responsible bond in the drug is the β-lactam moiety, this side effect is caused by the pharmacophore of the drug and is unlikely to be overcome by molecular manipulation.

Individual Penicillins

The penicillins usually are discussed under various groups based on spectrum of activity and sensitivity or resistance toward β-lactamase. One of the earliest and still most commonly used penicillin is benzylpenicillin.

Benzylpenicillin Group

Benzylpenicillin (Penicillin G, Table 38.5). With the exception of *Neisseria gonorrhoeae* and *Haemophilus influenza* and a few bacteria encountered less frequently, the useful antimicrobial spectrum of benzylpenicillin is primarily against Gram-positive cocci. Because of its cheapness, efficacy, and lack of toxicity (except for acutely allergic patients), benzylpenicillin remains a remarkably useful agent for the treatment of diseases caused by susceptible microorganisms. As with most antibiotics, susceptibility tests must be performed, because many formerly highly sensitive microorganisms are now comparatively resistant. Infections of the upper and lower respiratory tract and of the genitourinary tract are the particular province of benzylpenicillin. Infections

caused by group A β-hemolytic streptococci (pharyngitis, scarlet fever, cellulitis, pelvic infections, and septicemia) are commonly responsive. Group B hemolytic streptococci infections; especially of neonates (acute respiratory distress, pneumonia, meningitis, septic shock, and septicemia) usually respond. *Pneumococcal* pneumonia, *Haemophilus influenza* pneumonia of children, *Streptococcus pneumoniae*– and *Streptococcus pyogenes*–caused otitis media and sinusitis, meningococcal meningitis and brain abscess, meningococcal and pneumococcal septicemia, streptococcal endocarditis (often by *Streptococcus viridans*), pelvic inflammatory disease (often by *Neisseria gonorrhoeae* and *S. pyogenes*), uncomplicated gonorrhea (*N. gonorrhoeae*), meningitis (*Neisseria meningitidis*), syphilis (*Treponema pallidum*), Lyme disease (*Borrelia burgdorferi*), gas gangrene (*Clostridium perfringens*), and tetanus (*Clostridium tetani*) are among the diseases that commonly respond to benzylpenicillin therapy, either alone or sometimes with other drugs used in combination. Nonpenicillinase-producing *Staphylococcus aureus* and *Staphylococcus epidermidis* are quite sensitive but are all too rare today. Other, less common bacterial diseases also respond, such as those caused by *Bacillus anthracis* (anthrax) and *Corynebacterium diphtheriae* (diptheria).

Because of its cheapness, mild infections with susceptible microorganisms can be treated with comparatively large oral doses, although the most effective route of administration is parenteral, because fivefold the blood level can be regularly achieved in this manner. As previously indicated (see Clinically relevant chemical instabilities above), penicillin G is unstable under the acidic conditions of the stomach.

Very water-insoluble penicillin salts form with procaine and with N, N′-benzathine. These find therapeutic application for deep intramuscular (IM) injections. This produces lower but prolonged levels of penicillin as the drug slowly diffuses from the injection site.

The need to improve defects in benzylpenicillin stimulated an intense research effort that persists to this

day. Overcoming such negative features as comparative instability (particularly to acid), comparatively poor oral absorption, allergenicity, sensitivity to β-lactamases, and relatively narrow antimicrobial spectrum have been objectives of this work. Only antigenicity has failed to respond significantly to this effort.

Phenoxymethyl penicillin (Penicillin V, Table 38.5). Penicillin V is produced by fermentation in which the medium is enriched in phenoxyacetic acid. It also can be prepared by semisynthesis, and it is considerably more acid stable than benzylpenicillin, as indicated by oral absorption (Table 38.6). This is rationalized as being caused by the electronegative oxygen atom in the C-7 amide side chain inhibiting participation in β-lactam bond hydrolysis. In any case, penicillin V was the first of the so-called oral penicillins, giving higher and more prolonged blood levels than penicillin G itself. Its antimicrobial and clinical spectrum is roughly the same as that of benzylpenicillin, although it is somewhat less potent and is not, as a rule, used for acutely serious infections. Penicillin V has approximately the same sensitivity to β-lactamases and allergenicity as penicillin G.

Penicillinase-Resistant Parenteral Penicillins

Methicillin (Table 38.5). Although archaic today, methicillin was the first of the penicillinase-resistant agents to reach the clinic. It is unstable to gastric acid, having a half-life of 5 minutes at pH 2, so it must be administered via injection. As shown in Figure 38.15, increased bulk resulting from the addition of the dimethoxybenzoyl group to 6-APA leads to methicillin and a β-lactamase–resistant drug. Methicillin has a significantly narrower antimicrobial spectrum and less potency, so it was restricted to clinical use primarily for parenteral use in infections caused by β-lactamase–producing *Staphylococcus aureus* and a few other infections. Lately, an increasing number of infections have been found that are caused by MRSA. The mode of resistance in these cultures appears to be a reduced uptake and alteration in the PBPs. In particular, an altered PBP-2 is formed that has a very low affinity for β-lactams, including methicillin. Furthermore, methicillin is an efficient inducer of penicillinases, further counting against it. Consequently, this drug fell out of favor, and methicillin has now been supplanted by a number of agents.

Nafcillin (Table 38.3). Nafcillin has a fused benzene ring on one flank and an ethoxy moiety on the other of the side-chain amide linkage. Although slightly more acid stable than methicillin, it is virtually identical to it clinically.

Oxacillin, cloxacillin, and dicloxacillin. Using an isoxazolyl ring as a bio-isosteric replacement for the benzene ring and a methyl on one flank and a substituted benzene ring on the other in place of the methoxyls of methicillin produces the isoxazolyl penicillins. These are oxacillin, cloxacillin, and dicloxacillin (Table 38.5). Chemically, they differ from one another in the number of chlorine substituents on the benzene ring. Like methicillin, these generally are less potent than benzylpenicillin against Gram-positive microorganisms (generally staphylococci and streptococci) that do not produce a β-lactamase but retain their potency against those that do. An added bonus exists in that they are somewhat more acid stable. Thus, they may be taken orally, and they are more potent as well. Because they are highly serum protein bound (Table 38.7), they are not good choices for treatment of septicemia. Microorganisms resistant against methicillin generally also are resistant to the isoxazolyl group of penicillins.

Like nafcillin, the isoxazoyl group of penicillins is primarily used against *Staphylococcus aureus* in osteomyelitis, septicemia, endocarditis, and CNS infections.

Vancomycin (discussed later) is the current favorite for treatment of infections by MRSA with cotrimoxazole and rifampin often of value as well.

Penicillinase-Sensitive, Broad-Spectrum, Oral Penicillins

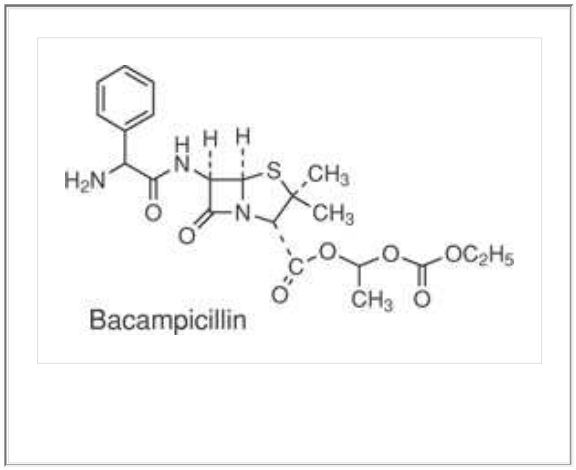
Ampicillin. The important first member of this group, ampicillin, is a benzylpenicillin analogue in which one of the hydrogen atoms of the side-chain methylene has been replaced with a primary amino group to produce an *R*-phenylglycine moiety (Table 38.5). In addition to significant acid stability, enhancing its successful oral use, the antimicrobial spectrum is shifted so that many common Gram-negative pathogens are sensitive to ampicillin. This is believed to result from greater penetration of ampicillin into Gram-negative bacteria. The acid stability generally is believed to be caused by the electron withdrawing character of the protonated primary amine group, reducing participation in hydrolysis of the β-lactam bond as well as to the comparative difficulty of bringing another positively charged species (H_3O^+) into the vicinity of the protonated amino

group. The oral activity of ampicillin is abetted, in part, by active uptake assisted by the small intestine peptide carrier. Ampicillin has an apparent half-life of approximately 15 to 20 hours at pH 2.0 and 35°C. It unfortunately lacks stability toward β-lactamases, and resistance is an ever-increasing phenomenon. To assist in dealing with this, several additives for coadministration have been developed that inhibit the action of the β-lactamases (β-lactamase inhibitors).

In addition to the usual mode of penicillin allergenicity, concentrated preparations of ampicillin can self-condense to form high-molecular-weight aggregates through reaction of its primary amino group with the β-lactam bond of another molecule. These aggregates are thought to be antigenic and to be responsible for ampicillin allergenicity—a form of hypersensitivity that differs in some details from the usual penicillin allergenicity, which ampicillin also possesses. Ampicillin and amoxicillin are the penicillins most commonly associated with drug-induced rash. Avoiding use of old preparations is a somewhat effective means of dealing with this potential problem.

Ampicillin is essentially equivalent to benzylpenicillin for pneumococcal, streptococcal, and meningococcal infections, and many strains of Gram-negative *Salmonella*, *Shigella*, *Proteus mirabilis*, and *Escherichia coli*, as well as many strains of *Haemophilus influenzae* and *Neisseria gonorrhoeae*, respond well to oral treatment with ampicillin.

Bacampicillin

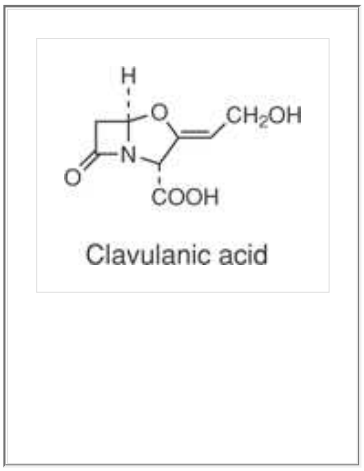


Although comparatively well absorbed (30–55%), the oral efficacy of ampicillin for systemic infections can be enhanced significantly through the preparation of pro-drugs. In contrast to ampicillin itself, which is amphoteric, bacampicillin is a weak base and is very well absorbed in the duodenum (80–98%). Enzymatic ester hydrolysis in the gut wall liberates carbon dioxide and ethanol, followed by spontaneous loss of acetaldehyde and production of ampicillin. The acetaldehyde is metabolized oxidatively by alcohol dehydrogenase to produce acetic acid, which joins the normal metabolic pool.

Amoxacillin (Table 38.5). Amoxicillin is a close analogue of ampicillin, in which a para-phenolic hydroxyl group has been introduced into the side-chain phenyl moiety. This adjusts the isoelectric point of the drug to a more acidic value, and this is believed to be partially responsible, along with the intestine peptide transporter, for the enhanced blood levels obtained with amoxicillin as compared to ampicillin itself (Table 38.6). Better oral absorption (74–92%) leads to less disturbance of the normal GI flora and, therefore, less drug-induced diarrhea. The antimicrobial spectrum and clinical uses of amoxicillin are approximately the same as those of ampicillin itself, and it is presently one of the most popular drugs in North America.

The addition of clavulanic acid (below) to amoxicillin (Augmentin) gives a combination in which the clavulanic acid serves to protect amoxicillin to a considerable extent against β-lactamases. This is now an extremely popular antimicrobial combination for outpatient use.

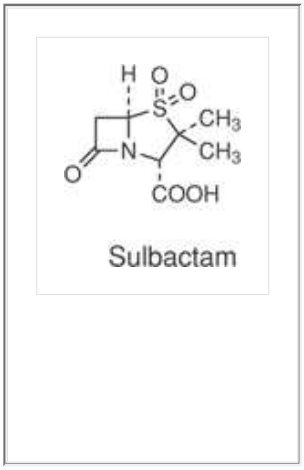
Clavulanic acid



Clavulanic acid

Clavulanic acid is a mold product with only weak intrinsic antibacterial activity, but it is an excellent irreversible inhibitor of most β-lactamases. It is believed to acylate the active site serine by mimicking the normal substrate. Hydrolysis occurs with some β-lactamases, but in many cases, subsequent reactions occur that inhibit the enzyme irreversibly. This leads to its classification as a mechanism-based inhibitor (or so-called suicide substrate). The precise chemistry is not well understood (Fig. 38.18), but when clavulanic acid is added to ampicillin and amoxicillin preparations, the potency against β-lactamase–producing strains is markedly enhanced.

Sulbactam



Sulbactam

Another β-lactamase–disabling agent is sulbactam. Sulbactam is prepared by partial chemical synthesis from penicillins. The oxidation of the sulfur atom to a sulfone greatly enhances the potency of sulbactam. The combination of sulbactam and ampicillin (Unasyn) is now clinically popular.

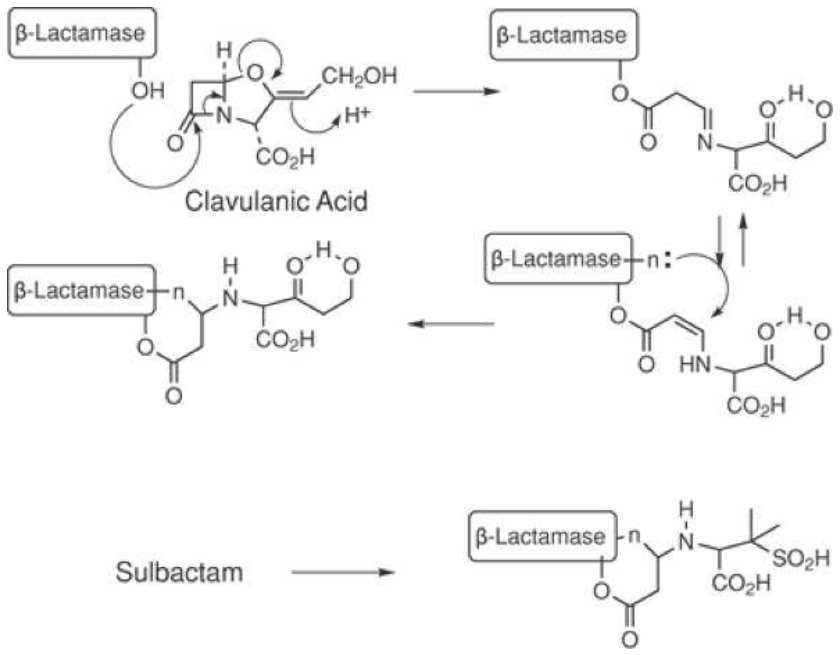


Fig. 38.18. Speculative mechanism for irreversible inactivation of β-lactamase by clavulanic acid and sulbactam.

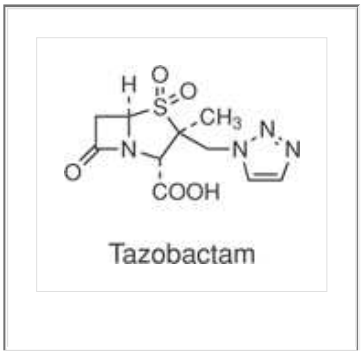
If instead of a β-lactamase, ampicillin resistance is caused by a penetration barrier, clavulanic acid and sulbactam are not able to overcome this, because the underlying mechanism is different. Not all β-lactamases, however, are sensitive to the presence of clavulanic acid or to sulbactam.

Penicillinase-Sensitive, Broad-Spectrum, Parenteral Penicillins

Mezlocillin and piperacillin. Mezlocillin and piperacillin are ampicillin derivatives in which the D–side chain amino group has been converted by chemical processes to a variety of substituted urea analogues (Table 38.5). They are known as acylureidopenicillins. They preserve the useful anti-Gram-positive activity of ampicillin but have higher anti-Gram-negative potency. Even some strains of *Pseudomonas aeruginosa* are sensitive to these agents. It is speculated that the added side-chain moiety mimics a longer segment of the peptidoglycan chain than ampicillin does. It is recalled that this cell wall fragment usually is a tetrapeptide, so there certainly is room for an extension in this direction. This would give more possible attachment points to the penicillin biding proteins, and perhaps these features are responsible for their enhanced antibacterial properties. These agents are used parenterally with particular emphasis on Gram-negative bacteria, especially *Klebsiella pneumoniae* and the anaerobe *Bacteroides fragilis*. Resistance caused by β-lactamases is a prominent feature of their use, so disk testing and incorporation of additional agents (e.g., an aminoglycoside) for the treatment of severe infections is advisable.

Piperacillin and tazobactam combination (Zosyn)



Tazobactam often is coadministered with piperacillin because of tazobactam's ability to inhibit β-lactamases. Tazobactam, like other β-lactamase inhibitors, has little or no antibacterial activity. This effect is analogous to that of clavulanic acid and sulbactam (discussed above).

Carbenicillin and indanyl carbenicillin. Carbenicillin is a benzylpenicillin analogue in which one of the methylene hydrogens of the side chain has been substituted with a carboxylic acid moiety (Table 38.5). The specific stereochemistry of this change is not very important, because both diastereoisomers are configurationally unstable and mutarotate with time to produce the same mixture of epimers. The introduction of the side-chain carboxyl produces enhanced anti-Gram-negative activity. In fact, carbenicillin is intrinsically one of the broadest spectrum penicillins. Carbenicillin is an order of magnitude less potent than the acylureidopenicillins. The drug is susceptible to β-lactamases and is acid unstable, so it must be given by injection.

Because it is a malonic acid hemiamide with a carbonyl (amide) moiety β to the carboxyl group, carbenicillin can decarboxylate readily to produce benzylpenicillin (Fig. 38.19). Although still an antibiotic, this degradation product has no activity against the organisms for which carbenicillin would be indicated, so this is still considered to be a degradation. In addition, the large doses of carbenicillin sodium that had to be employed (multigrams per day) resulted in ingestion of a significant amount of sodium ion, which could be a consideration with heart patients. Many of these problems were avoided by switching to the oral prodrug ester indanyl carbenicillin. This pro-drug is primarily used for oral treatment of urinary tract infections.

Ticarcillin. Ticarcillin is a sulfur-based bio-isostere of carbenicillin that cannot decarboxylate as the carboxyl group of carbenicillin does (Table 38.5). This agent is somewhat more potent against pseudomonads compared with indanyl carbenicillin.

When potassium clavulanate is added to ticarcillin (Timentin), the combination has enhanced antipse–domonad activity because of its enhanced stability to lactamases.

Summary Statement

The penicillins ushered in the era of powerful antibiotics, and their use transformed the practice of antimicrobial chemotherapy. A significant percentage of the population alive today owe their

longevity and relative freedom from morbidity to the use of these agents. The pace of discovery, however, has fallen off dramatically, and no new penicillin has been introduced into the market place for many years. The penicillins retain their important place in contemporary medicine, but research has turned elsewhere for novel agents.

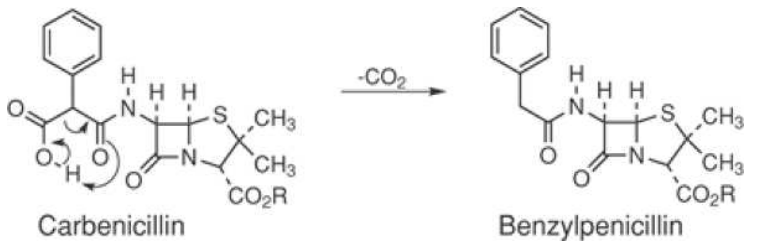


Fig. 38.19. Decarboxylation of carbenicillin to benzylpenicillin.

Cephalosporins History

In contrast to the discovery of the penicillins, in which the first agent had such outstanding biological antibiotic properties that it entered clinical use with comparatively little modification, the cephalosporins are remarkable for the level of persistence that was required before their initial discovery yielded economic returns. The original cephalosporin-producing fungus, *Cephalosporium acremonium*, was discovered in a sewage outfall off the Sardinian coast by Brotsu. In England, Abraham and Newton pursued it, because one of the constituents had the useful property of activity against penicillin-resistant cultures as a result of its stability to β-lactamases. Cephalosporin C, the component of special interest, is not potent enough to be a useful antibiotic, but removal, through chemical means, of the natural side chain produced 7-aminocephalosporanic acid (7-ACA), which, analogous to 6-APA, could be fitted with unnatural side chains (Fig. 38.20). Many of the compounds produced in this way are remarkably useful antibiotics. They differ from one another in antimicrobial spectrum, β-lactamase stability, absorption from the GI tract, metabolism, stability, and side effects (detailed below). Exploitation of sulfenic acid chemistry by Robert Morin, then at Eli Lilly and Company, resulted in the conversion of penicillins to cephalosporins, including 3-desacetoxy-7-ACA (7-ADCA). This process is practical because the penicillin fermentation is much more efficient than cephalosporin fermentation, making the transformation financially rewarding. Unfortunately, the chemistry involved is too complex to be covered in the space available here. Intensive investigation of the chemistry of 7-ACA and 7-ADCA has resulted in the subsequent preparation of many thousands of analogues from these two starting materials.

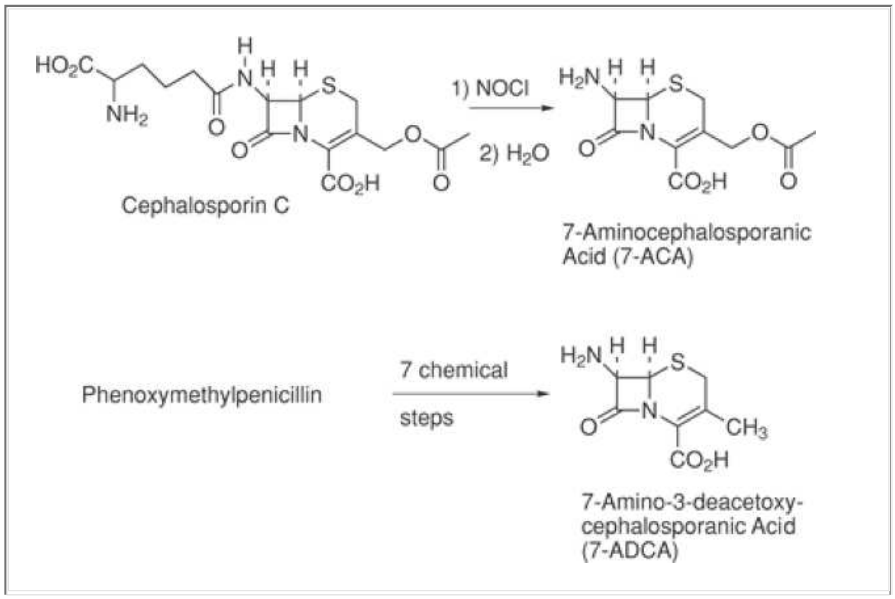

Fig. 38.20. Chemical preparation of 7-ACA and 7-ADCA.

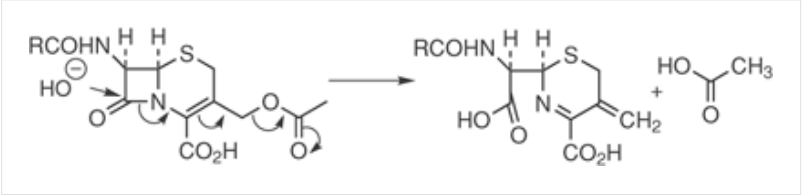
Chemical Properties

The cephalosporins have their β-lactam ring annealed to a 6-membered dihydrothiazine ring in contrast to the penicillins, wherein the β-lactam ring is fused to a 5-membered thiazolidine ring. As a consequence of the bigger ring, the cephalosporins should be less strained and less reactive/potent. Much of the reactivity loss, however, is made up by possession of an olefinic linkage at C-2,3 and a methyleneacetoxy group at C-3. When the β-lactam ring is opened by hydrolysis, the acetoxy group can be ejected, carrying away the developing negative charge. This greatly reduces the energy required for the process. Thus, the facility with which the β-lactam bond of the cephalosporins is broken is modulated both by the nature of the C-7 substituent (analogous to the penicillins) as well as by the nature of the C-3 substituent and its ability to serve as a leaving group. Considerable support for this hypothesis comes from the finding that isomerization of the olefinic linkage to C-3,4 leads to great losses in antibiotic activity. In practice, most cephalosporins are comparatively unstable in aqueous solutions, and the pharmacist often is directed to keep injectable preparations frozen before use. Being carboxylic acids, they form water-soluble sodium salts, whereas the free acids are comparatively water insoluble. In many cases, when the free acids are supplied, the injectable forms contain sodium bicarbonate to facilitate solution.

Clinically Relevant Chemical Instabilities

The principal chemical instability of the cephalosporins is associated with β-lactam bond hydrolysis. The role of the C-7 and C-3 side chains in these reactions was discussed previously. Ejection of the C-3 substituent following β-lactam bond cleavage usually is drawn for convenience as though this is an unbroken (concerted) process. Evidence on this point being equivocal, ejection of the side chain may, at certain times and with specific cephalosporins, involve a discrete intermediate with the β-lactam bond broken, but with the C-3 substituent not yet eliminated, whereas other cephalosporins have nonejectable C-3 substituents. The methylthiotetrazole (MTT) group, found in a number of cephalosporins, is capable of elimination. When this happens, this moiety is believed to be responsible, in part, for clotting difficulties and acute alcohol intolerance in certain patients. The role of the C-7 side chain in all of these processes is clearly important, but active participation of the amide moiety in a manner analogous to the penicillins rarely is specifically invoked. The same considerations that modulate the chemical stability of cephalosporins also are involved in dictating β-lactamase sensitivity, potency, and allergenicity as well.



Metabolism

Those cephalosporins that have an acetyl group in the side chain are subject to enzymatic hydrolysis

in the body. The result is molecules with a hydroxymethyl moiety at C-3. A hydroxy moiety is a poor leaving group, so this change is considerably deactivating with respect to breakage of the β-lactam bond. In

addition, the particular geometry of this part of the molecule leads to facile lactonization with the carboxyl group attached to C-2 (Fig. 38.21). In principle, this should result in formation of a different but reasonable leaving group; instead, the result is inactivation of the drugs involved. The penicillin biding proteins have an absolute requirement for a free carboxyl group to mimic that of the terminal carboxyl of the D-alanyl-D-alanine moiety in their normal substrate. Lactonization masks this docking functional group and, as a result, blocks affinity of the inhibitor for the enzyme.

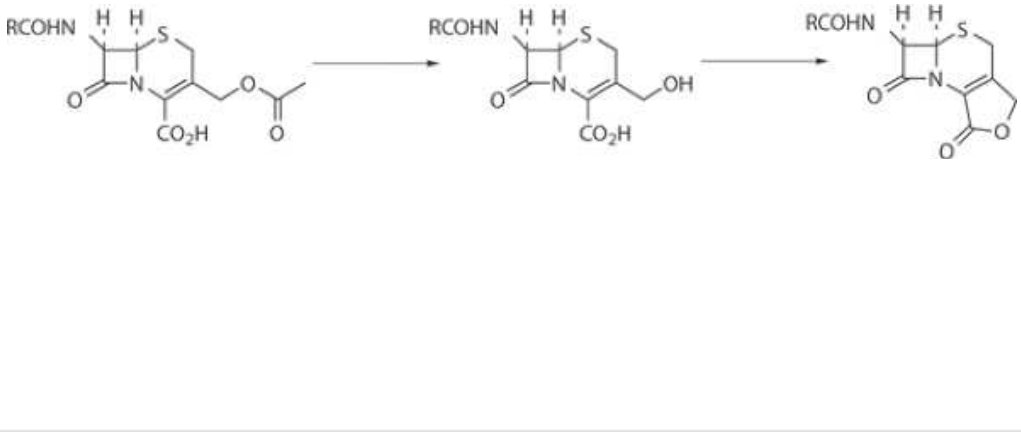


Fig. 38.21. Metabolism of C-3-acetyl–substituted cephalosporins.

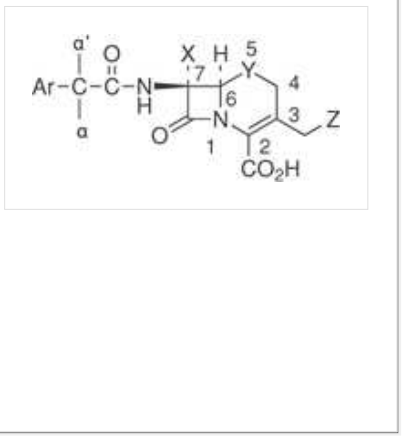
Structure-Activity Relationship



As with the penicillins, various molecular changes in the cephalosporin can improve in vitro stability, antibacterial activity, and stability toward β-lactamases. The addition of an amino and a hydrogen to the α and α′ position, respectively, results in a basic compound that is protonated under the acidic conditions of the stomach. The ammonium ion improves the stability of the β-lactam of the cephalosporin, leading to orally active drugs.

The 7β amino group is essential for antimicrobial activity (X = H), whereas replacement of the hydrogen at C-7 (X = H) with an alkoxy (X = OR) results in improvement of the antibacterial activity of the cephalosporin. Within specific cephalosporin derivatives, the addition of a 7α methoxy also improves the drugs stability toward β-lactamase. The derivatives where Y = S exhibit greater antibacterial activity than if Y = O, but the reverse is true when stability toward β-lactamase is considered. The 6α hydrogen is essential for biological activity. Finally, antibacterial activity is improved when Z is a 5-membered heterocycle versus a 6-membered heterocycle.

In a study examining the stability of cephalosporins toward β-lactamase, it was noted that the following

changes improved β-lactamase resistance: 1) The L-isomer of an α amino α′ hydrogen derivative of a cephalosporin was 30- to 40-fold more stable than the D-isomer, 2) the addition of a methoxyoxime to the α and α′ positions increased stability nearly 100-fold, and 3) the Z-oxime was as much as 20,000-fold more stable than the E-oxime (Fig. 38.22). These changes have been incorporated into a number of marketed and experimental cephalosporins (Cefuroxime, Ceftizoxime, Ceftazidime, and Cefixime).

Mechanism of Action

The cephalosporins are believed to act in a manner analogous to that of the penicillins by binding to the penicillin biding proteins, followed by cell lysis (Fig. 38.16). The full details of the manner in which bacterial cells are killed are still obscure. Cephalosporins are bactericidal in clinical terms.

Resistance

Analogous to the penicillins, susceptible cephalosporins can be hydrolyzed by β-lactamases before they reach the penicillin biding proteins. Many β-lactamases are known. Some are more efficient at hydrolysis of penicillins, some at hydrolysis of cephalosporins and some are indiscriminate. Certain β-lactamases are constitutive (chromosomally encoded) in certain strains of Gram-negative bacteria (*Citrobacter*, *Enterobacter*, *Pseudomonas*, and *Serratia* sp.) and normally are repressed. These are induced (or derepressed) by certain β-lactam antibiotics (e.g., imipenem, cefotetam, and cefoxitin). As with the penicillins, specific examples will be seen below wherein resistance to β-lactamase hydrolysis is conveyed by strategic steric bulk near the side-chain amide linkage. Recently, an increasing number of metallo-β-lactamases have been discovered. The mechanism of these enzymes is dependent on divalent metal ions, commonly zinc. These are both chromosomally and plasmid derived and are as yet confined to the Gram-negative rods. Commonly, these enzymes attack some penicillins, cephalosporins, and carbapenems. Penetration barriers to the cephalosporins also are well known.

Allergenicity

Allergenicity is less commonly experienced and is less severe with cephalosporins than with penicillins. Cephalosporins frequently are administered to patients who have had a mild or delayed penicillin reaction. Cross-allergenicity is comparatively common, however, and cephalosporins should be administered with caution for patients who have a history of allergies. Patients who have had a rapid and severe reaction to penicillins should not be treated with cephalosporins.

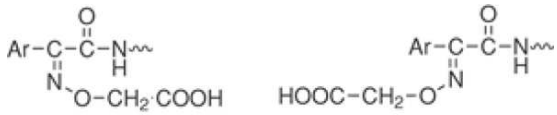


Fig. 38.22. Z- and E-oxime configuration.

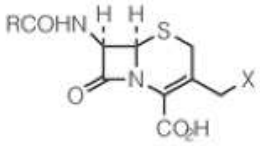
Nomenclature and Classification

Most cephalosporins have generic names beginning with cef- or ceph-. This is convenient for classification, but it makes discriminating between individual members a true memory test. The cephalosporins are

classified by a trivial nomenclature system loosely derived from the chronology of their introduction but more closely related to their antimicrobial spectrum. The first-generation cephalosporins primarily are active in vitro against Gram-positive cocci (penicillinase-positive and -negative *Staphylococcus aureus* and *S. epidermis*), group A β-hemolytic streptococci (*Streptococcus pyogenes*), group B streptococci (*Streptococcus agalactiae*), and *Streptococcus pneumoniae*. They are not effective against MRSA. They are not significantly active against Gram-negative bacteria, although some strains of *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus mirabilis*, and *Shigella* sp. may be sensitive. The second-generation cephalosporins generally retain the anti-Gram-positive activity of the first-generation agents but include *Haemophilus influenzae* as well and add to this better anti-Gram-negative activity so that some strains of *Acinetobacter*, *Citrobacter*, *Enterobacter*, *Escherichia coli*, *Klebsiella*, *Neisseria*, *Proteus*, *Providencia*, and *Serratia* also are sensitive. Cefotetan, cefmetazole, and cefoxitin have some antianaerobic activity as well. The third-generation cephalosporins are less active against staphylococci than the first-generation agents but are much more active against Gram-negative bacteria than either the first- or the second-generation drugs. They frequently are particularly useful against nosocomial multidrug-resistant hospital-acquired strains. One also adds *Morganella* sp. and *Pseudomonas aeruginosa* to the list of species that often are sensitive. Unfortunately, the third-generation agents tend to be more expensive. The fourth-generation cephalosporins have an antibacterial spectrum like the third-generation drugs but add some enterobacteria that are resistant to the third-generation cephalosporins. They also are more active against some Gram-positive organisms.



Generic names	Trade names	R	X	Salt

Oral and Parenteral Agent:				
Cephradine	Velosef		H	-

Table 38.10. First Generation Cephalosporins

Therapeutic Application

The incidence of cephalosporin resistance is such that it usually is preferable to do sensitivity disk testing before instituting therapy. Infections of the upper and lower respiratory tract, skin and related soft tissue, urinary tract, bones, and joints, as well as septicemias, endocarditis, intra-abdominal, and bile tract infections caused by susceptible Gram-positive organisms usually are responsive to cephalosporins. When a Gram-positive bacteria is involved, a first-generation agent is preferable. When the pathogen is Gram-negative and the infection is serious, parenteral use of a third-generation agent is recommended. For pelvic inflammatory disease, the number-one cause of sterility in sexually active young women, a

combination with doxycycline is preferred. This infection often is mixed and frequently includes *Chlamydia trachomitis*, anaerobes, and penicillinase-producing *Neisseria gonorrhoeae*.

Adverse Effects

Aside from mild or severe allergic reaction, the most commonly experienced cephalosporin toxicities are mild and temporary nausea, vomiting, and diarrhea associated with disturbance of the normal flora. Rarely, a life-threatening pseudomembranous colitis diarrhea associated with the opportunistic and toxin-producing anaerobic pathogen, *Clostridium difficile*, can be experienced. Rare blood dyscrasias, which can even include aplastic anemia, also are seen. Certain structural types (details below) are associated with prolonged bleeding times and an antabuse-like acute alcohol intolerance.

First-generation Cephalosporins (Table 38.10)

Cephapirin

Cephapirin has a pyridylthiomethylene containing side chain at C-7. It is comparatively resistant to

staphylococcal β-lactamase, although it is sensitive to many other β-lactamases. Cephapirin also is sensitive to host deacetylation in the liver, kidneys, and plasma, which reduces potency by about half. Nonetheless, it finds significant use in the parenteral treatment of infections because of susceptible bacteria. It is a substitute for the nafcillin subgroup of penicillins. It is not orally active. It is comparatively painful on IM injection, and its doses must be reduced in the presence of renal impairment. Following injection, it is excreted primarily in the urine, partly by glomerular filtration and partly by tubular secretion.

Cefazolin

Cefazolin has the natural acetyl side chain at C-3 replaced by a thio-linked thiadiazole ring. Although this group is an activating leaving group, the moiety is not subject to the inactivating host hydrolysis reaction that characterizes cephapirin. At C-7, it possesses a tetrazoylmethylene unit. Cefazolin is less irritating on injection than its cohort in this generation of drugs and has a longer half-life than cephapirin. Its dosing should be reduced in the presence of renal impairment. It is comparatively unstable and should be protected from heat and light.

Cephalexin

Use of the ampicillin-type side chain conveys oral activity to cephalexin. Whereas it no longer has an activating side chain at C-3 and, as a consequence, is somewhat less potent, it does not undergo metabolic deactivation and, thus, maintains potency. It is rapidly and completely absorbed from the GI tract and has become quite popular. Somewhat puzzling is the fact that the use of the ampicillin side chain in the cephalosporins does not result in a comparable shift in antimicrobial spectrum. Cephalexin, like the other first-generation cephalosporins is active against many Gram-positive aerobic cocci but is limited against Gram-negative bacteria. It is a widely used drug, particularly against Gram-negative bacteria causing urinary tract infections, Gram-positive infections (*Staphylococcus aureus*, *Streptococcus pneumoniae* and *Streptococcus pyogenes*) of soft tissues, pharyngitis, and minor wounds.

Cefadroxil

Cefadroxil has an amoxicillin-like side chain at C-7 and is orally active. There are some indications that cefadroxil has some immunostimulant properties mediated through T-cell activation and that this is of material assistance to patients in fighting infections. The prolonged biological half-life of cefadroxil allows once-a-day dosage.

Cephradine

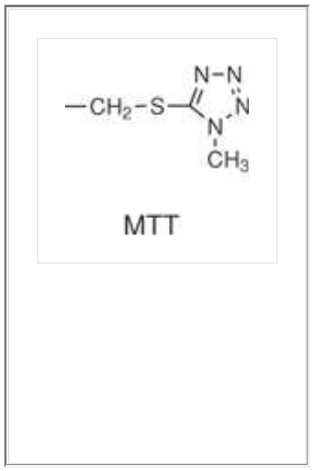
In cephradine, an interesting drug design device has been used. The aromatic ring in the ampicillin side chain has been partially hydrogenated by a Birch reduction such that the resulting molecule is still planar and π-electron excessive but has no conjugated olefinic linkages. It is comparatively acid stable and, therefore, is rapidly and nearly completely absorbed from the GI tract. Cephradine has the useful

characteristic that it can be used both orally and IM so that parenteral therapy can be started in an institutional setting and then the patient can be sent home with the oral form, thus avoiding the risk of having to establish a different antibiotic. This is consistent with the present economics requiring sending patients home earlier than some physicians prefer. Unfortunately, however, for other reasons the IM and intravenous (IV) versions of cephradine are no longer available in the United States.

Second-Generation Cephalosporins (Table 38.11)

Cefamandole nafate

Cefamandole nafate has a formylated D-mandelic amide moiety at C-7. The formate ester is cleaved rapidly in the host to release the more active cefamandole. The esterification also apparently overcomes the instability of cefamandole when it is stored in dry form. This agent has increased activity against *Haemophilus influenzae* and some Gram-negative bacilli as compared with the first-generation cephalosporins. Loss of the 5-thio-l-methyl-l-H-tetrazole moiety (referred to sometimes by the acronym MTT) from C-3 is associated with prothrombin deficiency and bleeding problems as well as with an Antabuse-like acute alcohol intolerance. On the other hand, this grouping enhances potency and prevents metabolism by deacetylation. Like the other second-generation cephalosporins, cefamandole is more active against Gram-negative bacteria. The principle clinical use is for lower respiratory tract, skin and skin structures, and bone and joint infections as well as septicemia and urinary tract infections when the organisms are sensitive.



Cefonicid

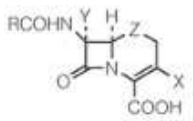
Cefonicid has an unesterified D-mandelic acid moiety at C-7 and a methylsulfothiotetrazole group at C-3. The latter is related to the MTT moiety mentioned above under cefamandole nafate; however, the clotting problems and Antabuse-like side effects associated with MTT have not been reported with cefonicid. The extra acid group in the C-3 side chain leads to this molecule being sold as an injectable disodium salt. Pain and discomfort at IM sites is experienced by some patients, as is a burning sensation and phlebitis. Cefonicid has a longer half-life than the other members of its group but achieves this at the price of somewhat lower potency against Gram-positive bacteria and aerobes. The drug is somewhat unstable, needs to be protected from light and heat, and may yellow or darken. If modest, however, this does not necessarily mean that the potency has decreased significantly, but overt precipitation does. Kirby-Bauer disk testing may overestimate the sensitivity of β-lactamase–producing bacteria to this agent, so some extra caution in interpretation of laboratory results is required.

Cefuroxime

Cefuroxime has a *Z*-oriented methoxyimino moiety as part of its C-7 side chain (Fig. 38.22). This conveys

considerable resistance to attack by many β-lactamases, but not by all. This is believed to result from the steric demands of this group. This hypothesis is supported by the finding that the *E*-analogue is attacked by β-lactamases. Resistance by *Pseudomonas aeruginosa*, on the other hand, is attributed to lack of penetration of the drug rather than to enzymatic hydrolysis. The carbamoyl moiety at C-3 is intermediate in

metabolic stability between the classic acetyl moieties and the thiotetrazoles. Cefuroxime penetrates comparatively well into cerebral spinal fluid and is used in cases of *Haemophilus influenzae* meningitis.



Generic name	Trade name	R	X	Y	Z	Salt
Parenteral Agents

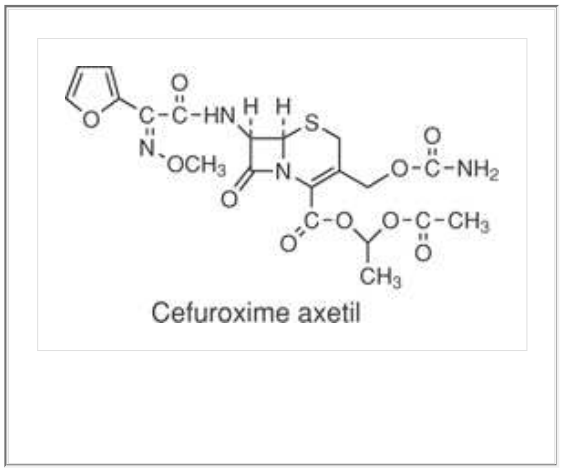
Loracarbef	Lorabid		Cl	H	CH_2	-
Cefprozil	Cefzil			H	S	-

Table 38.11. Second Generation Cephalosporins

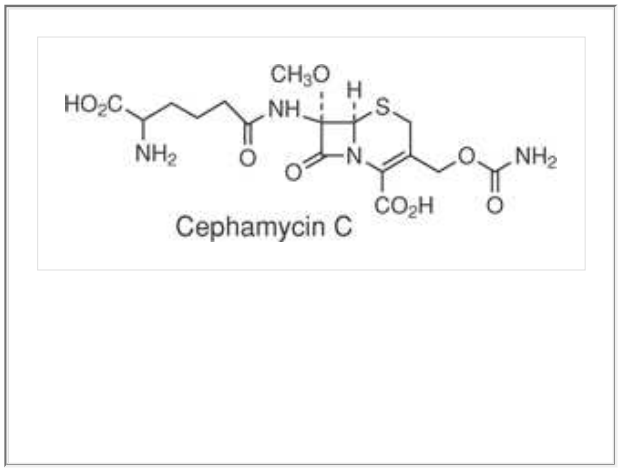
In the form of its axetil ester (1-[acetyloxy]ethyl ester) pro-drug, cefuroxime axetil, a more lipophilic drug is produced that gives satisfactory blood levels on oral administration. The ester bond is cleaved metabolically, and the resulting intermediate form loses acetaldehyde spontaneously to produce cefuroxime itself. Conveniently for the patient, cefuroxime axetil is stable for approximately 24 hours when it is dissolved in apple juice. The axetil is the only antibiotic officially labeled for treatment of Lyme disease (although doxycycline often is the first choice even without a label indication for that purpose).



Cefoxitin

Cefoxitin contains the same C-7 side chain as cephalothin and the same C-3 side chain as cefuroxime. The most novel chemical feature of cefoxitin is the possession of an α-oriented methoxyl group in place of the normal H-atom at C-7. This increased steric bulk conveys very significant stability against β-lactamases. The inspiration for these functional groups was provided by the discovery of the naturally occurring antibiotic cephamycin C

derived from fermentation of *Streptomyces lactamdurans*. Cephamycin C itself has not seen clinical use but, rather, has provided the structural clue that led to useful agents such as cefoxitin. Agents that contain this 7α methoxy group are commonly referred to as cephamycins. Ingenious chemical transformations now enable synthetic introduction of such a methoxy group into cephalosporins lacking this feature.



Cefoxitin has useful activity against gonorrhea and some anaerobic infections as compared with its second-generation relatives. On the negative side, cefoxitin has the capacity to induce certain broad-spectrum β-lactamases.

Cefotetan

Clearly, cefotetan also is inspired by cephamycin C but has a rather unusual sulfur-containing C-7 side-chain amide. Possession of two carboxyl groups leads to marketing it as a disodium salt. The C-3 MTT side chain suggests caution in monitoring prothrombin levels and bleeding times as well as in ingesting alcohol when using this agent. Like cefoxitin, cefotetan has better activity than the rest of this group against anaerobes. Cefotetan is comparatively stable, lasting for approximately 24 hours at room temperature when reconstituted. Slight yellowing and slight darkening produce materials that are still acceptable for therapy. Cefotetan is chemically incompatible with tetracycline, aminoglycosides, and with heparin, often forming precipitates with them. With respect to its molecular mode of action, it has a special affinity for PBP-3 of Gram-negative bacteria, consequently producing filamentous forms. It also binds well with PBP-1A and -1B,

therefore leading to cell lysis and death. Whereas it is stable to a wide range of β-lactamases, it also is a potent inducer in some bacteria.

Cefaclor

Cefaclor differs from cephalexin primarily in the bio-isosteric replacement of methyl by chlorine at C-3 and is quite acid stable, allowing oral administration. It also is quite stable to metabolism. It is less active against Gram-negative bacteria compared with the other second-generation cephalosporins but is more active against Gram-negative bacteria compared with the first-generation drugs.

Loracarbef

Loracarbef is a synthetic C-5 "carba" analogue of cefaclor. The smaller methylene moiety (as compared to sulfur) would be expected to make loracarbef more reactive/potent, and this seems to be the case. It is more stable chemically, however, and this adds to its virtues. Diarrhea is the most common adverse effect with loracarbef and, along with certain other adverse effects, is seen more frequently with children, so this lessens enthusiasm for the drug in patients younger than 12 years.

Cefprozil

Cefprozil has an amoxicillin-like side chain at C-7, but at C-3, there is now a l-propenyl group conjugated with the double bond in the 6-membered ring. The double bond is present in its two geometric isomeric forms, both of which are antibacterially active. Fortunately, the predominant trans form (Table 38.11) is much more active against Gram-negative organisms. Cefprozil most closely resembles cefaclor in its properties but is a little more potent. It is approximately 90% bioavailable following oral administration, and peak levels are not significantly smaller when taken with food. The oral suspension of cefprozil is sweetened with aspartame, so phenylketonuric patients should be wary of this formulation.

Cefmetazole

Cefmetazole is a cephamycin with a nonaromatic side chain at C-7. In addition to a fairly characteristic second-generation cephalosporin antimicrobial spectrum, it possess fairly significant anti-antiaerobic activity. The ejection of its C-3 side chain leads to alcohol intolerance of the disulfuram type and prolonged clotting times.

Third-Generation Cephalosporins (Table 38.12)

Cefotaxime

Cefotaxime, like cefuroxime, has a *Z*-methoxyimino moiety at C-7 that conveys significant β-lactamase resistance. Microorganisms that produce chromosomally mediated β-lactamases usually are resistant following mutation to derepression of these enzymes. Cefoxitin, cefotetan, and imipenems are quite effective inducers of these enzymes. The enzymes that result either hydrolyze the drug in the usual way or bind tightly to them, preventing them from attaching to the PBPs. The clinical importance of this phenomenon is unclear.

The oxime moiety of cefotaxime is connected to an aminothiazole ring. Like other third-generation cephalosporins, it has excellent anti-Gram-negative activity and is useful institutionally. It has a metabolically vulnerable acetoxy group attached to C-3 and loses approximately 90% of its activity when this is hydrolyzed. This metabolic feature also complicates the pharmacokinetic data, because both active forms are present and have different properties. Cefotaxime should be protected from heat and light and may color slightly without significant loss of potency. Like other third-generation cephalosporins, cefotaxime has less activity against staphylococci but has greater activity against Gram-negative organisms.

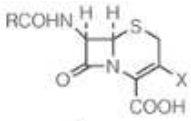
Ceftizoxime

In ceftizoxime, the whole C-3 side chain has been omitted to prevent deactivation by hydrolysis. It rather resembles cefotaxime in its properties; however, not being subject to metabolism, its pharmacokinetic properties are much less complex.

Ceftriaxone

Ceftriaxone has the same C-7 side-chain moiety as cefotaxime and ceftizoxime, but the C-3 side chain consists of a metabolically stable and activating thiotriazinedione in place of the normal acetyl group. The C-3 side chain is sufficiently acidic that at normal pH, it forms an enolic sodium salt; thus, the commercial

product is a disodium salt. It is useful for many severe infections and, notably, in the treatment of some meningitis infections caused by Gram-negative bacteria. It is quite stable to many β-lactamases but is sensitive to some inducible chromosomal β-lactamases.



Generic name	Trade name	R	X	Salt
Parenteral Agents				
Cefotaxime	Claforan		CH_2OAc	Na
Ceftizoxime	Cefizox		H	Na

Cefditoren pivoxil (2-carboxyester= )	Spectracef			-

Table 38.12. Third Generation Cephalosporins

Ceftazidime

In ceftazidime the oxime moiety is more complex, containing two methyl groups and a carboxylic acid. This assemblage conveys even more pronounced β-lactamase stability, greater anti–*Pseudomonas aeruginosa*, and increased activity against Gram-positive organisms. The C-3 side chain has been replaced by a charged pyridinium moiety. The latter considerably enhances water solubility and also highly activates the β-lactam bond toward cleavage. The drug must be protected against heat and light and may darken without significant loss of potency. It is not stable under some conditions. such as the presence of aminoglycosides and vancomycin. It also is attacked readily in sodium bicarbonate solutions. Resistance is mediated by chromosomally mediated β-lactamases and by lack of penetration into target bacteria. Otherwise, it has a very broad antibacterial spectrum.

Cefoperazone

Cefoperazone has a C-7 side chain reminiscent of piperacillin's and also possesses the C-3 side chain (MTT) that often is associated with the bleeding and alcohol intolerance problems among patients taking cephalosporins. Its useful activity against pseudomonads partly compensates for this, although it is not potent enough to be used as a single agent against this difficult pathogen. The C-7 side chain does not convey sufficient resistance to many β-lactamases, although the addition of clavulanic acid or sulbactam would presumably help.

There are comparatively few orally active third-generation agents. This group currently is represented by ceftibuten, cefixime, cefdinir, and cefpodoxime proxetil.

Cefixime

In cefixime, in addition to the β-lactamase–stabilizing *Z*-oximino acidic ether at C-7, the C-3 side chain is a vinyl group analogous to the propenyl group of cefprozil. This is believed to contribute strongly to the oral activity of the drug. Cefixime has anti-Gram-negative activity that is intermediate between that of the second-and third-generation agents described previously. It is poorly active against staphylococci, because it does not bind satisfactorily to PBP-2.

Ceftibuten

Ceftibuten has a *Z*-ethylidinecarboxyl group at C-7 instead of the *Z*-oximino ether linkages seen previously. This conveys enhanced β-lactamase stability and may contribute to oral activity as well. Ceftibuten has no C-3 side chain, so it is not measurably metabolized. It is highly (75–90%) absorbed on oral administration, but this is decreased significantly by food. Being lipophilic and acidic, it is significantly (65%) serum protein bound. Some isomerization of the geometry of the olefinic linkage appears to take place in vivo before excretion. It is mainly used for respiratory tract infections, otitis media, and pharyngitis as well as for urinary tract infections by susceptible microorganisms.

Cefpodoxime proxetil

Cefpodoxime proxetil is a pro-drug. It is cleaved enzymically to 2-propanol, carbon dioxide, acetaldehyde, and cefpodoxime in the gut wall. It has better anti–*Staphylococcus aureus* activity than cefixime and is used to treat pharyngitis, urinary tract infections, upper and lower respiratory tract infections, otitis media, skin and soft tissue infections, and gonorrhea.

Cefdinir

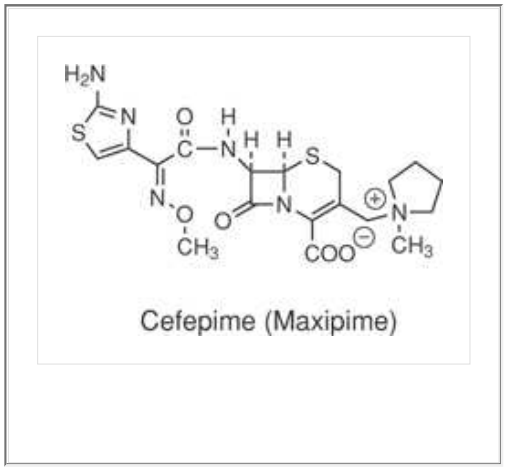
Cefdinir has an unsubstituted *Z*-oxime in its C-7 side chain, the consequence of which is attributed to its somewhat enhanced anti-Gram-positive activity—its main distinguishing feature. It has a vinyl moiety attached to C-3 that is associated with its oral activity. It has reasonable but not spectacular resistance to β-lactamases and is 20 to 25% absorbed on oral administration unless taken with fatty foods, which significantly diminishes blood levels.

Cefditoren Pivoxil

Cefditoren pivoxil is a new orally active pro-drug. Similar to cefpodoxime proxetil, the pivoxil ester is hydrolyzed following intestinal absorption to release the active drug, cefditoren, along with formaldehyde and pivalic acid. Cefditoren pivoxil should not be administered with drugs that reduce stomach acidity, because this may result in decreased absorption. The bioavailability of cefditoren pivoxil is increased if taken with food. Cefditoren pivoxil is indicated for mild to moderate infections in adults and adolescents with chronic bronchitis, pharyngitis/tonsillitis, and uncomplicated skin infections associated with Gram-negative bacteria. Effectiveness is reported against *Haemophilus influenzae* and *Moraxella catarrhalis* and includes β-lactamase–producing strains.

Fourth-Generation Cephalosporins

Cefepime



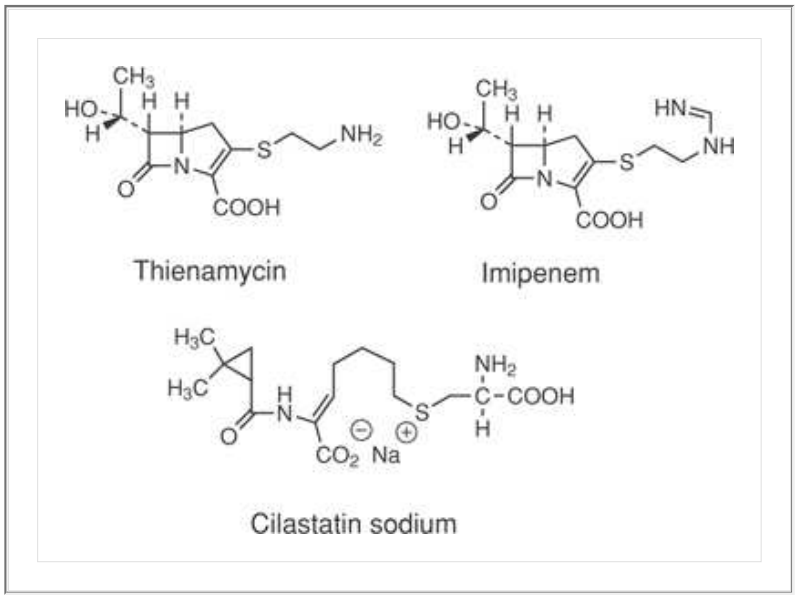
Cefepime is a semisynthetic agent containing a *Z*-methoxyimine moiety and an aminothiazolyl group at C-7, broadening its spectrum and increasing its β-lactamase stability as well as increasing its antistaphylococcal activity. The quaternary N-methylpyrrolidine group at C-3 seems to help penetration into Gram-negative bacteria. The fourth-generation cephalosporins are characterized by enhanced antistaphylococcal activity and broader anti-Gram-negative activity than the third-generation group. Cefepime is used IM and IV against urinary tract infections, skin and skin structure infections, pneumonia, and intra-abdominal infections.

Summary Statement

With their broader spectrum, including many very dangerous bacteria, the cephalosporins have come to dominate β-lactam chemotherapy despite often lacking oral activity. Because the cephalosporin field is still being very actively pursued, the student can expect continual introduction of new agents into the foreseeable future.

Carbapenems

Thienamycin, the first of the carbapenems, was isolated from *Streptomyces cattleya*. Because of its extremely intense and broad-spectrum antimicrobial activity as well as its ability to inactivate β-lactamases, it combines in one molecule the functional features of the best of the β-lactam antibiotics as well as the β-lactamase inhibitors. It differs structurally in several important respects from the penicillins and cephalosporins. The sulfur atom is not part of the 5-membered ring but, rather, has been replaced by a methylene moiety at that position. Carbon is roughly half the molecular size of sulfur. Consequently, the carbapenem ring system is highly strained and very susceptible to reactions cleaving the β-lactam bond. The sulfur atom is now attached to C-3 as part of a functionalized side chain.



The endocyclic olefinic linkage also enhances the reactivity of the β-lactam ring. Both make thienamycin unstable, which caused great difficulties in the original isolation studies. The terminal amino group in the side chain attached to C-3 is nucleophilic and attacks the β-lactam bond of a nearby molecule through an intermolecular reaction destroying activity (Fig. 38.23). Ultimately, this problem was overcome by changing the amino group to a less nucleophilic N-formiminoyl moiety by a semisynthetic process to produce imipenem. At C-6, there is a 2-hydroxyethyl group attached with α-stereochemistry. Thus, the absolute stereochemistry of the molecule is 5*R*,6*S*,8*S*. With these striking differences from the penicillins and cephalosporins, it is not surprising that thienamycin analogues bind differently to the penicillin biding proteins (especially strongly to PBP-2), but it is gratifying that the result is very potent broad-spectrum activity.

Imipenem

Imipenem, as well as thienamycin, penetrates very well through porins and is very stable, even inhibitory, to many β-lactamases. Imipenem is not, however, orally active. When used to treat urinary tract infections, renal dehydropeptidase-1 hydrolyzes imipenem through hydrolysis of the β-lactam and deactivates it. An inhibitor for this enzyme, cilastatin, is coadministered with imipenem to protect it. Inhibition of human dehydropeptidase does not seem to have deleterious consequences to the patient, making this combination highly efficacious against urinary tract infections.

The combination of imipenem and cilastatin (Primaxin) is approximately 25% serum protein bound. On injection, it penetrates well into most tissues, but not cerebrospinal fluid, and is subsequently excreted in the urine. It is broader in its spectrum than any other antibiotic presently available in the United States. This very potent combination is especially useful for treatment of serious infections by aerobic Gram-negative bacilli, anaerobes, and *Staphylococcus aureus*. It is used clinically for severe infections of the gut in adults as well as of the genitourinary tract, bone, skin, and endocardia, with allergic reactions as its main risk factor; imipenem also has the unfortunate property of being a good β-lactamase inducer. Because of these features, imipenem–cilastatin is rarely a drug of first choice but, rather, is reserved for use in special circumstances.

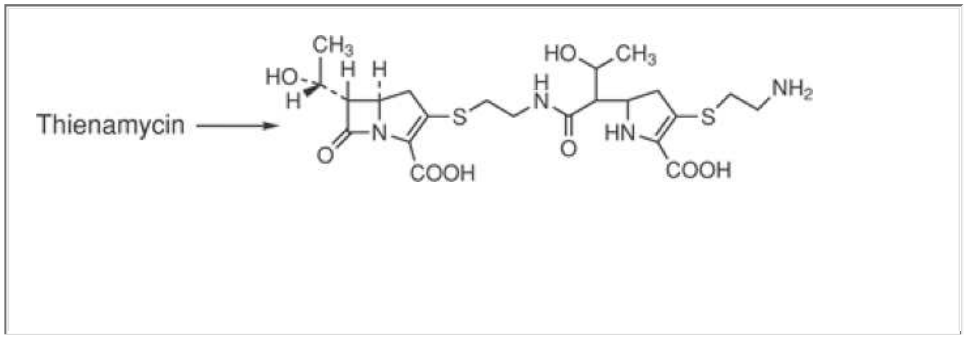


Fig. 38.23. Intermolecular instability reaction of thienamycin.

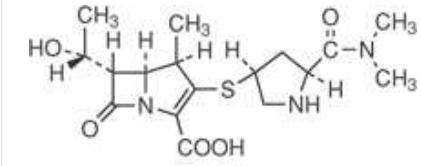
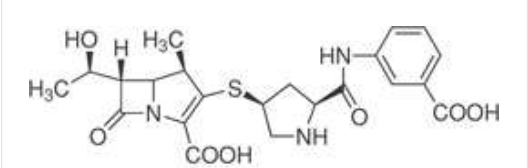
Meropenem



Meropenem is a synthetic carbapenem possessing a complex side chain at C-3. It also has a chiral methyl group at C-4. This methyl group conveys intrinsic resistance to hydrolysis by dehydropeptidase-1. As a consequence, it can be administered as a single agent for the treatment of severe bacterial infections.

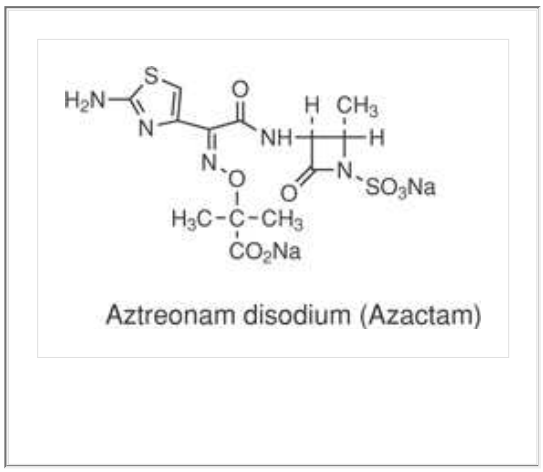
Ertapenem



Ertapenem is another synthetic carbapenem with a rather complex side chain at C-3. It is used once daily parenterally, with special application against anaerobes. As with meropenem, the 4-β-methyl group confers stability toward dehydropeptidase-1 It is not active against pseudomonads or acinetobacteria and, therefore, should not be substituted for imipenem or meropenem. It is relatively strongly bound to serum proteins, so it has a prolonged half-life, making it more convenient to use than the other carbapenems when its spectrum warrants this. Its reported indications include complicated intra-abdominal and complicated skin/skin structure infections caused by sensitive organisms (for intra-abdominal: *Escherichia coli, Clostridium clostridoforme, Bacteroides fragilis*, and *Peptostreptococcus* sp; for skin/skin structures: *Staphylococcus aureus* (methicillin-susceptible strains), *Streptococcus pyogenes, E. coli*, or *Peptostreptococcus* sp.). It can be administered once daily.

This class of antimicrobial agents is under intensive investigation, and several analogues were in various phases of preclinical investigation as of 2005.

Monobactams Aztreonam



Fermentation of unusual microorganisms led to the discovery of a class of monocyclic β-lactam antibiotics, named monobactams. None of these natural molecules have proven to be important, but the group served as the inspiration for the synthesis of aztreonam. Aztreonam is a totally synthetic parenteral antibiotic, the antimicrobial spectrum of which is devoted almost exclusively to Gram-negative microorganisms, and it is capable of inactivating some β-lactamases. Its molecular mode of action is closely similar to that of the penicillins, cephalosporins, and carbapenems, the action being characterized by strong affinity for PBP-3, producing filamentous cells as a consequence. Whereas the principal side chain closely resembles that of ceftazidime, the sulfamic acid moiety attached to the β-lactam ring was unprecedented. Remembering the comparatively large size of sulfur atoms, this assembly may sufficiently spatially resemble the corresponding C-2 carboxyl group of the precedent β-lactam antibiotics to confuse the penicillin binding protons. The strongly electron-withdrawing character of the sulfamic acid group probably also makes the β-lactam bond more vulnerable to hydrolysis. In any case, the monobactams demonstrate that a fused ring is not essential for antibiotic activity. The α-oriented methyl group at C-2 is associated with the stability of aztreonam towards β-lactamases.

The protein binding is moderate (~50%), and the drug is nearly unchanged by metabolism. Aztreonam is given by injection and is primarily excreted in the urine. The primary clinical use of aztreonam is against severe infections caused by Gram-negative microorganisms, especially those acquired in the hospital. These are mainly urinary tract, upper respiratory tract, bone, cartilage, abdominal, obstetric and gynecologic infections, and septicemias. The drug is well tolerated, and adverse effects are infrequent. Interestingly, allergy would not be unexpected, but cross-allergenicity with penicillins and cephalosporins has not often been reported.

Antibiotics: Inhibitors of Protein Biosynthesis

Basis for selectivity

Once the bacterial cell wall is traversed, complex cellular machinery deeper within the cell becomes available to antibiotics. Some of the most successful antibiotic families exert their lethal effects on bacteria by inhibiting ribosomally mediated protein biosynthesis. At first glimpse, this may seem to be anomalous, because eukaryotic organisms also construct their essential proteins on ribosomal organelles and the sequence of biochemical steps is closely analogous to that in prokaryotic microorganisms. At a molecular level, however, the apparent anomaly resolves itself, because the detailed architecture of prokaryotic ribosomes is rather different. In *Escherichia coli*, for example, the 70S ribosomal particle is composed not only of three RNA molecules but also of 55 different structural and functional proteins arranged in a nonsymmetrical manner. The small (30S) subunit has a 16S rRNA molecule and approximately 20 different proteins. The large subunit has a 23S and a 5S rRNA and more than 30 proteins. Quite recently, the x-ray

crystal structure of the components of the bacterial ribosome has been determined. This is a landmark achievement given the size and complexity of this organelle. The available picture is still fuzzy but allows one to unravel the molecular details not only of how proteins are biosynthesized but also where important antibiotics bind when they interrupt this process. The functioning parts of the ribosome are the RNA molecules, and the proteins organize the whole and catalyze some portions of the biosynthetic cycle. The tRNA molecules bind roughly at the interface where the 50S and 30S subparticles come together. The codon–anticodon interaction with mRNA takes place in the 30S subunit, and the incoming amino acid and the growing peptide chain being made lies in the 50S subunit. Upsetting the view held for decades that the antibiotics bound to ribosomal proteins, it is now known that they bind to the rRNA instead. Aside from this important fact, most of the other key beliefs are still valid. Of key importance, the vital repeated movement of the tRNA bases mostly take place near interfaces between individual rRNA molecules, where this would be easiest. In agreement, it has been found that this region is comparatively disordered consistent with that movement (Fig. 38.24).

At normal doses, antibiotics do not bind to or interfere with the function of eukaryotic 80S ribosomal particles. The basis for the selective toxicity of these antibiotics is then apparent. Interference with bacterial protein biosynthesis prevents repair, cellular growth, and reproduction and can be clinically bacteriostatic or bactericidal.

Aminoglycosides and aminocyclitols

Introduction

The aminoglycoside/aminocyclitol class of antibiotics contains a pharmacophoric 1,3-diaminoinositol moiety consisting of either streptamine, 2-deoxystreptamine, or spectinamine (Fig. 38.25). Several of the alcoholic functions of the 1,3-diaminoinositol are substituted through glycosidic bonds with characteristic amino sugars to form pseudo-oligosaccharides. The chemistry, spectrum, potency, toxicity, and pharmacokinetics of these agents are a function of the specific identity of the diaminoinositol unit and the arrangement and identity of the attachments. The various aminoglycoside antibiotics

are freely water soluble at all achievable pH values, are basic and form acid addition salts, are not absorbed in significant amounts from the GI tract, and are excreted in active form in fairly high concentrations in the urine following injection. When the kidneys are not functioning efficiently, the concentrations injected must be reduced to prevent accumulation to toxic levels. When given orally, their action is primarily confined to the GI tract. They are more commonly given IM or by perfusion. Recently, tobramycin has been sprayed into the lungs to successfully treat *Pseudomonas aeruginosa* infections in patients with cystic fibrosis. This route of administration results in significantly reduced toxicity to the patient. These agents have intrinsically broad antimicrobial spectra, but their toxicity potential limits their clinical use to severe infections by Gram-negative bacteria. The aminoglycoside antibiotics are widely distributed (mainly in extracellular fluids) and have low levels of protein binding.

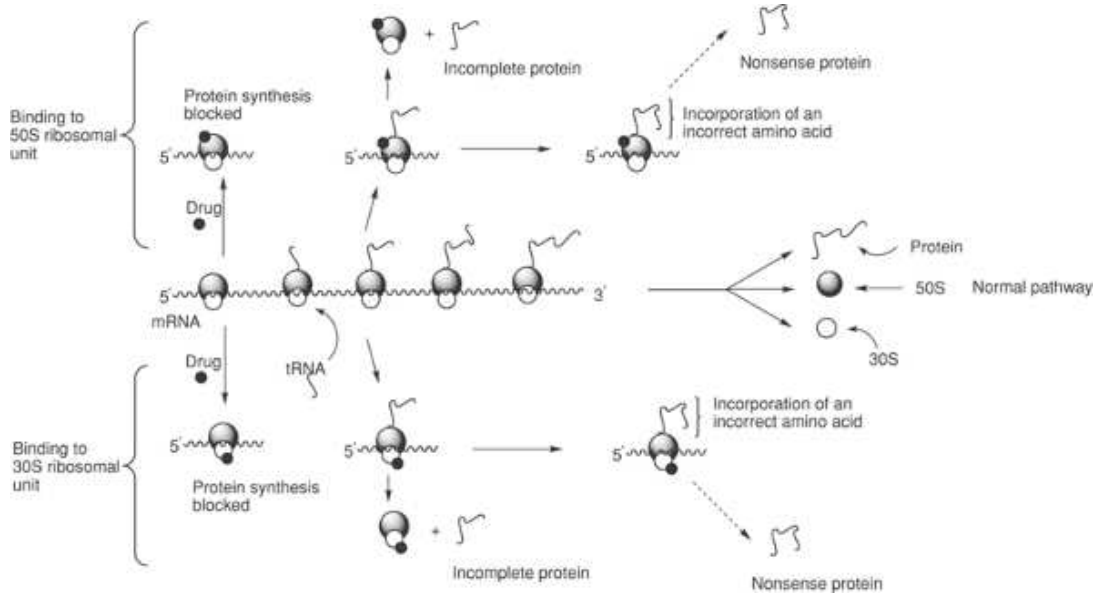


Fig. 38.24. General mechanism of action of drugs that block protein synthesis by binding to ribosomal units.

Mechanism of Action

The aminoglycosides are bactericidal because of a combination of toxic effects. At less than toxic doses, they bind to the 16S rRNA portion of the 30S ribosomal subparticle, impairing the proofreading function of the ribosome. A conformational change occurs in the peptidyl A site of the ribosome on aminoglycoside binding. This leads to mistranslation of RNA templates and the consequent selection of wrong amino acids and formation of so-called nonsense proteins (Fig. 38.24). The most relevant of these unnatural proteins are involved in upsetting bacterial membrane function. Their presence destroys the semipermeability of the membrane, and this damage cannot be repaired without de novo programmed protein biosynthesis. Among the substances that are admitted by the damaged membrane are large additional quantities of aminoglycoside. At these increased concentrations, protein biosynthesis ceases altogether. These combined effects are devastating to the target bacterial cells. Given their highly polar properties, the student may wonder how these agents can enter bacterial cells at all. Aminoglycosides apparently bind initially to external lipopolysaccharides and diffuse into the cells in small amounts. The uptake process is inhibited by Ca^{2+} and Mg^{2+} ions. These ions are, then, partially incompatible therapeutically. Passage through the cytoplasmic membrane is dependent on electron transport and energy generation. At high concentrations, eukaryotic protein biosynthesis also can be inhibited by aminoglycoside/aminocyclitol antibiotics.

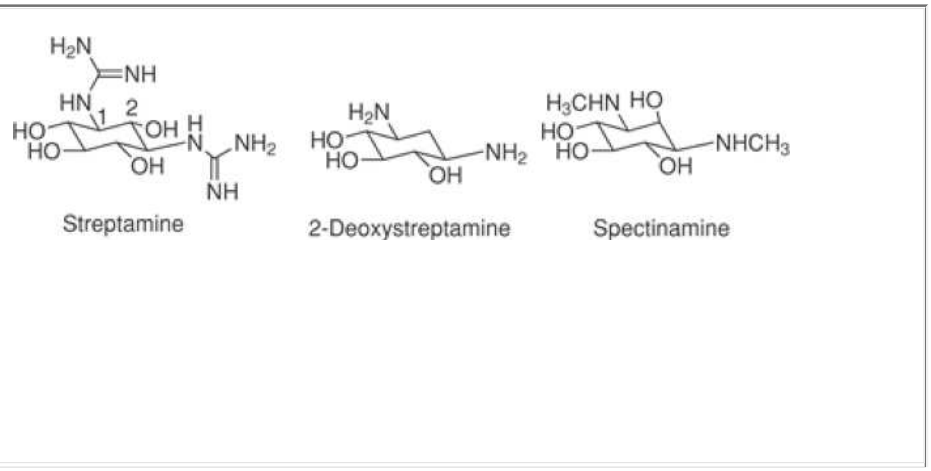

Fig. 38.25. 1,3-Diaminoinositol moieties in aminoglycosides.

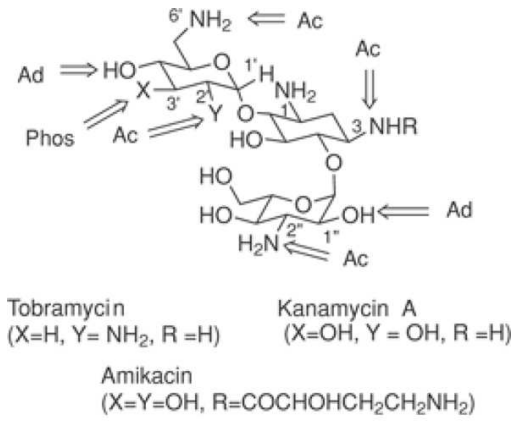
Bacterial Resistance

Bacterial resistance to aminoglycoside antibiotics in the clinic is most commonly the result of bacterial elaboration of R factor–mediated enzymes that N-acetylate (aminoglycoside acetylase [AAC]), O-phosphorylate (aminoglycoside phosphorylase [APH]), and O-adenylate (aminoglycoside nucleotide transferase [ANT]) specific functional groups, preventing subsequent ribosomal binding (Fig. 38.26). In some

cases, chemical deletion of the functional groups transformed by these enzymes leaves a molecule that is still antibiotic but is no longer a substrate; thus, agents with an intrinsically broader spectrum can be made semisynthetically in this way. In some other cases, novel functional groups can be attached to remote functionality that converts these antibiotics to poorer substrates for these R factor–mediated enzymes, and this expands their spectra (discussed later). Resistance also can involve point mutations of the ribosomal A site. These involve single-nucleotide residues at specific positions. The substituent at position 6′ of the aminoglycoside, the number of protonated amino groups, and the linkage between the sugar rings and the central deoxystreptamine moiety are particularly important in the interactions with the rRNA. Resistance caused by decreased aminoglycoside/aminocyclitol uptake into bacterial cells also is encountered.

Therapeutic Application

Intrinsically, aminoglycosides have broad antibiotic spectra against aerobic Gram-positive and Gram-negative bacteria but are reserved for use in serious infections caused by Gram-negative organisms because of serious toxicities that often are delayed in onset. They are active against Gram-negative aerobes, such as *Acinetobacter* sp., *Citrobacter* sp., *Enterobacter* sp., *Escherichia coli, Klebsiella* sp., *Proteus vulgaris, Providencia* sp., *Pseudomonas aeruginosa, Salmonella* sp., *Serratia marscesans, Shigella* sp., and Gram-positive aerobes (e.g., *Staphylococcus epidermidis*).



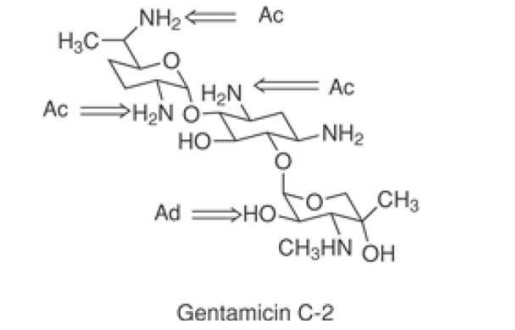


Fig. 38.26. Commercially important 2-desylstreptamine–containing aminoglycosides. Some points of inactivating attack by specific R factor–medicated enzymes are indicated by the following symbols. Ad ⇒ adenylation; Ac ⇒ acetylation; Phos ⇒ phosphorylation. APH(3′)-1, for example, is an acronym for an enzyme that phosphorylates aminoglycosides at the 3′-OH position.

Streptomycin and spectinomycin differ from the others in their useful antimicrobial spectra. Streptomycin is most commonly used for the treatment of tuberculosis and spectinomycin for treatment of gonorrhea. The other antibiotics of this class are inferior for these purposes.

These antibiotics have similar clinical spectra to those of the quinolones and are decreasing in popularity as quinolone use increases. Some aminoglycoside antibiotics in present clinical use are illustrated in Figure 38.26 along with some of their sites of enzymatic inactivation. There has not been a new aminoglycoside antibiotic introduced since the 1970s.

Adverse Effects

The toxicities associated with the aminoglycosides involve ototoxicity to functions mediated by the eighth cranial nerve, such as hearing loss and vertigo. Their use also can lead to kidney tubular necrosis, producing decreases in glomerular function. These toxic effects are related to blood levels and, apparently, are mediated by the special affinity of these aminoglycosides to kidney cells and to the sensory cells of the inner ear. The effects may have a delayed onset, making them all the more treacherous, because the patient can be injured significantly before symptoms appear. Less common is a curare-like neuromuscular blockade believed to be caused by competitive inhibition of calcium ion–dependent acetylcholine release at the neuromuscular junction. This effect can exaggerate the muscle weakness of patients with myasthenia gravis or Parkinson's disease. In current practice, all these toxic phenomena are well known; therefore, creatinine clearance should be determined and the dose adjusted downward accordingly so that these adverse effects are less common and less severe.

Specific Agents Kanamycin (Kantrex)

Kanamycin is a mixture of at least three components (A, B, and C, with A predominating) isolated from *Streptomyces kanamyceticus*. In addition to typical aminoglycoside antibiotic properties, kanamycin, along with gentamicin, neomycin, and paromomycin, is among the most chemically stable of the common antibiotics. Kanamycin can be heated without loss of activity for astonishing periods in acid or alkaline solutions and can even withstand autoclaving temperatures. Kanamycin, however, is unstable to R-factor enzymes, being O-phosphorylated on the C-3′hydroxyl by enzymes APH(3′)-I and APH(3′)-II and also is N-acetylated on the C-6′amino group, among others (Fig. 38.26). These transformation products are antibiotically inactive. Kanamycin is used parenterally against some Gram-negative bacteria, but *Pseudomonas aeruginosa* and anaerobes usually are resistant. Although it also can be used in combination with other agents against certain mycobacteria (*Mycobacterium kansasii, Mycobacterium marinum*, and *Mycobacterium intracellulare*), its popularity for this use is fading. Injections of kanamycin are painful enough to require use of a local

anesthetic. Kanamycin occasionally is used in antitubercular admixtures.

Amikacin (Amikin)

Amikacin is made semisynthetically from kanamycin A. Interestingly, the L-hydroxyaminobutyryl amide (HABA) moiety attached to N-3 inhibits adenylation and phosphorylation in the distant amino sugar ring (at C-2′ and C-3′), even though the HABA substituent is not where the enzymatic reaction takes place. This effect is attributed to decreased binding to the R factor–mediated enzymes. With this change, both potency and spectrum are strongly enhanced, and amikacin is used for the treatment of sensitive strains of *Mycobacterium tuberculosis, Yersinia tularensis*, and severe *Pseudomonas aeruginosa* infections resistant to other agents.

Tobramycin (Nebcin)

Tobramycin is one component (factor 6) of a mixture produced by fermentation of *Streptomyces tenebrarius*. Lacking the C-3′ hydroxyl group, it is not a substrate for APH(3′)-1 and APH(3′)-II and so has an intrinsically broader spectrum than kanamycin. It is a substrate, however, for adenylation at C-2′ by ANT(2′) and acetylation at C-3 by AAC(3)-I and AAC(3)-II and at C-2′ by AAC(2′) (Fig. 38.26). It is widely used parenterally for difficult infections, especially those by gentamicin-resistant *Pseudomonas aeruginosa*. It is believed by some clinicians to be less toxic than gentamicin.

Gentamicin (Garamycin)

Gentamicin is a mixture of several antibiotic components produced by fermentation of *Micromonospora purpurea* and other related soil microorganisms (hence its name is spelled with an “i” instead of a “y”). Gentamicins C-1, C-2, and C-1a are most prominent. Gentamicin is the most important of the aminoglycoside antibiotics still in use. Gentamicin was, for example, one of the first antibiotics to have significant activity against *Pseudomonas aeruginosa* infections. This water-loving, opportunistic pathogen frequently is encountered in burns, pneumonias, and urinary tract infections. It is highly virulent. As noted above, some of the functional groups that serve as targets for R factor–mediated enzymes are missing in the structure of gentamicins, so their antibacterial spectrum is enhanced. They are, however, inactivated through C-2′ adenylation by the enzyme ANT(2′) and acetylation at C-6′ by AAC(6′), at C-1 by AAC(1)-I and AAC(1)-II, and at C-2′ by AAC(2′). It often is combined with other anti-infective agents, and an interesting incompatibility has been uncovered. With certain β-lactam antibiotics, the two drugs react with each other so that N-acylation on C-1 of gentamicin by the β-lactam antibiotic takes place, thus inactivating both antibiotics (Fig. 38.27). The two agents should not, therefore, be mixed in the same solution and should be administered into different tissue compartments (usually one in each arm) to prevent this. This incompatibility is likely to be associated with other aminoglycoside antibiotics as well.

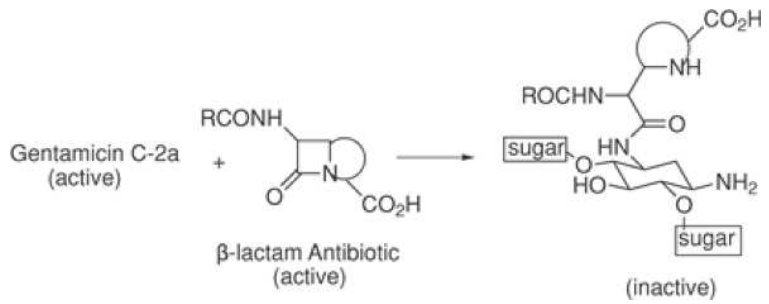

Fig. 38.27. A chemical drug–drug incompatibility between gentamicin C-2a and β-lactams.

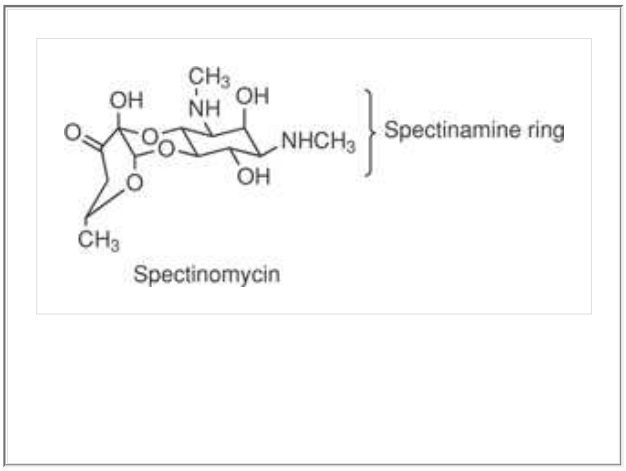
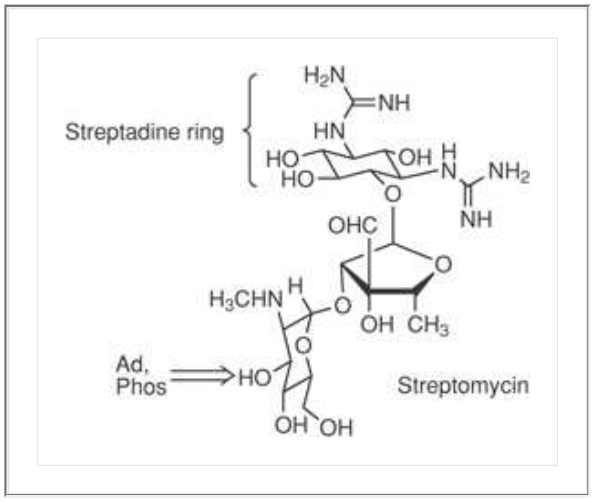
Gentamicin is used for urinary tract infections, burns, some pneumonias, and bone and joint infections caused by susceptible Gram-negative bacteria. It often is used to prevent fouling of soft contact lenses. It also is used in polymer matrices in orthopaedic surgery to prevent sealed-in sepsis. It is given topically, sometimes in special dressings, to burn patients.

Spectinomycin (Trobicin)



An unusual aminoglycoside antibiotic, spectinomycin is produced by fermentation of *Streptomyces spectabilis* and differs substantially in its clinical properties from the others. The diaminoinositol unit (spectinamine) contains two mono-N-methyl groups, and the hydroxyl between them has a stereochemistry opposite to that in streptomycin. The glycosidically attached sugar also is unusual in that it contains three consecutive carbonyl groups, either overt or masked, and is fused by two adjacent linkages to spectinamine to produce an unusual, fused, three-ring structure. Spectinomycin is bacteriostatic as normally employed. It is used almost exclusively in a single bolus injection IM against *Neisseria gonorrhea*, especially penicillinase-producing strains, in cases of urogenital or oral gonorrhea and does not apparently produce any serious oto- or nephrotoxicity when used in this way. It is particularly useful for the treatment of patients allergic to penicillin and patients not likely to comply well with a medication scheme. It would likely be more widely used except that syphilis and chlamydia do not respond to it. It causes significant mistranslation following ribosomal binding but does not cause much inhibition of overall programmed protein biosynthesis. Resistance to spectinomycin by a kinase phosphorylating a hydroxyl group has been reported.

Streptomycin



Streptomycin is produced by fermentation of *Streptomyces griseus* and several related soil microorganisms. It was introduced in 1943 primarily for the treatment of tuberculosis (see Chapter 41). Control of this ancient scourge was greeted with such enthusiasm that Selmon Waksman, the discoverer of streptomycin, received a Nobel Prize in 1952. Streptomycin differs from the typical aminoglycosides with a modified pharmacophore in that the diaminoinositol unit is streptamine. Streptomycin also has an axial hydroxyl group at C-2 and two highly basic guanido groups at C-l and C-3 in place of the primary amine moieties of 2-deoxystreptamine. It is possible that the unusual pharmacophore of streptomycin accounts in large measure for its unusual antibacterial spectrum. Another molecular feature, the α-hydroxyaldehyde moiety, is a center of instability such that streptomycin cannot be sterilized by autoclaving, so streptomycin sulfate solutions that need

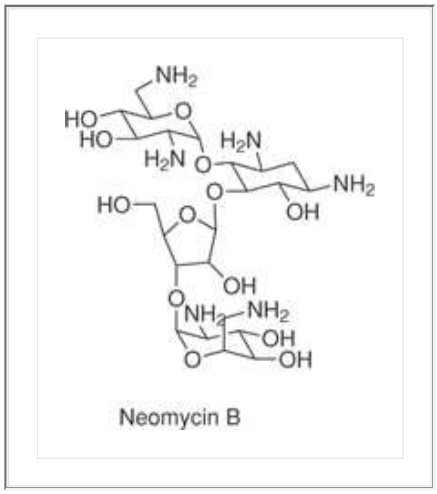
sterilization are made by ultrafiltration. Streptomycin is rarely used today as a single agent.

Resistance to streptomycin takes the familiar course of N-acetylation, O-phosphorylation, and O-adenylation of specific functional groups.

Orally Used Aminoglycosides

Kanamycin and another archaic member of the aminoglycoside antibiotic group, paromomycin (Humatin) finds some oral use for the suppression of gut flora. Paromomycin is also used for the oral treatment of amoebic dysentery. Amoebas are persistent pathogens causing chronic diarrhea and are acquired most frequently by travelers who consume food supplies contaminated with human waste.

Neomycin



Neomycin B

Neomycin is a mixture of three compounds produced by fermentation of *Streptomyces fradiae*, with neomycin B predominating. It is most commonly used in preoperative bowel sanitation and the treatment of enteropathogenic *Escherichia coli* infections. It also is found in nonprescription ointments and is used topically for treatment of bacterial skin infections. When applied to intact skin, the drug is not absorbed, but when applied to large, denuded areas, systemic absorption occurs with the potential for toxic side effects. It also has seen some use in lowering serum cholesterol.

Macrolide antibiotics

Introduction

The term “macrolide” is derived from the characteristic large lactone (cyclic ester) ring found in these antibiotics. The clinically important members of this antibiotic family (Fig. 38.28) have two or more characteristic sugars (usually cladinose and desosamine) attached to the 14-membered ring. One of these sugars usually carries a substituted amino group, so their overall chemical character is weakly basic (pK_a ~ 8). They are not very water-soluble as free bases. Salt formation with certain acids (glucoheptonic and lactobiononic acids in Fig. 38.28), however, increases water solubility, whereas other salts decrease solubility (laurylsulfate and stearic). Macrolide antibiotics with 16-membered rings are popular outside the United States, but one example, tylosin, finds extensive agricultural use in the United States. The 14-membered ring macrolides are biosynthesized from propionic acid units so that every second carbon of erythromycin, for example, bears a methyl group and the rest of the ring carbons, with one exception, are oxygen bearing. Two carbons bear so-called “extra” oxygen atoms introduced later in the biosynthesis (not present in a propionic acid unit), and two hydroxyls are glycosylated (Fig. 38.29).

Chemical Properties

The early macrolides of the erythromycin class are chemically unstable because of rapid acid-catalyzed internal cyclic ketal formation, leading to inactivity (Fig. 38.30). This reaction that occurs in the GI tract is clinically important. Most acid-susceptible macrolides are administered in coated tablets to minimize this

effect. Semisynthetic analogues have been prepared that are structurally incapable of undergoing this reaction (clarithromycin, dirithromycin, and azithromycin) (Fig. 38.28) and have become very popular of late in the clinic.

Many macrolides have an unpleasant taste, which is partially overcome with water-insoluble dosage forms that also reduce acid instability and gut cramps. Enteric coatings are beneficial in reducing these adverse effects as well.

Mechanism of Action

The macrolides inhibit bacteria by interfering with programmed ribosomal protein biosynthesis by binding to the 23S rRNA in the polypeptide exit tunnel adjacent to the peptidyl transferase center in the 50S subparticle (Fig. 38.24). Binding appears to occur at two specific regions within the rRNA, which are referred to as domain V at adenine 2058 and 2059 and domain II

at adenine 752. These sites are similar to those sites occupied by clindamycin, lincomycin, chloramphenicol, and streptogramin B antibiotics, leading to extensive cross-resistance. The ratio of binding is 1:1 between 23S and the macrolide. Binding of the macrolide to 23S rRNA prevents the growing peptide from becoming longer than a few residues, resulting in the dissociation of peptidyl tRNA molecules. The amino sugar moiety of the macrolides appears to be particularly important in the inhibition. Removal of the 3-L-cladinose results in reduced binding to domain V and an 100-fold decrease in biological activity. It also has been suggested that the L-cladinose is associated with GI distress resulting from the release of motilin

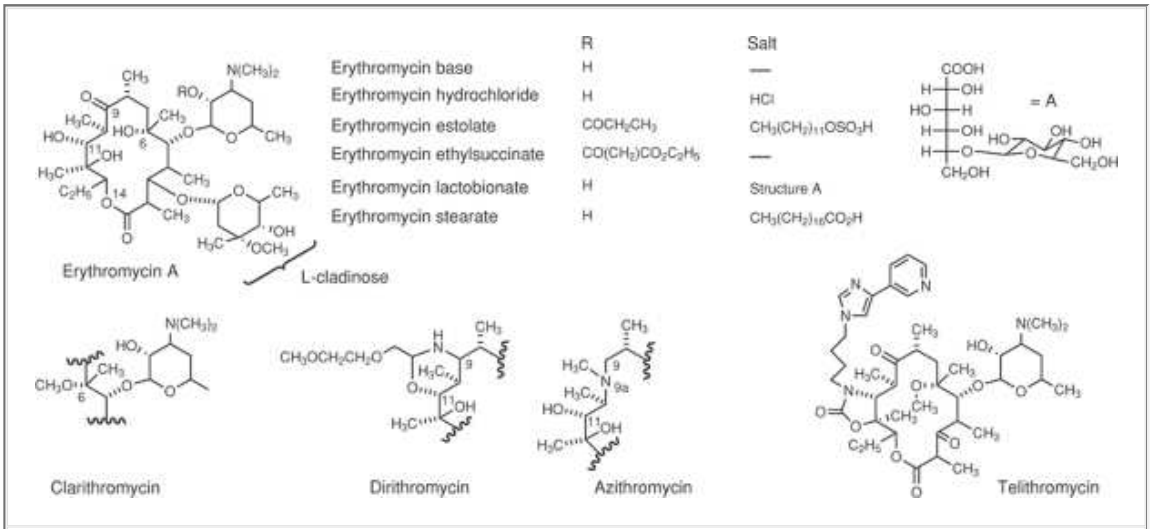


Fig. 38.28. Clinically important macrolide antibiotics.

Resistance

Developed bacterial resistance is primarily caused by bacteria possessing R-factor enzymes that methylate a specific guanine residue on their own rRNA, making them somewhat less efficient protein biosynthesizers but comparatively poor binders of macrolides. The erythromycin-producing soil organism utilizes the same ribosomal methylation technique to protect itself against the toxic effects of its own metabolite. This leads to the speculation that the origin of some antibiotic resistance genes may lie in the producing organism itself and that this genetic material is acquired by bacteria from this source.

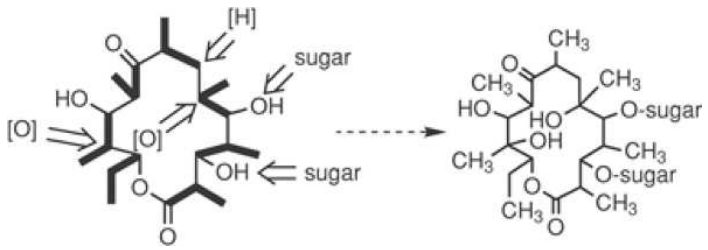

Fig. 38.29. Biosynthetic pathway to erythromycins from propionic acid units. [X] ⇒ refers to modifications to the basic ring skeleton.

A second mechanism of resistance is associated with the mutation of adenine to guanine that occurs in domain V at adenine 2058. This change results in a 10,000-fold reduction of binding capacity of erythromycin and clarithromycin to the 23S rRNA. This mutation is much less likely to occur with the ketolide derivatives (telithromycin).

Some bacterial strains, however, appear to be resistant to macrolides because of the operation of an active efflux process in which the drug is expelled from the cell at the cost of energy. Intrinsic resistance of Gram-negative bacteria is primarily caused by lack of penetration, because the isolated ribosomes from these organisms often are susceptible.

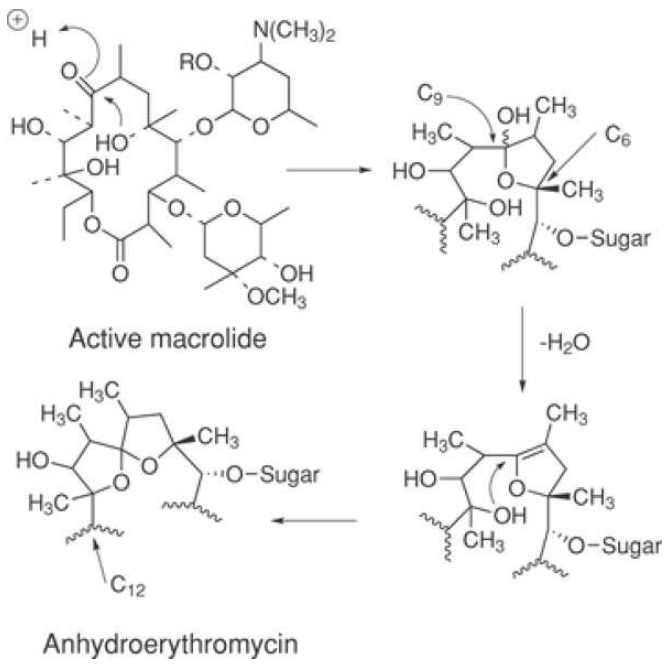

Fig. 38.30. Acid-catalyzed intramolecular ketal formation with erythromycin.

Drug Interactions

Drug–drug interactions with macrolides are comparatively common and usually involve competition for oxidative liver metabolism by a member (CYP3A4) of the cytochrome P450 oxidase family. Such drugs as ergotamine, theophylline, carbamazepine, bromocryptine, warfarin, digoxin, oral contraceptives, carbamazepine, cyclosporine, astemizole, terfenadine, midazolam, triazolam, and methylprednisone can be involved. These interactions can have severely negative consequences for the patient. The result of this interaction is a longer half-life and enhanced potential toxicity by increasing the effective dose over time. The interaction with astemizole and terfenadine can lead to very serious cardiovascular effects. The main product of liver metabolism of erythromycin is the N-demethylated analogue.

Therapeutic Application

The macrolides are among the safest of the antibiotics in common use and often are used for the treatment of upper and lower respiratory tract and soft-tissue infections primarily caused by Gram-positive microorganisms like *Streptococcus pyogenes* and *Streptococcus pneumoniae*, Legionnaire's disease, prophylaxis of bacterial endocarditis by *Streptococcus viridans*, upper and lower respiratory tract infections and otitis media caused by *Haemophilus influenzae* (with a sulfonamide added), mycoplasmal pneumonia, and in combination with rifabutin in *Mycobacterium avium* complex infections in patients with AIDS, and it also finds some use for certain sexually transmitted diseases, such as gonorrhea and pelvic inflammatory disease, caused by mixed infections involving cell wall–free organisms, such as *Chlamydia trachomitis*. Clarithromycin also is used to treat gastric ulcers because of *Helicobacter pylori* infection as a component of multidrug cocktails. Thus, the macrolides have a comparatively narrow antimicrobial spectrum, reminiscent of the medium-spectrum penicillins, but the organisms involved include many of the more commonly encountered community-acquired diseases and the macrolides are remarkably free of serious toxicity to the host and, of course, do not cause β-lactam allergy. The utility of the macrolides against upper respiratory tract infections is aided by their particular affinity for these tissues. Tissue levels in the upper respiratory tract often are several multiples of that seen in the blood. The macrolides are primarily used orally for mild systemic infections of the respiratory tract, liver, kidneys, prostate, and milk gland even though absorption is somewhat irregular, especially when taken with food. Some derivatives are propropulsive through stimulation of gastrin production. The resulting hyperperistalsis causes uncomfortable GI cramps in some patients. They are bacteriostatic in the clinic in achievable concentrations.

Specific Agents Erythromycin Esters and Salts

Estolate

One of the two most popular erythromycin pro-drugs, erythromycin estolate, is a C-2′-propionyl ester, N-laurylsulfate salt (Fig. 38.28). Administration of erythromycin estolate produces higher blood levels following metabolic regeneration of erythromycin. In a small number of cases, a severe, dose-related, cholestatic jaundice occurs in which the bile becomes granular in the bile duct, impeding flow so that the bile salts back up into the circulation. This seems to be partly allergic and partly dose related. If the drug causes hepatocyte damage, perhaps this releases antigenic proteins that promote further damage. When cholestatic jaundice occurs, the drug must be replaced by another, nonmacrolide antibiotic, such as one of the penicillins, one of the cephalosporins, or clindamycin. It is postulated that the propionyl ester group is transferred to a tissue component that is antigenic, although the evidence for this is not compelling.

Ethylsuccinate (EryPed, EES)

Erythromycin ethyl succinate is a mixed double ester pro-drug in which one carboxyl of succinic acid esterifies the C-2′ hydroxyl of erythromycin and the other ethanol (Fig. 38.28). This pro-drug frequently is used in an oral suspension for pediatric use largely to mask the bitter taste of the drug. Film-coated tablets also are used to deal with this. Some cholestatic jaundice is associated with the use of EES.

Stearate

Erythromycin stearate is a very insoluble salt form of erythromycin. The water insolubility helps to mask the taste of the drug and enhances its stability in the stomach.

Lactobionate

Erythromycin lactobionate is a salt with enhanced water solubility that is used for injections.

Clarithromycin (Biaxin)

Clarithromycin differs from erythromycin in that the C-6 hydroxy group has been converted semisynthetically to a methyl ether. The C-6 hydroxy group is involved in the process, initiated by protons, leading to internal cyclic ketal formation in erythromycin that results in drug inactivation (Fig. 38.30). This ketal, or one of the products of its subsequent degradation, also is associated with GI cramping. Conversion of the molecule to its more lipophilic methyl ether prevents internal ketal formation, which not only gives better blood levels through chemical stabilization but also results in less gastric upset. An extensive saturable first-pass liver metabolism of clarithromycin leads to formation of its C-14 hydroxy analogue, which has even greater antimicrobial potency, especially against *Haemophilus influenzae*. The enhanced lipophilicity of clarithromycin also allows lower and less frequent dosage for mild infections.

Azithromycin (Zithromax, Zmax)

Azithromycin, called an “azalide,” has been formed by semisynthetic conversion of erythromycin to a ring-expanded analogue in which an N-methyl group has been inserted between carbons 9 and 10, and the carbonyl moiety thus is absent (Fig. 38.28). Azithromycin has a 15-membered lactone ring.

This new functionality does not form a cyclic internal ketal. Not only is azithromycin more stable to acid degradation than erythromycin, it also has a considerably longer half-life, attributed to greater and longer tissue penetration, allowing once-a-day dosage. A popular treatment schedule with azithromycin is to take two tablets on the first day and then one tablet a day for the following 5 days and then to discontinue treatment. This is convenient for patients who comply poorly. The drug should be taken on an empty stomach. It does, however, give a metallic taste. Azithromycin tends to be broader spectrum than either erythromycin or clarithromycin. Both of these newer macrolides are quite similar in usage to erythromycin itself and are cross-resistant with it. Azithromycin has a significant postantibiotic effect against a number of pathogens. Azithromycin is commonly the first choice for treatment of infections that require a macrolide.

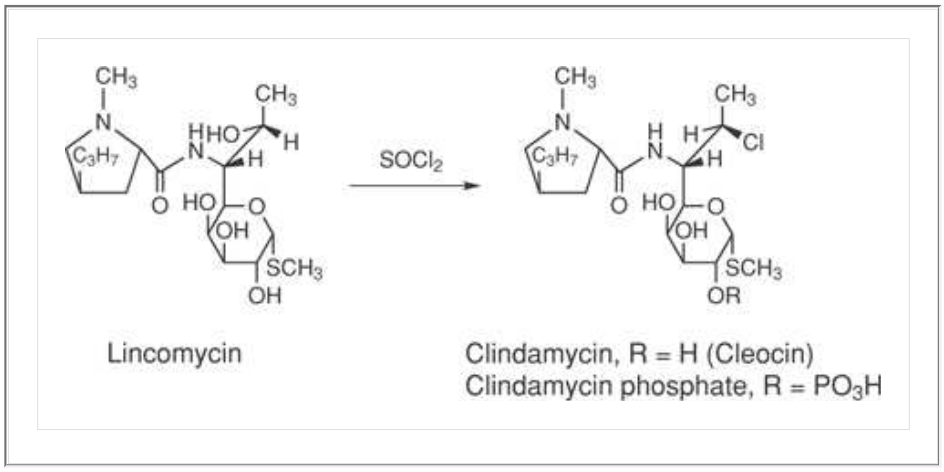
Ketolides

Research activity in the macrolide antibiotic class has been intense recently in attempts to reduce side effects and to broaden their antimicrobial spectra. The ketolides are a group of agents that are characterized by oxidation of the 3-position from an alcohol to a ketone. They are active against a significant number of erythromycin-resistant microorganisms. Recent investigation has been intense and a new agent has been introduced.

Telithromycin (Ketek)

Telithromycin (Fig. 38.28) is orally effective in the treatment of community-acquired pneumonia, acute bacterial exacerbations of chronic bronchitis, and acute sinusitis. Its principal advantage appears to be activity against drug-resistant infections. Telithromycin possesses several structural modifications from the traditional erythromycin nucleus, including removal of the L-cladinose sugar at C-3. The L-cladinose is thought to be associated with the release of motilin and the resulting GI discomfort. Removal of L-cladinose and oxidation of the free hydroxy to a nonpolar ketone reduces biological activity through reduced binding to domain V, but this is offset by the addition of the chain at C-11/12, which greatly improves binding to domain II. Strong binding to domain V and II reduces bacterial resistance. The C-6 methoxy improves acid stability. Telithromycin was approved by the U.S. FDA following a mammoth (24,000 patient) clinical trial. The cost of this will no doubt inhibit further trials of replacement agents.

Lincosamides



Introduction

The lincosamides contain an unusual 8-carbon sugar, a thiomethyl amino-octoside (O-thio-lincosamide), linked by an amide bond to an n-propyl–substituted N-methylpyrrolidylcarboxylic acid (N-methyl- n-propyl-*trans*-hygric acid). Lincosamides are weakly basic and form clinically useful hydrochloric acid salts. They are chemically distinct from the macrolide antibiotics but possess many pharmacological similarities to them. The lincosamides bind to 50S ribosomal subparticles at a site partly overlapping with the macrolide site, are mutually cross-resistant with macrolides, and work through essentially the same molecular mechanism of action (Fig. 38.24). The lincoamides undergo extensive liver metabolism, resulting primarily in N-demethylation. The N-desmethyl analogue retains biological activity.

Specific Agents Lincomycin (Lincocin)

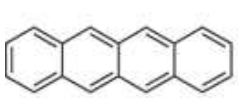
Lincomycin is a natural product isolated from fermentations of *Streptomyces lincolnensis* var. *lincolnensis*. It is active against Gram-positive organisms, including some anaerobes. It is indicated for the treatment of serious infections caused by sensitive strains of streptococci, pneumococci, and staphylococci. It generally is reserved for patients who are allergic to penicillin because of the increased risk of pseudomembranous colitis (described below). It also serves as the starting material for the synthesis of clindamycin (by a S_N-2 reaction that inverts the *R* stereochemistry of the C-7 hydroxyl to a C-7 *S*-chloride).

Clindamycin (Cleocin)

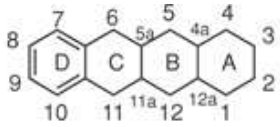
The substitution of the chloride for the hydroxy group consequently make clindamycin more bioactive and lipophilic than lincomycin and, thus, is better absorbed following oral administration. It is significantly less painful than erythromycin when injected IM as a C-2 phosphate ester pro-drug and is approximately 90% absorbed when taken orally. It also is available as a palmitate ester hydrochloride salt that, interestingly, when reconstituted as instructed for use as an oral solution, has a pH between 2.5 to 5.0 Clindamycin has a clinical spectrum rather like the macrolides, although it distributes better into bones. Clindamycin works well for Gram-positive coccal infections, especially in patients who are allergic to β-lactams, and also has generally better activity against anaerobes. As with lincomycin, however, it is associated with GI complaints (nausea, vomiting, cramps, and drug-related diarrheas). The most severe of these is pseudomembranous colitis caused by release of two toxins by *Clostridium difficile*, an opportunistic anaerobe. Its overgrowth results from suppression of the normal flora, the presence of which otherwise preserves a healthier ecological balance. The popularity of clindamycin in the clinic has decreased even though pseudomembranous colitis is a comparatively rare side effect and also now is associated with several other broad-spectrum antibiotics. A less common side effect is exudative erythema multiform

(Stevens-Johnson syndrome). Clindamycin has excellent activity against *Propionobacterium acnes* when applied topically to comedones, and because it is white, it can be cosmetically tinted to match flesh tones better than the yellow tetracyclines. A very water-insoluble palmitate hydrochloride pro-drug of clindamycin also is available (lacks bitter taste).

Tetracyclines and glycylcyclines



Naphthacene

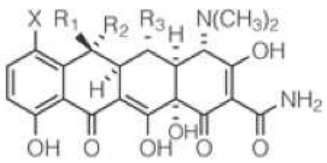


Tetracycline

(1,2,3,4,4a,5,5a,6,11,11a ,12,12a-dodecahydronaphthacene)

Introduction

The tetracycline family is widely, but not intensively, used in office practice. Of the agents in this family, minocycline and doxycycline are still frequently prescribed in the United States. This family of antibiotics is characterized by a highly functionalized, partially reduced naphthacene (four linearly fused, 6-membered rings) ring system, from which both the family name and the numbering system are derived. They possess a number of adverse effects, although most of them are annoying rather than dangerous. Because their antimicrobial spectrum is broad enough to include many of the pathogens encountered in a community setting, they were once very widely used. The advent of other choices and the high incidence of resistance that has developed has greatly decreased their medicinal prominence in recent years. Presently, they are recommended primarily for use against rickettsia, chlamydia, mycoplasma, anthrax, plague, and helicobacter organisms. A significant number of semisynthetic molecules derived from the antibacterial tetracyclines have shown potential activity in other therapeutic areas, such as antimetastasis, antitumor, anti-inflammatory, antiarthritic, antifungal, antineurotoxic, and antiperiodontal diseases, but discussion of these potential uses is beyond the scope of this chapter.



Generic name	Trade name	X	R_1	R_2	R_3
Tetracycline	Achromycin Sumycin Tetralan	H	OH	CH_3	H
Demeclocycline	Declomycin	Cl	OH	H	H
Minocycline	Minocin	$N(CH_3)_2$	H	H	H
Oxytetracycline	Terramycin	H	OH	CH_3	OH
Doxycycline	Vibramycin Doryx	H	H	CH_3	OH

Table 38.13. Commercially Available Tetracyclines

Chemical Properties

The tetracyclines are amphoteric substances with three pK_a values revealed by titration (2.8–3.4, 7.2–7.8, and 9.1–9.7) and have an isoelectric point at approximately pH 5. The basic function is the C-4-α-dimethylamino moiety. Commercially available tetracyclines (Table 38.13) generally are administered as comparatively water-soluble hydrochloride salts. The conjugated phenolic enone system extending from C-10 to C-12 is associated with the pK_a at approximately 7.5, whereas the conjugated trione system extending from C-1 to C-3 in ring A is nearly as acidic as acetic acid (pK_a ~ 3). These resonating systems can be drawn in a number of essentially equivalent ways with the double bonds in alternate positions. The formulae normally given are those settled on by popular convention.

Chelation

Chelation is an important feature of the chemical and clinical properties of the tetracyclines. The acidic functions of the tetracyclines are capable of forming salts through chelation with metal ions. The salts of polyvalent metal ions, such as Fe^{2+}, Ca^{2+}, Mg^{2+}, and Al^{3+}, are all quite insoluble at neutral pHs (Fig. 38.31). This insolubility not only is inconvenient for the preparation of solutions but also interferes with blood levels on oral administration. Consequently, the tetracyclines are incompatible with coadministered, multivalent ion–rich antacids and with hematinics, and concomitant consumption of daily products rich in calcium ion also is contraindicated. Further, the bones, of which the teeth are the most visible, are calcium-rich structures at nearly neutral pHs and so accumulate tetracyclines in proportion to the amount and duration

of therapy when bones and teeth are being formed. Because the tetracyclines are yellow, this leads to a progressive and, essentially, permanent discoloration in which, in advanced cases, the teeth are even brown. The intensification of discoloration with time is said to be a photochemical process. This is cosmetically unattractive but does not seem to be deleterious except in extreme cases, when so much antibiotic is taken up that the structure of bone is mechanically weakened. To avoid this, tetracyclines are not normally given to children once they are forming their permanent set of teeth (age, 6–12 years). In severe cases, the teeth can be treated with dilute HCl solution to dissolve away the colored antibiotic. This also significantly erodes the mineral matrix of the teeth, however, and must be repaired by plastic impregnation. People naturally prefer to avoid this heroic and expensive process. When concomitant oral therapy with tetracyclines and incompatible metal ions must be done, the ions should be given 1 hour before or 2 hours after the tetracyclines. Additionally, tetracyclines are painful on IM injection. This has been attributed, in part, to formation of insoluble calcium complexes. To deal with this, the injectable formulations contain ethylenediaminetetra-acetic acid and are buffered at comparatively acidic pH levels where chelation is less pronounced and water solubility is higher.

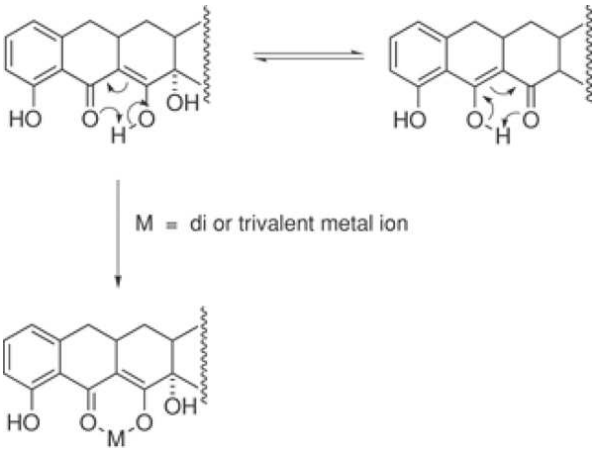


Fig. 38.31. Metal chelation with the tetracyclines.

Epimerization

The α-stereo orientation of the C-4 dimethylamino moiety of the tetracyclines is essential for their bioactivity. The presence of the tricarbonyl system of ring A allows enolization involving loss of the C-4 hydrogen (Fig. 38.32). Reprotonation can take place from either the top or bottom of the molecule. Reprotonation from the top of the enol regenerates tetracycline. Reprotonation from the bottom, however, produces inactive 4-epitetracycline. At equilibrium, the mixture consists of nearly equal amounts of the two diasteromers. Thus, old tetracycline preparations can lose approximately half their potency in this way. The epimerization process is most rapid at approximately pH 4 and is relatively slower in the solid-state.

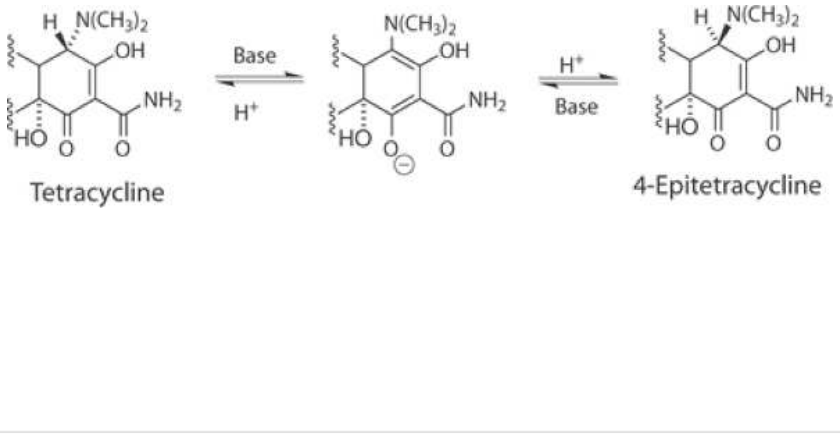

Fig. 38.32. Epimerization of tetracyclines.

Dehydration

Most of the natural tetracyclines have a tertiary benzylic hydroxyl group at C-6. This function has the ideal geometry for acid-catalyzed dehydration involving the C-5a α-oriented hydrogen (antiperiplanar *trans*). The resulting product is a naphthalene derivative, so there are energetic reasons for the reaction proceeding in that direction (Fig. 38.33). C-5a,6-anhydrotetracycline is much deeper in color than tetracycline and is biologically inactive.

Discolored old tetracyclines are suspect and should be discarded. Not only can inactive 4-epitetracyclines dehydrate to produce 4-epianhydrotetracyclines, anhydrotetracycline also can epimerize to produce the same product. This degradation product is toxic to the kidneys and produces a Fanconi-like syndrome that, in extreme cases, has been fatal. Commercial samples of tetracyclines are closely monitored for the presence of 4-epidehydrotetracycline, and injuries from this cause are now, fortunately, rare. Those tetracyclines, such as minocycline and doxycycline, which have no C-6-hydroxyl groups, cannot undergo dehydration and, therefore, are completely free of this toxicity.

Cleavage in Base

Another untoward degradation reaction involving a C-6-hydroxyl group is cleavage of the C-ring in alkaline solutions at or above pH 8.5 (Fig. 38.34). The lactonic product, an isotetracycline, is inactive. The clinical impact of this degradation under normal conditions is uncertain.

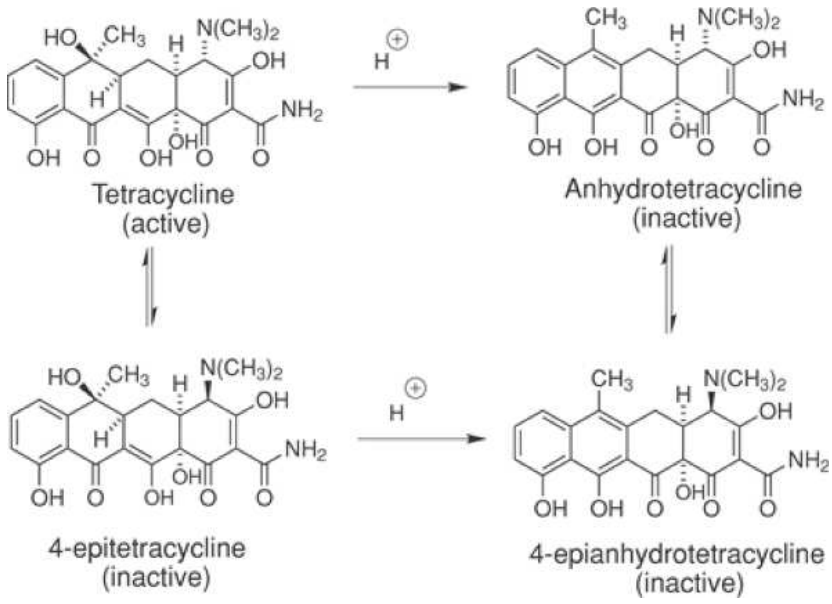

Fig. 38.33. Acid-catalyzed instability of tetracyclines.

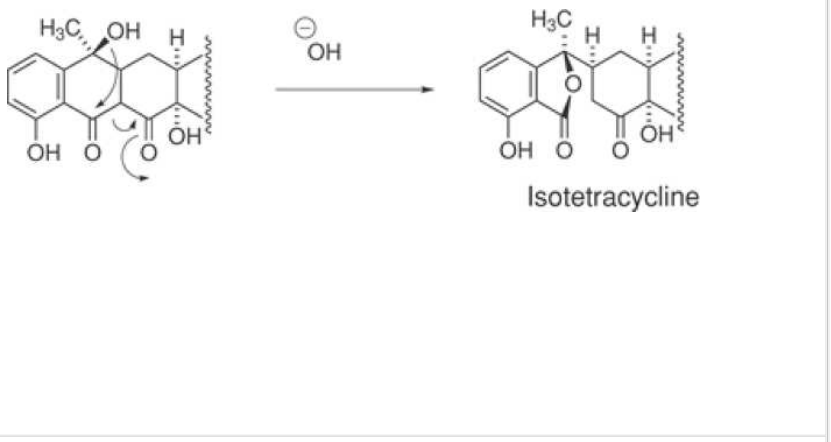

Fig. 38.34. Base-catalyzed instability of tetracyclines.

Phototoxicity

Certain tetracyclines, most notably those with a C-7-chlorine, absorb light in the visible region, leading to free radical generation and, potentially, cause severe erythema to sensitive patients on exposure to strong sunlight. Patients should be advised to be cautious about such exposure for at least their first few doses to avoid potentially severe sunburn. This effect is comparatively rare with most currently popular tetracyclines.

Mechanism of Action

The tetracyclines of clinical importance interfere with protein biosynthesis at the ribosomal level, leading to bacteriostasis. Tetracyclines bind to rRNA in the 30S subparticle with the possible cooperation of a 50S site by a process that remains imprecisely understood despite intensive study (Fig. 38.24). There is more than

one binding site, but only one is believed to be critical for its action. The points of contact with the rRNA are those associated with antibiosis with the puzzling exception of the dimethylamino function. Studies have suggested that the tetracyclines bind to the 16S rRNA via the functional groups located at the 1- and 10- to 12a-positions (referred to as the southern face of the tetracycline) and at the 2- and 3-positions (referred to as the eastern face of the tetracycline) (Fig. 38.35). The dimethylamino function is known to be essential for activity but does not appear to bind in the x-ray pictures that are presently available. Once the tetracycline binds, it inhibits subsequent binding of aminoacyltransfer-RNA to the ribosomes, resulting in termination of peptide chain growth. Newer analogues of the tetracyclines suggest that substitution on the western and northern faces of the tetracycline are allowed as indicated by the newest glycylcyclines (see Tigecycline below).

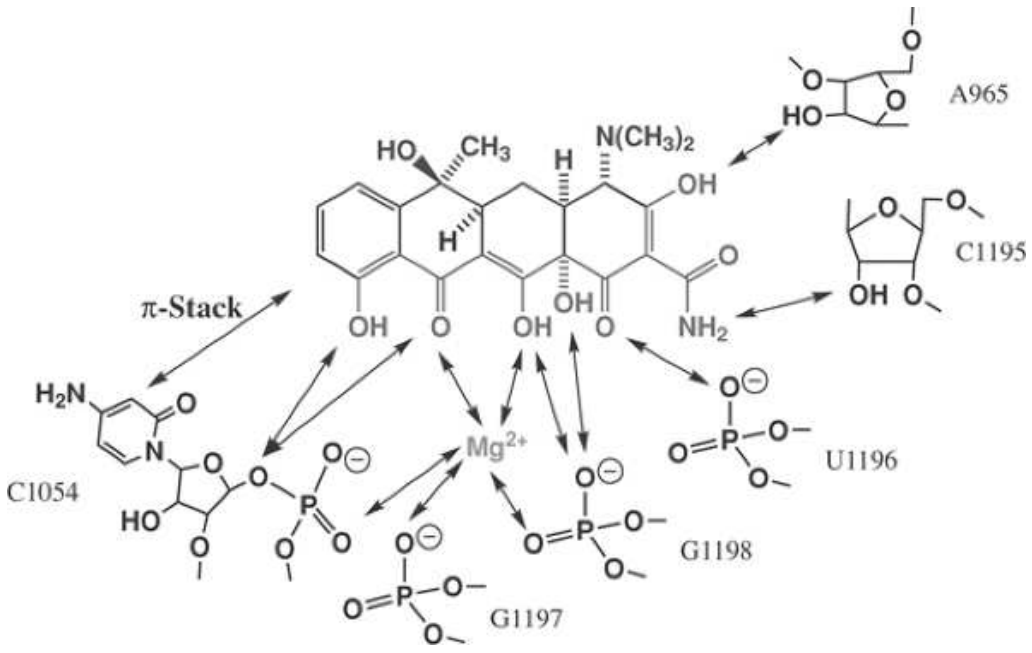

Fig. 38.35. Schematic representation of the primary binding site for a tetracycline and the sugar phosphate groups of 16S rRNA, which also involves a magnesium ion and the critical functional groups on the “southern” and “eastern” face of the tetracycline. (Adapted from Brodersen et al. The structural basis for the action of the antibiotics tetracycline, pactamycin, and hygromycin B on the 30S ribosomal subunit. Cell 2000;103:1143–1154, with permission from Elsevier.)

The more lipophilic tetracyclines, typified by minocycline, also are capable of disrupting cytoplasmic membrane function, causing leakage of nucleotides and other essential cellular components from the cell, and have bactericidal properties. The more lipophilic tetracyclines enter bacterial cells partly by passive diffusion and the more water-soluble members partly through water-lined protein porin routes, perhaps assisted by the formation of highly lipophilic calcium and magnesium ion chelates. Deeper passage, however, through the inner cytoplasmic membrane is an energy-requiring active process, suggesting that the tetracyclines are mistaken by bacteria as food.

Resistance

Resistance to tetracyclines results in part from an unusual ribosomal protection process involving elaboration of bacterial proteins. These proteins associate with the ribosome, thus allowing protein

biosynthesis to proceed even in the presence of bound tetracycline, although exactly how this works is not well understood. Another important resistance mechanism involves R factor–mediated, energy-requiring,

active efflux of tetracyclines from the bacterial cells. Some of the efflux proteins have activity that is limited to older tetracyclines, whereas others confer resistance to the entire family with the exception of glycylcyclines. Efflux resistance to glycylcylines, however, has been demonstrated in the laboratory, which suggests that it may occur clinically with extended use. Certain other microbes, such as *Mycoplasma* and *Neisseria* sp., seem to have modified membranes that either accumulate fewer tetracyclines or have porins through which tetracyclines have difficulty in passing. Because resistance is now widespread, these once extremely popular antibiotics are falling into comparative disuse.

Therapeutic Application

The tetracyclines possess very wide bacteriostatic antibacterial activity. Because of the resistance phenomenon and the comparative frequency of troublesome side effects, they are rarely the drugs of first choice today. Nonetheless, they are still popular for office use against susceptible microbes. The differences between the antimicrobial spectra of various tetracyclines are not large, although greater resistance to older agents may limit their use. They are used for low-dose oral and topical therapy for acne, first-course community-acquired urinary tract infections (largely caused by *Escherichia coli*), brucellosis, borreliosis, sexually transmitted diseases (especially chlamydia), rickettsial infections, mycoplasmal pneumonia, prophylaxis of malaria, prevention of traveler's diarrhea, cholera, *Enterobacter* infections, as part of *Helicobacter* cocktails, Lyme disease, Rocky Mountain spotted fever, anthrax, and for many other less common problems. The tetracyclines also are widely used for agricultural purposes.

Adverse Effects

In addition to the adverse effects mentioned earlier (tooth staining, phototoxicity, and potential kidney damage with outdated drug), the tetracyclines are associated with nausea, vomiting, diarrhea, and some CNS effects (dizziness and vertigo). Rapid administration or prolonged IV use can lead to thrombophlebitis. Therefore, tetracyclines generally are administered orally, because they are well absorbed. They also distinguish imperfectly between the bacterial 70S ribosomes and the mammalian 80S ribosomes, so in high doses or special situations (i.e., IV use during pregnancy), these drugs demonstrate a significant antianabolic effect. This may lead to severe liver and kidney damage; therefore, tetracyclines generally are not recommended in these situations. In cases of significant renal impairment, higher serum levels of tetracyclines can lead to azotemia. Additionally, inducers of cytochrome P450 metabolism (i.e., rifampin, barbiturates, and carbamazepine) increase metabolism of tetracyclines (especially doxycycline), so the dose of the tetracycline may require adjustment.

Specific Agents (Table 38.11) Tetracycline

Tetracycline is produced by fermentation of *Streptomyces aureofaciens* and related species or by catalytic reduction of chlortetracycline. The blood levels achieved on oral administration often are irregular. Food and milk lower absorption by approximately 50%.

Demeclocycline

Demeclocycline lacks the C-6-methyl of tetracycline and is produced by a genetically altered strain of *Streptomyces aureofaciens*. Because it is a secondary alcohol, it is more chemically stable than tetracycline against dehydration. Food and milk co-consumption decrease absorption by half, although it is 60 to 80% absorbed by fasting adults. It is the tetracycline most highly associated with phototoxicity and has been shown to produce dose-dependent, reversible diabetes insipidus with extended use.

Oxytetracycline

It also is one of the classic tetracyclines. It is produced by fermentation of *Streptomyces rimosis* and other soil microorganisms. The most hydrophilic tetracycline on the market, it has largely now been replaced by its semisynthetic descendants. It is primarily used today for IM injections.

Minocycline

An important antibiotic produced by semisynthesis from demeclocycline is minocycline. It is much more lipophilic than its precursors, gives excellent blood levels following oral administration (90–100% available),

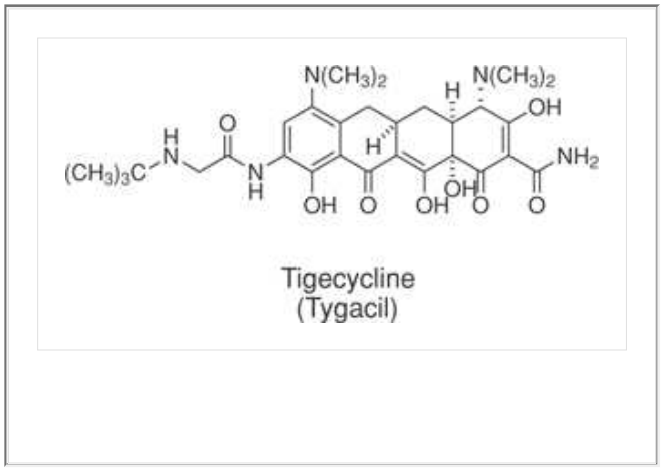
and can be given once a day. Its absorption is lowered by approximately 20% when taken with food or milk. It is less dependent on active uptake mechanisms and has a somewhat broader antimicrobial spectrum. It also, apparently, is less painful on IM or IV injection, but it has vestibular toxicities (e.g., vertigo, ataxia, and nausea) not generally shared by other tetracyclines.

Doxycycline

It is produced by semisynthesis from other tetracycline molecules and is the most widely used of the tetracycline family. Doxycycline is well absorbed on oral administration (90–100% when fasting; reduced by 20% by co-consumption with food or milk), has a half-life permitting once-a-day dosing for mild infections, and is excreted partly in the feces and partly in the urine.

Once very widely used, tetracyclines have faded considerably in popularity because of widespread resistance and the introduction of newer broad-spectrum agents, such as amoxicillin with clavulanate. Research, however, continues, and novel analogues can be expected as indicated by the recent U.S. FDA approval of tigecycline, the first of a new class of tetracyclines referred to as the glycylcyclines.

Tigecycline

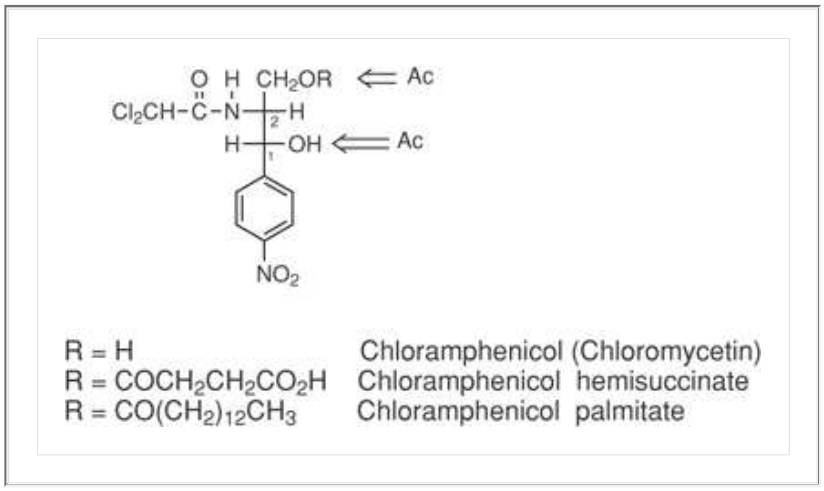


The increased incidence of resistance to the tetracyclines led to a renewed research effort to find novel agents within this class. This effort led to the discovery of a new class of antibiotics, the glycylcyclines, that are closely related structurally to the tetracyclines but lack many of the clinical resistance issues. They are characterized by having an additional glycylamido substitution at the 9-position. As indicated earlier, substitution on the western face does not appear to interfere with binding of the drug to the rRNA. Tigecycline is the first of these agents to be marketed. Although it has limited indications (treatment of complicated skin/skin structure and complicated intra-abdominal infections), this agent is a broad-spectrum antibiotic based on the in vitro data. It is administered IV and, like the tetracyclines, can cause injection site pain and thrombophlebitis. It is expected to have other adverse effects similar to the tetracyclines.

Special purpose antibiotics

This group of antibiotics consists of a miscellaneous collection of structural types for which the toxicities or narrow ranges of applicability give them a more specialized place in antimicrobial chemotherapy than those covered to this point. They generally are reserved for special purposes.

Chloramphenicol (Chloromycetin)



Introduction

Chloramphenicol was originally produced by fermentation of *Streptomyces venezuelae*, but its comparatively simple chemical structure soon resulted in several efficient total chemical syntheses. With two asymmetric centers, it is one of four diastereomers, only one of which (1*R*,2*R*) is significantly active. Because total synthesis produces a mixture of all four, the unwanted isomers must be removed before use. Chloramphenicol is a neutral substance that is only moderately soluble in water, because both nitrogen atoms are nonbasic under physiologic conditions (one is an amide and the other a nitro moiety). It was the first broad-spectrum oral antibiotic used in the United States (1947) and was once very popular. Severe potential blood dyscrasia has greatly decreased its use in North America. Although its cheapness and efficiency makes it still very popular in much of the rest of the world where it can often be purchased over-the-counter without a prescription.

Mechanism of action

Chloramphenicol is bacteriostatic by virtue of inhibition of protein biosynthesis in both bacterial and, to a lesser extent, host ribosomes. Chloramphenicol binds to the 50S subparticle in a region near where the macrolides and lincosamides bind (Fig. 38.24).

Resistance is mediated by several R-factor enzymes that catalyze acetylation of the secondary and, to some extent, the primary hydroxyl groups in the aliphatic side chain. These products no longer bind to the ribosomes and so are inactivated. *Escherichia coli* frequently is resistant because of chloramphenicol's lack of intercellular accumulation.

Metabolism

When given orally, it is rapidly and completely absorbed but has a fairly short half-life. It is mainly excreted in the urine in the form of its metabolites, which are a C-3 glucuronide, and, to a lesser extent, its deamidation product and the product of dehalogenation and reduction. These metabolites are all inactive. The aromatic nitro group also is reduced metabolically, and this product can undergo amide hydrolysis. The reduction of the nitro group, however, does not take place efficiently in humans but, rather, primarily occurs in the gut by the action of the normal flora. Chloramphenicol potentiates the activity of some other drugs by inducing liver metabolism. Such agents include anticoagulant coumarins, sulfonamides, oral hypoglycemics, and phenytoin.

Pro-Drug Forms

Two pro-drug forms of chloramphenicol are available (only the injectable form is available in the United States). The drug is intensively bitter, but this can be masked for use as a pediatric oral suspension by the C-3 palmitate, which is cleaved in the duodenum to liberate the drug. Chloramphenicol's poor water solubility is largely overcome by conversion to the C-3 hemisuccinoyl ester, which forms a water-soluble sodium salt. This is cleaved in the body by lung, liver, kidney, and blood esterases to produce active chloramphenicol. Because cleavage in muscles is slow, this pro-drug is used IV rather than IM.

Therapeutic Applications

Despite potentially serious limitations, chloramphenicol is an effective drug when used carefully. Its special value is in typhoid fever, *Haemophilus* infections (especially epiglottitis and meningitis, when given along with ampicillin), rickettsial infections, and in cases in which susceptible organisms have proven to be

resistant to other therapies. Safer antibiotics should be used whenever possible. It is approximately 60% serum protein bound and diffuses well into tissues, especially into inflamed cerebrospinal fluid and, therefore, is of value for meningitis. It also penetrates well into lymph and mesenteric ganglions, rationalizing its particular value in typhoid fever.

Adverse Effects

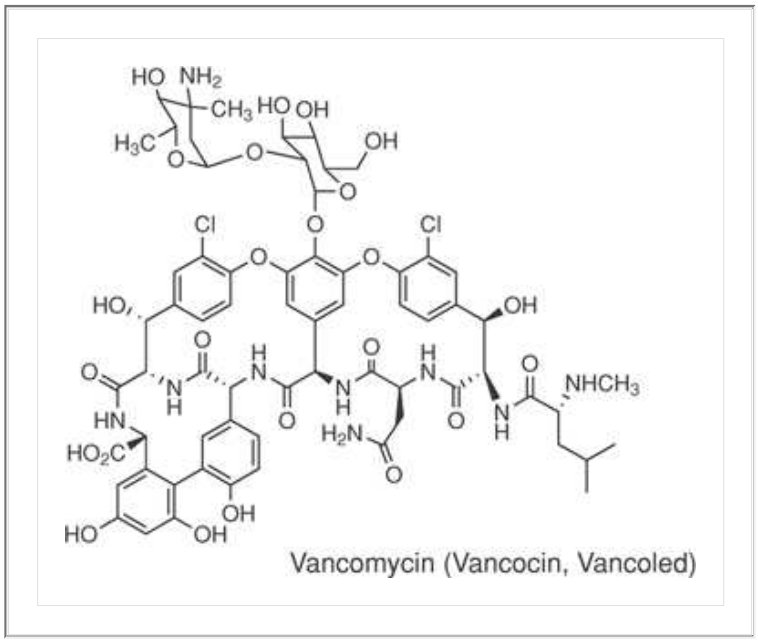
Toxicities prevent chloramphenicol from being more widely used. Blood dyscrasias are seen in patients predisposed to them. The more serious form is a pancytopenia of the blood that is fatal in approximately 70% of cases and is believed to be caused by one of the reduction products of the aromatic nitro group. This side effect is known as aplastic anemia, and it has even occurred following use of the drug as an ophthalmic ointment. There seems to be a genetic predisposition toward this in a very small percentage of the population. This devastating side effect is estimated to occur once in every 25,000 to 40,000 courses of therapy. Less severe, but much more common, is a reversible inhibition of hematopoiesis seen in older patients or in those with renal insufficiency. If cell counts are taken, this can be controlled, because it is dose-related and marrow function will recover if the drug is withdrawn.

The so-called “gray” or “gray baby” syndrome, a form of cardiovascular collapse, is encountered when chloramphenicol is given to young infants (especially premature infants) if liver glucuronidation is underdeveloped, and successive doses will lead to rapid accumulation of the drug because of impaired excretion. A dose-related, profound anemia accompanied by an ashen-gray pallor is seen, as are vomiting, loss of appetite, and cyanosis. Deaths have resulted, often involving cardiovascular collapse.

Cyclic Peptides Introduction

The usual physiologically significant peptides are linear. Several bacterial species, however, produce antibiotic mixtures of cyclic peptides, some with uncommon amino acids and some with common amino acids but with the D absolute stereochemistry. These cyclic substances often have a pendant fatty acid chain as well. One of the consequences of this unusual architecture is that these glycopeptide agents are not readily metabolized. These drugs usually are water soluble and are highly lethal to susceptible bacteria, because they attach themselves to the bacterial membranes and interfere with their semipermeability so that essential metabolites leak out and undesirable substances pass in. Unfortunately, they also are highly toxic in humans, so their use is reserved for serious situations in which there are few alternatives or to topical uses. Bacteria rarely are able to develop significant resistance to this group of antibiotics. They generally are unstable, so solutions should be protected from heat, light, and extremes of pH.

Vancomycin (Vancocin, Vancoled)



Vancomycin is produced by fermentation of *Amycolatopsis orientalis* (formerly *Nocardia orientalis*). It has been available for approximately 40 years, but its popularity has increased significantly with the emergence of MRSA in the early 1980s. Chemically, vancomycin has a glycosy lated hexapeptide chain that is rich in unusual amino acids, many of which contain aromatic rings cross-linked by aryl ether bonds into a rigid molecular framework.

Mechanism of Action

Vancomycin is a bacterial cell wall biosynthesis inhibitor. Evidence suggests that the active species is a homodimer of two vancomycin units. The binding site for its target is a peptide-lined cleft having high affinity for acetyl-D-alanyl-D-alanine and related peptides through five hydrogen bonds. It inhibits both transglycosylases (inhibiting the linking between muramic acid and acetyl glucosamine units) and transpeptidase (inhibiting peptide cross-linking) activities in cell wall biosynthesis (Fig. 38.10). Thus, vancomycin functions like a peptide receptor and interrupts bacterial cell wall biosynthesis at the same step as the β-lactams do, but by a different mechanism. By covering the substrate for cell wall transamidase, it prevents cross-linking resulting in osmotically defective cell walls.

Resistance

Only very recently, despite decades of intensive use, have some vancomycin-resistant bacteria emerged (vancomycin-resistant enterococcus [VRE] and vancomycin-resistant *Staphylococcus aureus*) [VRSA]. It is alleged that these resistant strains emerged as a consequence of the agricultural use of avoparcin, a structurally related antibiotic that has not found use for human infections in the United States but was used in Europe before its recent ban. The mechanism of resistance appears to be alteration of the target D-alanyl-D-alanine units on the peptidoglycan cell wall precursors to D-alanyl-D-lactate. This results in lowered affinity for vancomycin due to lack of a key hydrogen bonding interaction. It is greatly feared that this form of resistance will become common in the bacteria for which vancomycin is presently the last sure hope for successful chemotherapy. If so, such infection

would become untreatable. These resistant strains are not yet common in clinically relevant strains, but most authorities believe that this is only a question of time. Vancomycin-intermediate *S. aureus*, also called glycoprotein-intermediate *S. aureus* (VISA), also has been reported. It appears to be resistant because of a thickened peptidoglycan layer.

Therapeutic Applications

Although a number of adverse effects can result from IV infusion (see below), vancomycin has negligible oral activity. It can be used orally for action in the GI tract, especially in cases of *Clostridium difficile*

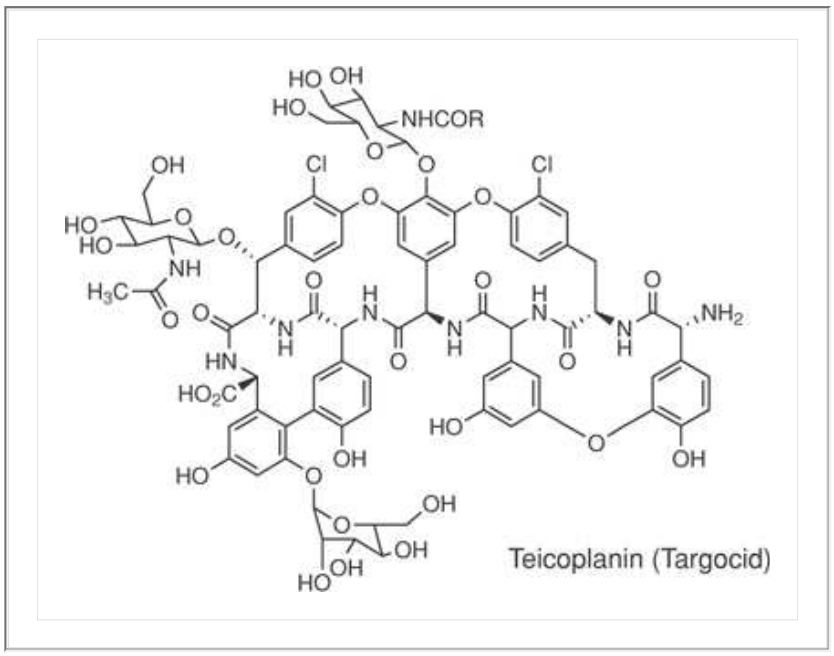
overgrowth. The useful spectrum is restricted to Gram-positive pathogens, with particular utility against multiply-resistant, coagulase-negative staphylococci and MRSA, which causes septicemias, endocarditis, skin and soft-tissue infections, and infections associated with venous catheters.

Adverse Effects

Vancomycin is highly associated with adverse infusion-related events. These are especially prevalent with higher doses and a rapid infusion rate. A rapid infusion rate has been shown to cause anaphylactoid reactions, including hypotension, wheezing, dyspnea, urticaria, and pruritus. A significant drug rash (the so-called red man syndrome) also can occur. These events are much less frequent with a slower infusion rate.

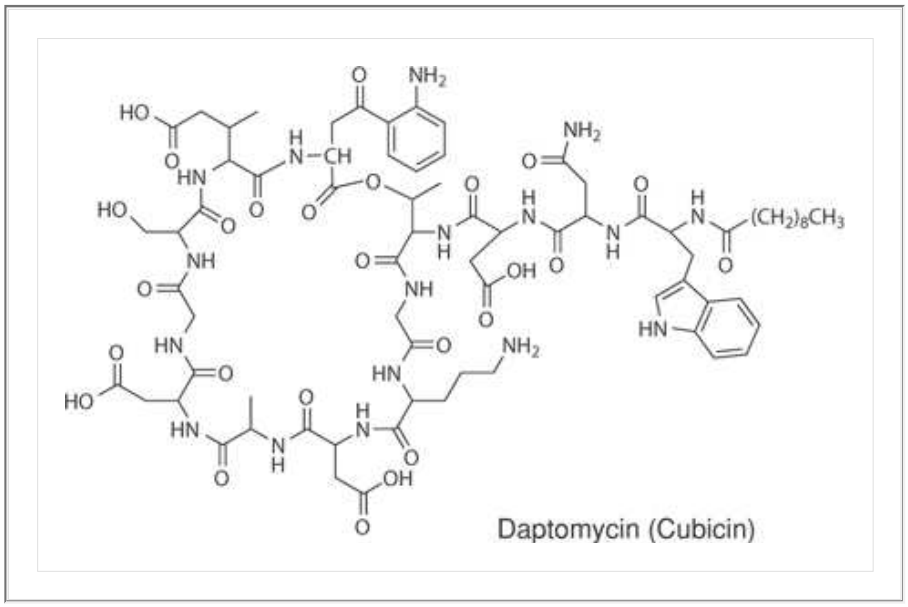
In addition to the danger of infusion-related events, higher doses of vancomycin can cause nephrotoxicity and auditory nerve damage. The risk of these effects is increased with elevated, prolonged concentrations, so vancomycin use should be monitored, especially in patients with decreased renal function. The ototoxicity may be transient or permanent and more commonly occurs in patients receiving high doses, patients with underlying hearing loss, and patients being treated concomitantly with other ototoxic agents (i.e., aminoglycosides).

Other Glycopeptides



Teicoplanin is a mixture of five related fermentation products related to vancomycin. It is more lipid soluble and, therefore, distributes better into tissues and bacteria. It also is highly protein bound, so it can be used IM or IV once daily. It is markedly less irritating than vancomycin on injection; therefore, it appears to be better tolerated by patients and on IV administration. It is not presently available in the United States but is available in a number of other countries. The glycopeptide field is under intense investigation, and a number of agents are at various stages of preclinical evaluation.

Daptomycin (Cubicin)



Daptomycin is a fermentation product having a cyclic lipopeptide structure. It is primarily active against Gram-positive infections, especially those involved in skin/skin structure infections. It is given IV but must be administered over a period of 30 minutes or more. It binds to cell membranes and causes depolarization, which interrupts protein, DNA, and RNA synthesis. Daptomycin is bactericidal. Although resistance can be achieved in vitro, resistance has been slow to emerge in the clinic. Patients should be monitored for muscle pain or weakness, because some incidence of elevated serum creatinine phosphokinase is associated with its use. A small number of clinical trial patients also developed conditions related to decreases in nerve conduction (e.g., paresthesias and Bell's palsy). Daptomycin is eliminated primarily by the kidney, so dose adjustment may be necessary in cases of renal insufficiency.

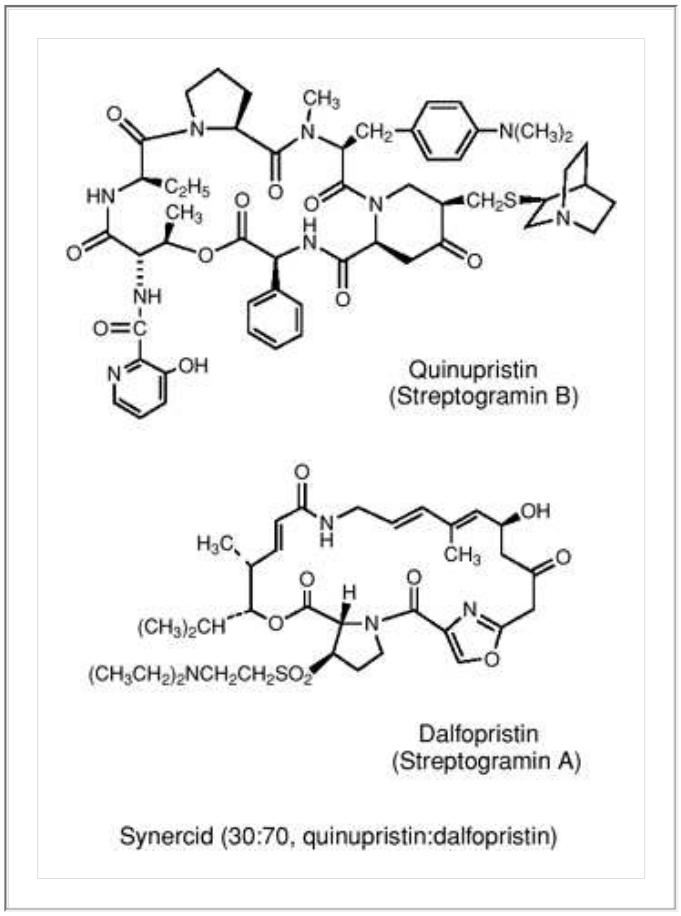
Streptogramins

The streptogramins are a group of natural occurring antibiotics isolated from *Streptomyces pristinasprialis.* The streptogramin antibiotics consist of A-type molecules and B-type molecules, which when combined have a synergistic activity. The mechanism of action of the two different types of molecules appear to be quite different.

Quinupristin/Dalfopristin

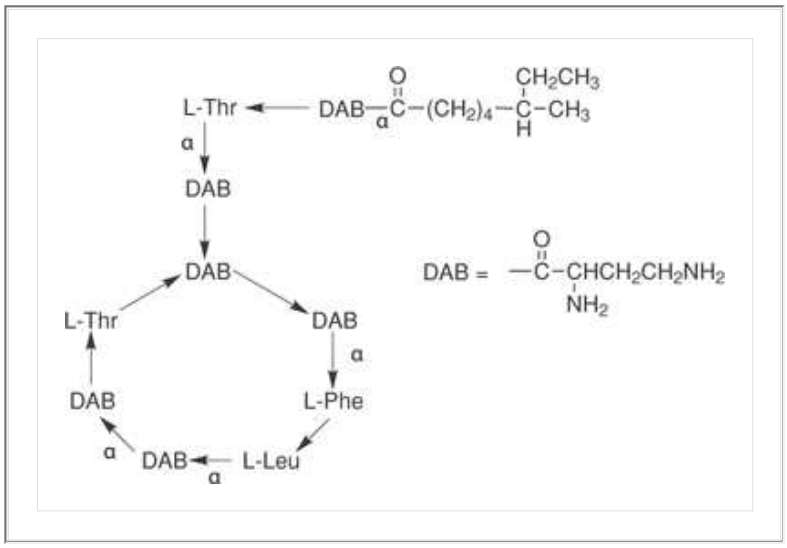
A drug combination of the streptogramins, quinupristin and dalfopristin was approved for IV use in the treatment of infections caused by vancomycin-resistant *Enterococcus faecium* bacteremia as well as skin/skin structure infections caused by MRSA and methicillin-sensitive *Streptococcus pyogenes*. Certain strains of *E. faecium* are resistant to essentially all

other antibiotics, including vancomycin. The streptogramin type A compound dalfopristin binds to the 50S ribosomal subparticle, resulting in a conformational change in the substrate. It appears that dalfopristin binding creates a high-affinity binding site for quinupristin, accounting for the synergy. Its site of action appears to be similar to that of chloroamphenicol, with effects on both the 30S and 50S subparticles. Quinupristin, the type B streptogramin, binds to the 50S subparticle overlapping the sites occupied by the macrolides and lincosamides (MLS_B compounds) (Fig. 38.24). As a result, resistance to the later two classes of antibiotics confers resistance to quinupristin but not to dalfopristin. The two drugs are bacteriostatic when administered individually but act synergistically when combined (quinupristin:dalfopristin, 30:70 w/w) to produce a bactericidal effect. The combination is found to inhibit protein synthesis. Synercid is a strong inhibitor of the CYP3A4 isozyme, and a number of drug interactions are to be expected. Although the combination does not appear to prolong the QT_c interval, it inhibits the metabolism of a number of agents that have been shown to have this effect, so concomitant administration should be avoided. Synercid also can produce a number of other adverse effects, including infusion site reactions (e.g., pain, edema, and inflammation), arthralgia and myalgia, and hyperbilirubinemia.

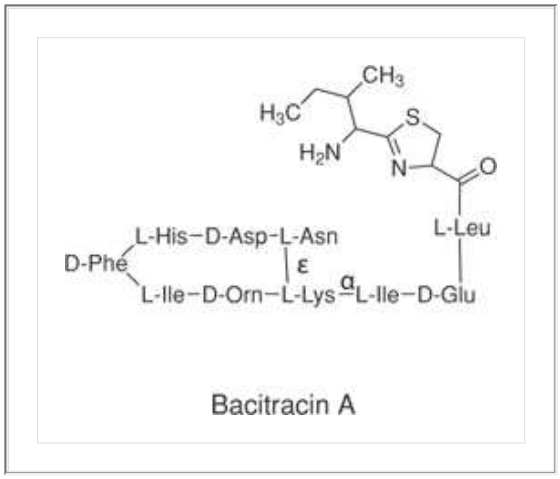


Polymyxin B

Polymyxin B is produced by fermentation of *Bacillus polymyxa*. It is separated from a mixture of related cyclic peptides and is primarily active against Gram-negative microorganisms. It apparently binds to phosphate groups in bacterial cytoplasmic membranes and disrupts their integrity. It is used IM or IV as a sulfate salt to treat serious urinary tract infections, meningitis, and septicemia, primarily caused by *Pseudomonas aeruginosa*, but some other Gram-negative bacteria also will respond. Irrigation of the urinary bladder with solutions of polymyxin B sulfate is employed as well by some to reduce the incidence of infections subsequent to installation of indwelling catheters. Additionally, it is used ophthalmically to treat infections by *P. aeruginosa*. When given parenterally, the drug is neuro- and nephrotoxic and, therefore, is employed only after other drugs have failed.



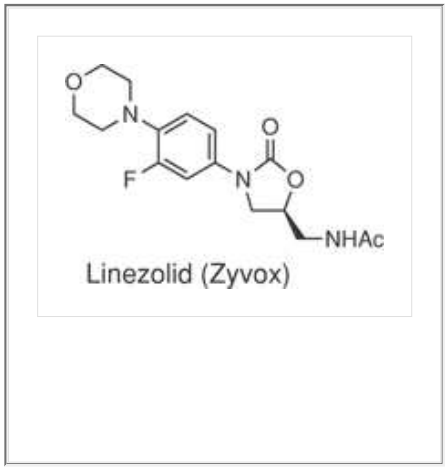
Bacitracin



Bacitracin A

Bacitracin is a mixture of similar peptides produced by fermentation of the bacterium *Bacillus subtilis*. The A-type component predominates. Its mode of action is to inhibit both peptidoglycan biosynthesis at a late stage (probably at the dephosphorylation of the phospholipid carrier step) and disruptions of plasma membrane function. It is predominantly active against Gram-positive microorganisms, and parenteral use is limited to IM injection for infants with pneumonia and empyema caused by staphylococci resistant to other agents. It is rather neuro- and nephrotoxic and, therefore, is used in this manner with caution. Bacitracin also is widely employed topically to prevent infection in minor cuts, scrapes, and burns.

Linezolid

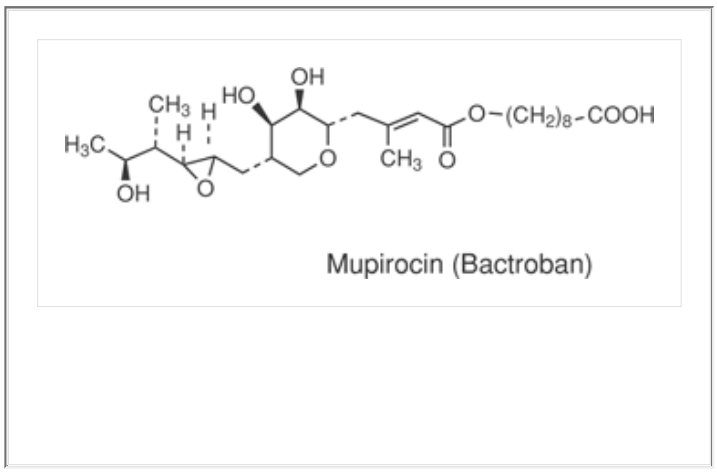


Linezolid (Zyvox)

Linezolid is the first member of the oxazolidinone class of agents and represents a new synthetic class of antibacterials. It is active primarily against Gram-positive aerobic organisms and is indicated for treatment of MRSA, nosocomial pneumonia, community-acquired pneumonia, complicated and uncomplicated skin/skin structure infections because of susceptible organisms, and vancomycin-resistant *Enterococcus faecium* infections. The mechanism of action is inhibition of protein synthesis, but at a stage different from that of other protein synthesis inhibitors. The oxazolidinones bind to the 23S rRNA of the 50S subparticle to prevent formation of a functional 70S initiation complex (Fig. 38.24). It is considered to be bacteriostatic against enterococci and staphylococci but bacteriocidal against streptococci. Resistance to oxazolidinones is encountered in the clinic because of a mutation in the 23S rRNA. This is believed to distort the linezolid binding site. Gram-negative microorganisms are intrinsically resistant to linezolid because of the presence of endogenous efflux pumps that keep it from accumulating in the cells. Linezolid is well absorbed orally and is generally well tolerated; however, some severe cases of reversible blood dyscrasias have been noted, resulting in a package insert warning that complete blood counts should be monitored weekly, especially in patients with poorly draining infections and who are receiving prolonged therapy with the drug. Some

interference with monoamine oxidase action has been seen, so patients should be cautious about ingesting tyramine-rich foods. Coadministration with adrenergic and serotonergic agents also is unadvisable. Additionally, lactic acidosis has been reported in patients receiving linezolid. Significant oxidative metabolism of the morpholine ring occurs but is not caused by cytochrome P450, so it does not interfere with other drugs metabolized by this system. Significant activity is underway to prepare and evaluate other oxazolidinone analogues.

Mupirocin



Mupirocin is a member of a group of lipid acids produced by fermentation of *Pseudomonas fluorescens*. It can only be used topically because of hydrolysis in vivo that inactivates the drug. It has an intrinsically broad spectrum, but its primary indication is topical use against staphylococcal and streptococcal skin infections. It is commonly used nasally in infection control programs to eradication nasal colonization by MRSA. Mupirocin binds to bacterial isoleucyl transfer-RNA synthase, preventing incorporation of isoleucine into bacterial proteins. Resistance is caused by alterations of the synthase target such that the enzyme still functions but does not bind mupirocin.

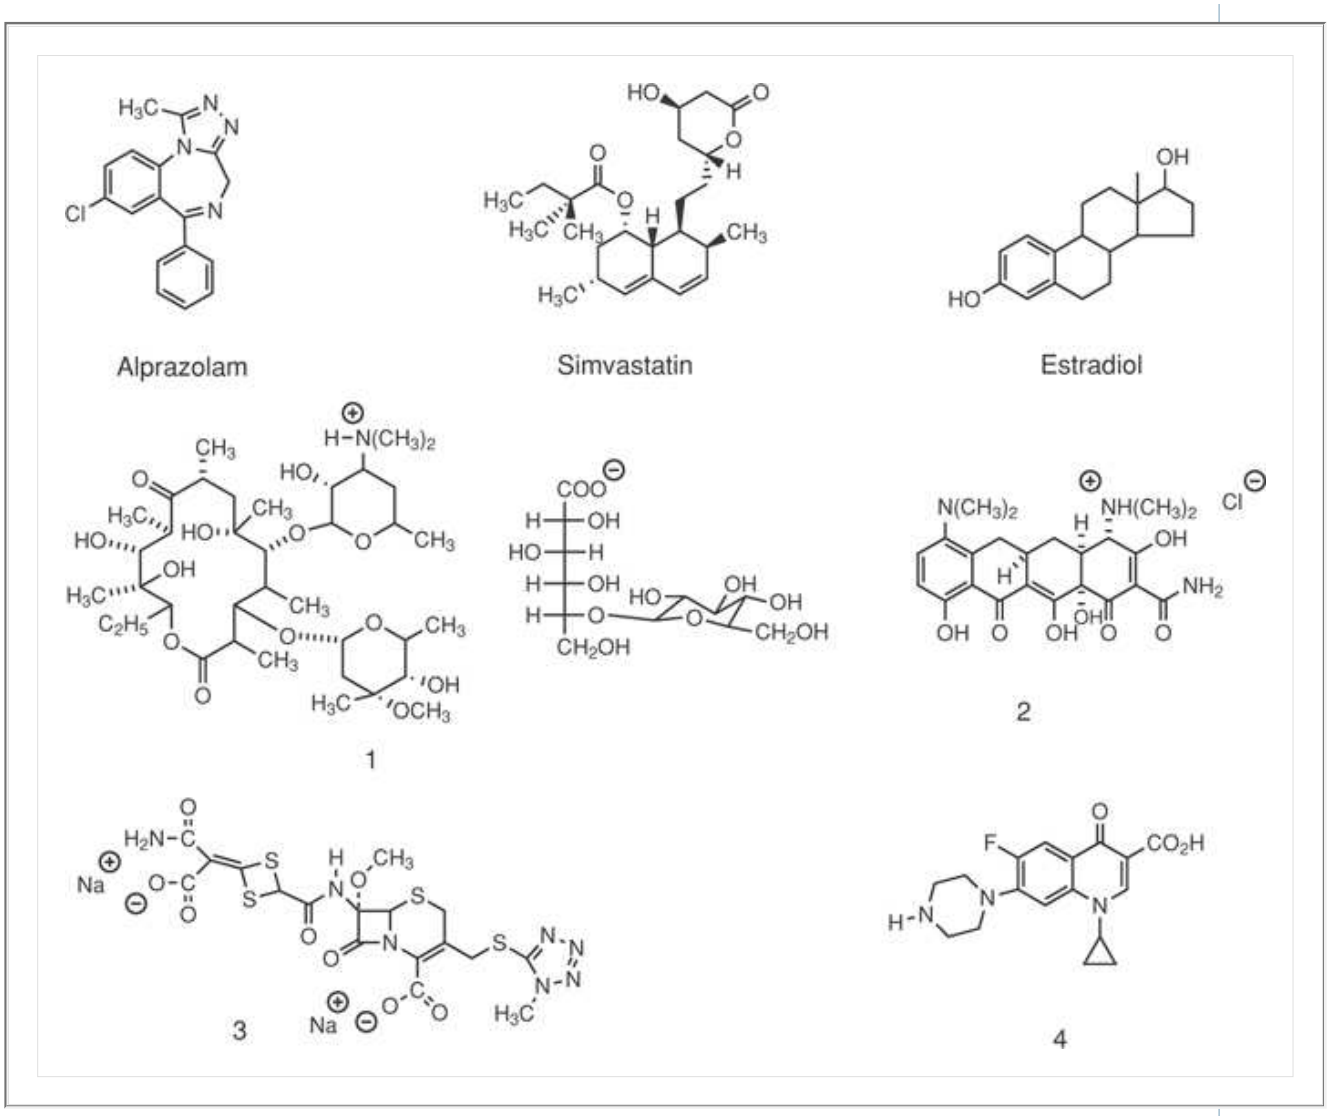
Case Study

Victoria F. Roche

S. William Zito

MR is an 87-year-old, widowed woman living in a facility designed for healthy seniors capable of independent care. An unusually cold and harsh winter has curtailed the number of field trips and outings that could be planned, but the Activities Director has engaged the residents in many popular indoor events, such as line dancing, “chairobics” exercise sessions, board games, and musical entertainment. MR is a regular participant in these activities, because she gets lonely in her apartment and thoroughly enjoys the stimulation of interacting with her fellow residents (plus partaking of the refreshments served).

Recently, there has been an outbreak of community-acquired pneumonia in the facility, and unfortunately, MR has fallen victim. Although normally independent, she is somewhat frail and was sufficiently ill to require short-term hospitalization to identify appropriate therapy. The offending organism was confirmed to be *Streptococcus pneumoniae*, and the physician would like to maintain her on parenteral therapy for a few days before sending her home on oral medication. MR is concerned about out-of-pocket costs, because her late husband's insurance coverage, which she has been able to maintain, does not have a very extensive drug plan. MR's medical history includes a severe penicillin allergy and lactose intolerance, and her current medications include extended-release alprazolam (1 mg at bedtime for mild anxiety), simvastatin (Zocor, 20 mg q.d. in the evenings) for dyslipidemia, and low-dose micronized estradiol (0.5 mg q.d.), along with Viactive calcium chews (t.i.d.) to minimize bone loss. Her renal and hepatic function is suboptimal, as would be expected in someone of her advanced years. Consider the structures of the antibiotics drawn below, and prepare to make a therapeutic recommendation.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 39

Antiparasitic Agents

Thomas L. Lemke

Drugs covered in this chapter:

Drug treatment of amebiasis, giardiasis, trichomoniasis

- Diloxanide furoate
- Metronidazole
- Nitazoxanide
- Tinidazole

Treatment of pneumocystis

- Atovaquone
- Penamidine isethionate
- Sulfamethoxazole–trimethoprim
- Trimetrexate glucuronate

Treatment of trypanosomiasis

- Benznidazole
- Eflornithine
- Melarsoprol
- Niturtimox
- Pentamidine isethionate
- Suramin sodium

Treatment of leishmaniasis

- Sodium stibogluconate

Antimalarials

- Atovaquone–proguanil
- Chloroquine
- Halofantrine
- Mefloquine
- Pyrimethamine
- Quinine

Anthelmintics

- Albendazole
- Diethylcarbamazine

- Ivermectin
- Mebendazole
- Oxamniquine
- Praziquantel
- Pyrantel pamoate
- Thiabendazole

Scabicides and pediculocides

- Crotamiton
- Lindane
- Permethrin
- Pyrethrin

General Considerations

An introduction to the topic of parasitic diseases usually emphasizes two points. First, parasitic infections affect huge numbers of individuals. It is estimated that well over 1 billion people are infected worldwide. Second, the majority of these parasitic infections are found in developing nations, in which the cost of health care is the dominant factor that determines whether the patient is (or is not) treated. The incidence of some parasitic diseases may exceed 80% of the population. The high cost of drug discovery and the low incidence of many of the parasitic infections in affluent Western countries have combined to reduce the incentive for both the study of the diseases and the development of effective therapy. This may be changing, however, because of global travel, improved communications, and growth of the developing countries, leading to an increased demand for more effective treatments.

The diseases associated with parasitic infections represent a large and diverse number of conditions, some common and some relatively unheard of by the general population. Included under the title of parasitic infections are the numerous types of protozoal infections: amebiasis, giardiasis, babesiosis, Chagas' disease, leishmaniasis, malaria, sleeping sickness, toxoplasmosis, trichomoniasis, and pneumocystosis (also considered to be a fungal infection). Helminth infections (worms) also are considered to be parasitic infections and may be caused by any of three classes of helminths: nematodes, cestodes, and trematodes. Insect infections, such as scabies, lice (pediculosis), and chiggers, also are considered to be parasitic infections.

Protozoal Diseases

Amebiasis

Amebiasis is a disease of the large intestine caused by *Entamoeba histolytica.* The disease occurs mainly in the tropics, but it also is seen in temperate climates. Amebiasis may be carried without significant symptoms or may lead to severe, life-threatening dysentery. The organism exists in one of two forms, the motile trophozoite form or the dormant cyst form. The trophozoite form is found in the intestine or wall of the colon and may be expelled from the body with the stools. The cyst form is encased by a chitinous wall that protects the organism from the environment, including chlorine used in water purification; thus, the organism may be transmitted through contaminated water and foods. It is the cyst form that is responsible for transmission of the disease. The cyst is spread by direct person-to-person contact and is commonly associated with living conditions in which poor personal hygiene, poor sanitation, poverty, and ignorance

exist. The hosts may be rendered susceptible to infection by preexisting conditions, such as protein malnutrition, pregnancy, HIV infection, or high carbohydrate intake. Under these conditions, the organism is capable of invading body tissue. The protozoal invasion is not well understood. but it does appear to involve the processes indicated in Table 39.1. Symptoms may range from intermittent

diarrhea (foul-smelling loose/watery stools) to tenderness and enlargement of the liver (with the extraintestinal form) to acute amoebic dysentery. Many patients may experience no symptoms, and the organism remains in the bowels as a commensal organism.

Clinical Significance

Parasitic infections affect more than half the world's population and are responsible for significant health complications, especially in underdeveloped areas. Drug therapy for parasitic infections is quite challenging to practitioners for multiple reasons. Many practitioners lack experience with these agents and are unfamiliar with the toxicities and monitoring parameters associated with these drugs. Certain agents are available in only a limited number of countries, and opinions regarding safety and efficacy vary greatly among practitioners. Understanding the medicinal chemistry, pharmacodynamics, and pharmacokinetics of these agents is of utmost importance.

Despite efforts of vaccine development, drug therapy remains the most effective means to control parasitic infections. Limited introduction of new antiparasitic agents and drug shortages make the treatment of parasitic infestations challenging. Understanding which drugs work at different parts of the life cycle of the parasite also must be taken into consideration. Furthermore, the use of many antiparasitic agents are associated with toxicities, including precipitating severe inflammatory reactions, which may then be treated with anti-inflammatory agents and other supportive measures.

Laura Gerard Pharm.D. BCPS

Clinical Assistant Professor, Department of Clinical Science & Administration, University of Houston College of Pharmacy.

Giardiasis

Giardiasis is a disease that shows considerable similarity to amebiasis. It is caused by *Giardia lamblia*, an organism that may be found in the duodenum and jejunum. The organism exists in a motile trophozoite form and an infectious cyst form. The cyst form can be deposited in water (lives up to 2 months), and the contaminated water may then be ingested by the human. The trophozoite, if expelled from the gastrointestinal (GI) tract, normally will not survive. *Giardia lamblia* is the single most common cause of waterborne diarrhea in the United States. Giardiasis is a common disease among campers who drink water from contaminated streams. It also may be spread between family members, children in day care centers, and dogs and their masters. The organism can attach to the mucosal wall via a ventral sucking disk, and similar to amebiasis, the patient may be asymptomatic or develop watery diarrhea, abdominal cramps, distention and flatulence, anorexia, nausea, and vomiting. Usually, the condition is self limiting in 1 to 4 weeks.

Intestinal form	a. Disintegration of cyst wall in small intestine
	b. Movement of trophozoites into the colon
	c. Adhesion of trophozoite to cells of the host which involves a change in composition and production of mucus
Extraintestinal form	d. Penetration of intestinal lining and entrance into portal circulation form
	e. Invasion of liver tissue

Table 39.1. *Entamoeba Histolytidavasion* of Host

Trichomoniasis

Trichomoniasis is a protozoal infection caused by *Trichomonas vaginalis*, which exists only in a trophozoite form. The organs most commonly involved in the infection include the vagina, urethra, and prostate; thus, the disease is considered to be a venereal infection. The condition is transmitted by sexual contact, and it is estimated that trichomoniasis affects 180 million individuals worldwide. Infections in the male may be asymptomatic, whereas in the female, the symptoms may consist of vaginitis, profuse and foul-smelling discharge, burning and soreness on urination; and vulvar itching. Diagnosis is based on microscopic identification of the organism in fluids from the vagina, prostate, or urethra.

Pneumocystis

The organism responsible for pneumocystis (pneumocystosis) in humans is *Pneumocystis carinii*. It has the morphologic

characteristics of a protozoan (i.e., lack of ergosterol in its cell membrane), but its rRNA and mitochondrial DNA pattern resembles that of fungi. Acute pneumocystis rarely strikes healthy individuals, although the organism is harbored in a wide variety of animals and most humans without any apparent adverse effect. *Pneumocystis carinii* becomes active only in those individuals who have a serious impairment of their immune systems. Thus, the organism is considered to be an opportunistic pathogen. More recently, this disease has appeared in patients with AIDS, 80% of whom ultimately contract *P. carinii* pneumonia (PCP), as one of the main causes of death. The disease also occurs in those receiving immunosuppressive drugs to prevent rejection following organ transplantation or for the treatment of malignant disease. Additionally, pneumocystis is seen in malnourished infants whose immunologic systems are impaired. The disease is thought to be transmitted via an airborne route. The disease is characterized by a severe pneumonia caused by rapid multiplication of the organisms, almost exclusively in lung tissue, with the organism lining the walls of the alveoli and gradually filling the alveolar spaces. Untreated, the acute form of the disease generally is fatal. Even patients who recover from pneumocystosis are at risk of recurrent episodes. Patients with AIDS experience a recurrence rate of approximately 50%.

Organisms that Commonly Cause Vaginitis

Vaginitis also may be caused by *Haemophilus vaginalis* (bacteria) or *Candida albicans* (fungus), which are treated differently from the protozoal infection.

Extrapulmonary pneumocystosis—that is, pneumocystosis outside of the lungs—also is known to exist and may be more common than presently recognized. This infection may be complicated by the presence of coinfectious organisms. Fortunately, drug therapy utilized for treatment of the pulmonary infection is beneficial for the extrapulmonary condition, although intravenous (IV) administration of the drugs may be necessary.

Tritryps

Three protozoan pathogens that belong to the family Trypanosomatidae, the order Kinetoplastida, and the genus *Trypanosoma* are *Leishmania major*, which is responsible for leishmaniasis; *Trypanosoma brucei*, which is responsible for African trypanosomiasis (African sleeping sickness); and *Trypanosoma cruzi*, which is responsible organism for Chagas' disease. Referred to as the "tritryps," these eukaryotic organisms share characteristic subcellular structures of a kinetoplast and glycosomes, are unicellular motile protozoa, are transmitted by various insect vectors, and infect mammalian hosts. The genomes of tritryps have recently been reported (1,2,3). Together, they infect hundreds of millions of people annually.

Trypanosomiasis (4)

There are two distinct forms of trypanosomiasis: Chagas' disease, and African sleeping sickness.

Chagas' disease

Chagas' disease, also known as American trypanosomiasis, is caused by the parasitic protozoa *Trypanosoma cruzi* and is found only in the Americas, primarily in Brazil but also in the southern United States. The protozoa lives in mammals and is spread by the bloodsucking insect known as the reduviid bug, assassin bug, or kissing bug. The insect becomes infected by drawing blood from an infected mammal and releasing the protozoa with discharged feces. The pathogen then enters the new host through breaks in the skin. Inflammatory lesions are seen at the site of entry. The disease also may be spread through transfusion with contaminated blood. Signs of initial infection may include malaise, fever, anorexia, and skin edema at the site where the protozoa entered the host. The disease ultimately may invade the heart, where after decades of infection with chronic Chagas' disease, the patient may experience an infection-associated heart attack. It is estimated that 5% of the Salvadorian and Nicaraguan immigrants to the United States may have chronic Chagas' disease.

African trypanosomiasis

African trypanosomiasis, or sleeping sickness, is caused by several subspecies of *Trypanosoma brucei* (*T. brucei rhodesiense* [east African sleeping sickness] and *T. brucei gambiense* [west African sleeping sickness]). In this case, the infected animal is bitten by the bloodsucking tsetse fly, which in turn transmits the protozoa via inoculation during a subsequent bite of a human. The protozoa, initially present in the gut of the vector. appears in the salivary gland for inoculation during the subsequent biting of a human. It is estimated that some 50 million people are at risk of African sleeping sickness, with 300,000 to 500,000 cases occurring in sub-Saharan Africa each year. The infection progresses through two stages. Stage I may present as fever and high temperatures lasting several days; hematologic and immunologic changes occur during this stage. Stage II occurs after the organism enters the central nervous system (CNS) and may involve symptoms suggesting the disease name—daytime somnolence, loss of spontaneity, halting speech, listless gaze, and extrapyramidal signs (e.g., tremors and choreiform movements). A breakdown of neurological function leading to coma and death may occur. Death may occur within weeks if

untreated (*T. brucei rhodesiense*) or only after several years (*T. brucei gambiense*).

It should be noted that the sole source of energy for the trypanosomal organism is glycolysis, which in turn may account for the hypoglycemia seen in the host. In addition, the migration of the organism into the CNS may be associated with the organism's search for a rich source of available glucose.

Leishmaniasis

Leishmaniasis is a disease caused by a number of protozoa in the genus *Leishmania*. The protozoa may be harbored in diseased rodents, canines, and various other mammals and transmitted from the infected mammal to man by bites from female sandflies of the genus *Phlehotomus* and then appears in one of four major clinical syndromes: visceral leishmaniasis, cutaneous leishmaniasis, mucocutaneous leishmaniasis, or diffuse cutaneous leishmaniasis.

The sandfly, the vector involved in spreading the disease, breeds in warm, humid climates; thus, the disease is more common in the tropics. As many as 12 million individuals, worldwide are infected by this organism.

The visceral leishmaniasis, also known as kala azar (black fever), is caused by *Leishmania donovani*. This form of the disease is systemic and is characterized in patients by fever, typically nocturnal, diarrhea, cough, and enlarged liver and spleen. The skin of the patient may become darkened. Without treatment, death may occur in 20 months and is commonly associated with diarrhea, superinfections, or GI hemorrhage. Visceral leishmaniasis is most commonly found in India and Sudan.

Both cutaneous and monocutaneous leishmaniasis are characterized by single or multiple localized lesions. These slow-healing and, possibly, painful ulcers can lead to secondary bacterial infections. The Old World cutaneous leishmaniasis is caused by *Leishmania topica*, which is found most commonly in children and young adults in regions bordering the Mediterranean, the Middle East, Southern Russia, and India. *Leishmania major* is endemic to desert areas in Africa, the Middle East, and Russia, whereas *Leishmania aethiopica* is found in the Kenyan highlands and Ethiopia. The New World disease caused by *Leishmania peruviana*, *Leishmania braziliensis*, and *Leishmania panamensis* is found in South and Central America, whereas *Leishmania mexicana* may be endemic to southcentral Texas. The incubation period for cutaneous leishmaniasis ranges from a few weeks to several months. The slow-healing lesions may be seen on the skin in various regions of the body depending on the specific strain of organism. Usually, these conditions exhibit spontaneous healing, but this also may occur over an extended period of time (1–2 years).

Malaria

Malaria is transmitted by the infected female *Anopheles* mosquito. The specific protozoan organisms causing malaria are from the genus *Plasmodium.* Only 4 of approximately 100 species cause malaria in humans. The remaining species affect birds, monkeys, livestock, rodents, and reptiles. The four species that affect humans are *Plasmodium falciparum, Plasmodium vivax, Plasmodium malariae*, and *Plasmodium ovale.* Concurrent infections by more than one of these species are seen in endemically affected regions of the world. Such multiple infections further complicate patient management and the choice of treatment regimens.

Malaria affects as many as 500 million humans globally and causes more than 2 million deaths annually. It is estimated that a third of these fatalities occur in children younger than 5 years. Although this disease is found primarily in the tropics and subtropics, it has been observed far beyond these boundaries.

Malaria has essentially been eradicated in most temperate-zone countries. However, more than

1,000 cases of malaria were documented recently in U.S. citizens returning from travel abroad. Today, malaria is found in most countries of Africa, Central and South America, and Southeast Asia. It is reported to be on the increase in Afghanistan, Bangladesh, Brazil, Burma, Cambodia, Colombia, China, Iran, India, Indonesia, Mexico, the Philippines, Thailand, and Vietnam. Infection from plasmodia can cause anemia, pulmonary edema, renal failure, jaundice, shock, cerebral malaria, and if not treated in a timely manner, even death.

Types of Malaria

Malarial infections are known according to the species of the parasite involved.

Plasmodium falciparum

Infection with *Plasmodium falciparum* has an incubation period (time from mosquito bite to clinical symptoms) of 1 to 3 weeks (average, 12 days). The *P. falciparum* life cycle in humans begins with the bite of an infected female mosquito. The parasites in the sporozoite stage enter the circulatory system, through which they can reach the liver in approximately 1 hour. These organisms grow and multiply 30,000- to 40,000-fold by asexual division within liver cells in 5 to 7 days. Then, as merozoites, they leave the liver to reenter the blood stream and invade the erythrocytes, or red blood cells (RBCs), where they continue to grow and multiply further for 1 to 3 days. Specific receptors on the surface of the erythrocytes serve as binding sites for the merozoite. These infected RBCs rupture, releasing merozoites in intervals of approximately 48 hours. Chemicals released by the ruptured cell in turn cause activation and release of additional substances associated with the patient's symptoms. The clinical symptoms include chills, fever, sweating, headaches, fatigue, anorexia, nausea, vomiting, and diarrhea. Some of the released merozoites are sequestered in vital organs (brain and heart), where they continue to grow. Recurrence of the clinical symptoms on alternate days leads to the terminology of tertian malaria. The *P. falciparum* parasite also can cause RBCs to clump and adhere to the wall of blood vessels. Such a phenomenon has been known to cause partial obstruction and, sometimes, restriction of the blood flow to vital organs like the brain, liver, and kidneys. Reinfection of RBCs can occur, allowing further multiplication and remanifestation of the malaria symptoms. Some merozoites develop into male and female sexual forms, called gametocytes, which can then be acquired by the female mosquito after biting the infected human. Gametocytes mature in the mosquito's stomach to form zygotes. Growth of the zygotes leads to the formation of oocysts (spherical structures located on the outside wall of the stomach). Sporozoites develop from the oocysts, are released into the body cavity of the mosquito, and migrate to the salivary gland of the insect, from which they can be transmitted to another human following a mosquito bite. The life cycle of the malaria parasites is shown in the Figure 39.1. The genome of the *P. falciparum* is now known and is expected to provide potential new

avenues for drug development. Genome information also is expected to give insight regarding the mechanisms of resistance and improve drug treatment.

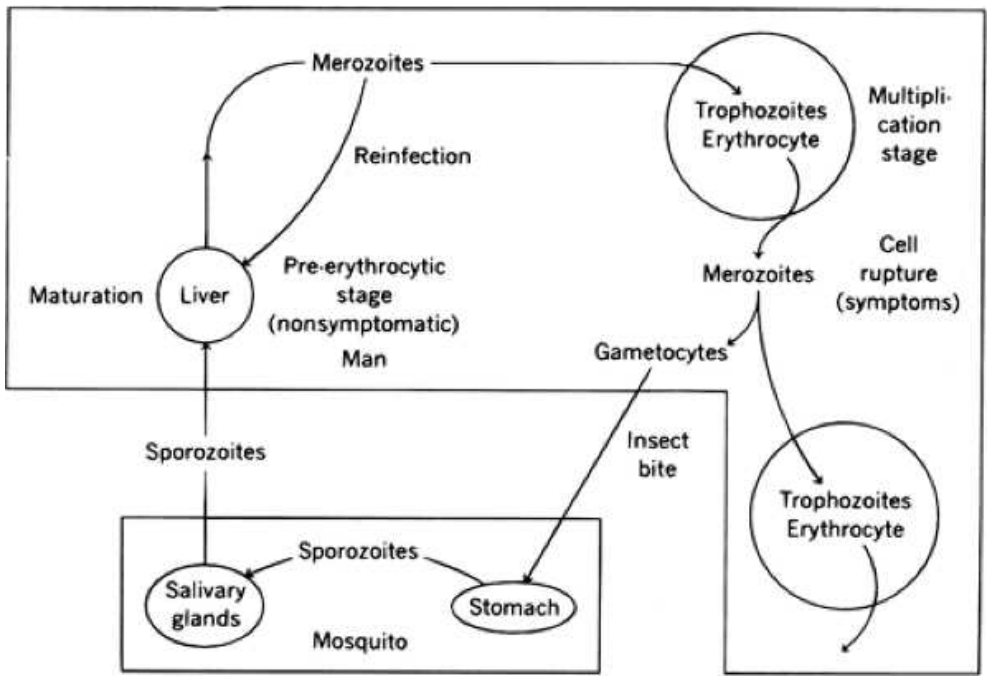

Fig. 39.1. Life cycle of malarial protozoa.

Plasmodium vivax

Plasmodium vivax (benign tertian) is the most prevalent form of malaria. It has an incubation period of 1 to 4 weeks (average, 2 weeks). This form of malaria can cause spleen rupture and anemia. Relapses (renewed manifestations of erythrocytic infection) can occur. This results from the periodic release of dormant parasites (hypnozoites) from the liver cells. The erythrocytic forms generally are considered to be susceptible to treatment.

Plasmodium malariae

Plasmodium malariae is responsible for quartan malaria. It has an incubation period of 2 to 4 weeks (average, 3 weeks). The asexual cycle occurs every 72 hours. In addition to the usual symptoms, this form also causes nephritis. This is the mildest form of malaria and does not relapse. The RBC infection associated with *P. malariae* can last for many years. The *P. malariae* is quite unlikely to become resistant.

Plasmodium ovale

Infection with *Plasmodium ovale* has an incubation period of 9 to 18 days (average, 14 days). Relapses have been known to occur in individuals infected with this plasmodium. The relapse may be indicative of ovale tertian malaria and is associated with the ability of the organism to lie dormant in hepatic tissue for extended periods of time.

Types of Chemotherapy

Tissue schizonticides

These drugs eradicate the exoerythrocytic liver-tissue stages of the parasite, which prevents the

parasite's entry into the blood. Drugs of this type are useful for prophylaxis. Some tissue schizonticides can act on the long-lived tissue form (hypnozoites of *P. vivax* and *P. ovale*) and, thus, can prevent relapses.

Blood schizonticides

These drugs destroy the erythrocytic stages of parasites and can cure cases of falciparum malaria or suppress relapses. This is the easiest phase to treat, because drug delivery into the blood stream can be accomplished rapidly.

Gametocytocides

Agents of this type kill the sexual forms of the plasmodia (gametocytes), which are transmittable to the *Anopheles* mosquito, thereby preventing transmission of the disease.

Sporontocides (sporozooiticides)

These drugs act against sporozoites and are capable of killing these organisms as soon as they enter the bloodstream following a mosquito bite.

It should be noted that antimalarials may operate against more than one form of the organism and may be effective against one species of plasmodium but lack efficacy against others. In addition, antimalarial drugs may be classified according to their structural types.

General Approaches to Protozoal Therapy

Amebiasis and Giardiasis

The most appropriate approach for treatment of this type of protozoal infection is through prevention. Because the infection usually occurs by consumption of contaminated drinking water and food, avoidance is the key to prevention. Drinking bottled water, or boiling or disinfecting the water, will reduce the risk. Improvement in personal hygiene and general sanitation also are beneficial.

Trypanosomiasis, Leishmaniasis, and Malaria

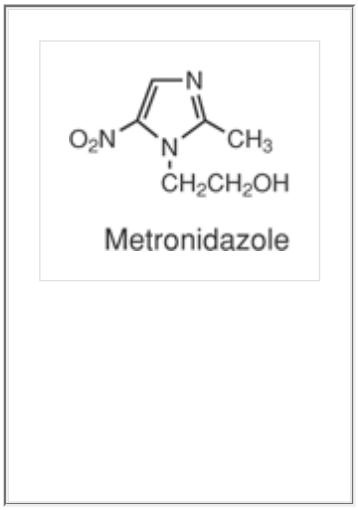
For these diseases that are spread by insect vectors, the use of insecticides, protective clothing, and insect repellents can greatly reduce the incidence of the disease. Unfortunately, many of these protozoal infections also

can infect other hosts beside humans; thus, even the most successful insect irradiation methods cannot destroy all the reservoirs of the protozoa. The use of insect repellents and protective clothing may be useful for visitors to regions with endemic infections, but these procedures may prove to be ineffective for those living in the area. For such individuals, early detection and drug therapy is the method of treatment.

Drug Therapy for Protozoal Infections

Treatment of Amebiasis, Giardiasis, and Trichomoniasis

Metronidazole (Flagyl, Metryl, Satric)



Metronidazole was initially introduced for the treatment of vaginal infections caused by *Trichomonas vaginalis* but has since been shown to be effective for treatment of amebiasis, giardiasis, and anaerobic bacterial infections, including *Clostridium difficile*.

Mechanism of action

Despite the availability of metronidazole since the late 1950s, the mechanism of action of the drug is still unknown. It generally is agreed that metronidazole is a pro-drug and that anaerobic organisms reduce the nitro group in metronidazole to a hydroxylamine, as shown in Figure 39.2, during which a reactive derivative or reactive species are produced that cause destructive effects on cell components (i.e., DNA, proteins, and membranes). Specifically, DoCampo (5) has reported that nitroaryl compounds (nitroimidazoles, metronidazole; nitrofurans, nifurtomox) are reduced to nitro radical anions, which in turn react with oxygen to regenerate the nitroaryl and the superoxide radical anion (Fig. 39.3). Further reduction of superoxide radical anion leads to hydrogen peroxide and homolytic cleavage of the latter leads to hydroxyl radical formation. Superoxide radical anion, hydrogen peroxide, and hydroxyl radicals are referred to as reactive oxygen species (ROS) and are the reactive substances that are implicated in damage to critical cellular components of the parasite.

Metabolism

Liver metabolism of metronidazole leads to two major metabolites: hydroxylation of the 2-methyl group to 2-hydroxymethylmetronidazole (HM), and oxidation to metronidazole acetic acid (6). Both compounds possess biological activity. Additionally, HM is found in the urine as glucuronide and sulfate conjugates. In addition, a small amount of metronidazole is oxidized to acetamide, a known carcinogen in rats but not in humans, and to the oxalate derivative shown in Figure 39.4 (7).

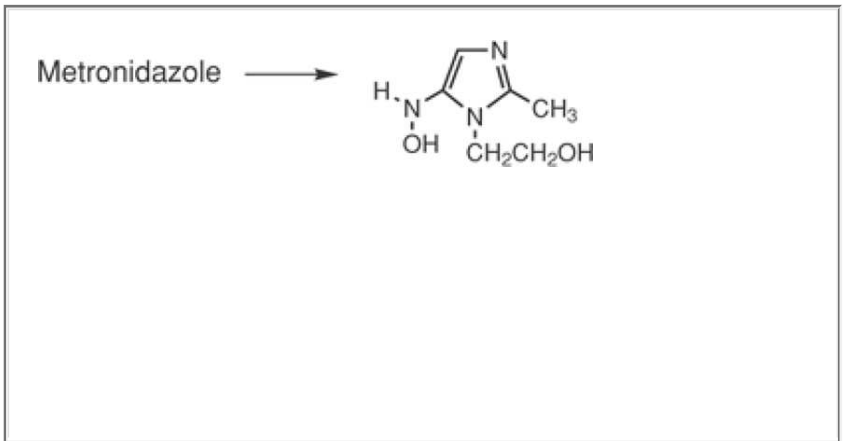


Fig. 39.2. Metabolic activation of metronidazole.

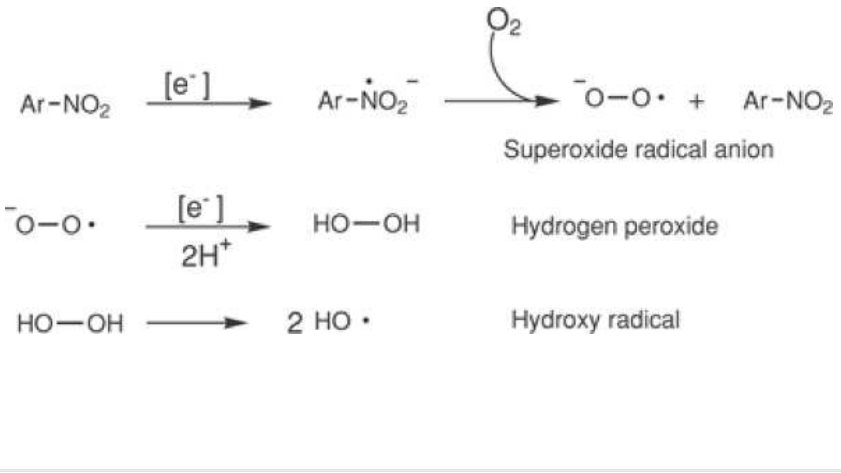

Fig. 39.3. Formation of ROS from nitroaryl compounds.

Pharmacokinetics (6)

Metronidazole is available in a variety of dosage forms, including IV, oral, rectal, and vaginal suppositories. The bioavailability of metronidazole is nearly 100% when administered orally but is significantly less when administered via the rectal route (67–82%) or the vaginal route (19–56%). The drug is not bound to plasma protein. Distribution of the drug is fairly uniform through out the body, including mother's milk.

Therapeutic application

Metronidazole is considered to be the drug of choice for treatment for the protozoal infections amebiasis (intestinal and extraintestinal), giardiasis, and trichomoniasis (8). It is the drug of choice for treatment of the Gram-positive bacilli *Clostridium difficile* and in combination is an alternative therapy for *Helicobacter pylori* infections (9). The common side effects exhibited with metronidazole include abdominal distress, a metallic taste, and a disulfiram-like effect if taken with alcohol. The drug is reported to be carcinogenic in mice, possibly related to the metabolite acetamide, and as a result should not be used during the first trimester of pregnancy.

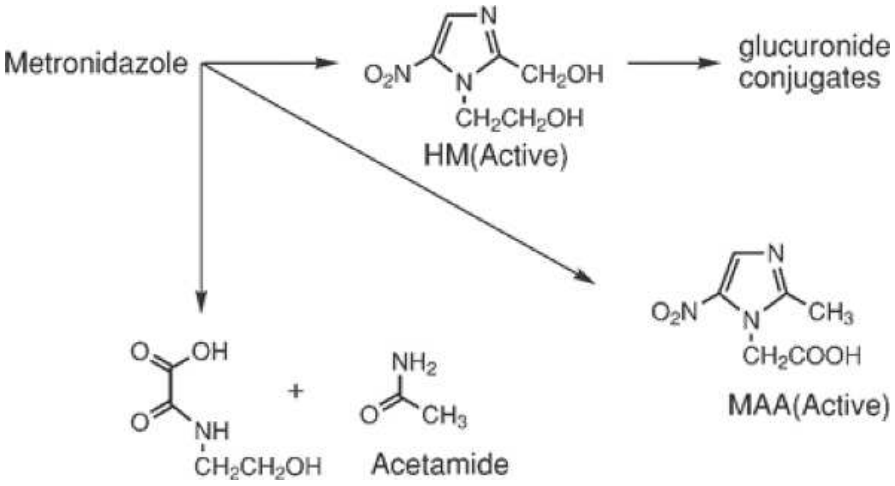

Fig. 39.4. Metabolism of metronidazole.

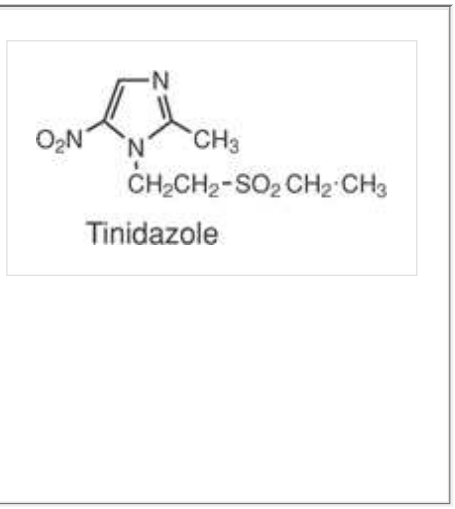
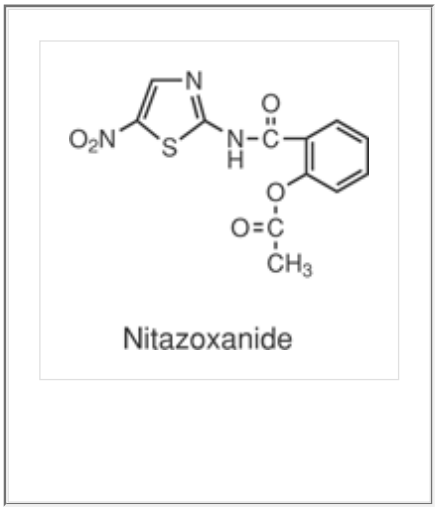
Tinidazole (Tindamax)



Tinidazole has recently been approved by the U.S. Food and Drug Administration (FDA) for the treatment of amebiasis, giardiasis, and trichomoniasis. It also appears to be highly effective against *Helicobacter pylori* infections, although it is not approved for this use. The drug is rapidly and completely absorbed following oral administration and can be administered with food to reduce GI disturbance. Tinidazole has a mechanism of action that parallels that of metronidazole as well as a similar metabolic pathway leading to hydroxylation at the 2-methyl group catalyzed by CYP3A4. Basically, tinidazole appears to mimic the actions of metronidazole, although there are reports that it is effective against some protozoa which are resistant to metronidazole.

Nitazoxanide (Alinia)



Nitazoxanide (NTZ) has been approved as an orphan drug for the treatment of diarrhea in children (age, 1–11 years) and is associated with giardiasis, but it also is approved for diarrhea caused by crytosporidiosis in patients with AIDS. Crytosporidiosis is a protozoal infection caused by *Cryptosporidium parvum*. The condition is uncommon in healthy individuals but can be life-threatening in immunosuppressed patients and those with HIV infections.

Mechanism of action (10)

Nitazoxanide is a pro-drug that is metabolically converted into the deactylated drug tizoxanide (TIZ) (Fig. 39.5). The TIZ then undergoes a four-electron reduction of the 5-nitro group giving various short-lived intermediates, which may include the hydroxylamine derivative. It is these reduced products that represent the active form of NTZ. Whereas these intermediates would suggest that NTZ has the same mechanism of action as metronidazole, this does not appear to be the case. Nitazoxanide is thought to inhibit the enzyme pyruvate:ferredoxin oxidoreductase in *Trichomonas vaginalis, Entamoeba histolytica*, and *Clostridium perfingens*. The results of this inhibition is disruption of the bioenergetics of these organisms. Unlike metronidazole and tinidazole, which fragment DNA and are suspected mutagenic agents, NTZ and TIZ do not cause DNA fragmentation and are not considered to be mutagenic. This might be associated with the higher redox potential found for NTZ, a nitrothiazole, in comparison with very low redox potential found for the nitroimidazoles, such as metronidazole and tinidazole. Additional metabolites of TIZ also includes the glucuronide, which shows some biological activity, and small amounts of an aromatic hydroxylation product (Fig. 39.5).

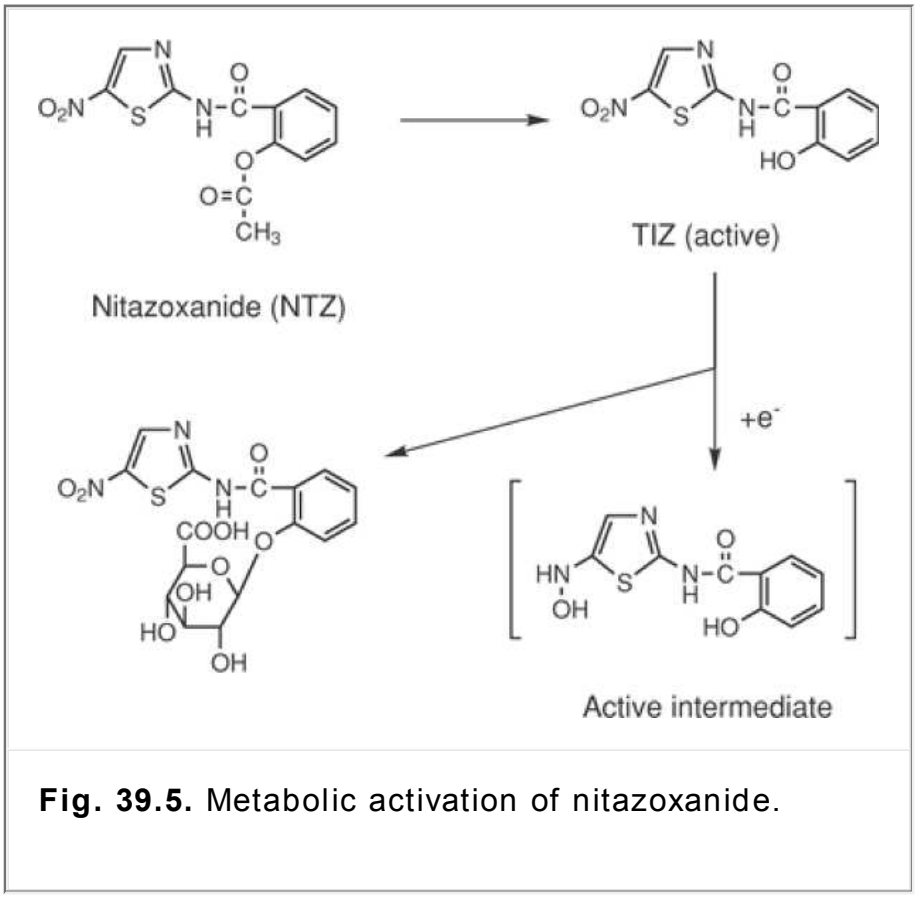


Fig. 39.5. Metabolic activation of nitazoxanide.

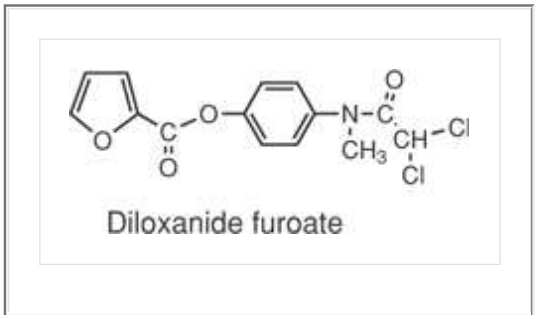
Pharmacokinetics

Nitazoxanide is available as powder that is reconstituted and dispensed as an oral suspension. The drug is well absorbed from the GI tract and rapidly metabolized, with elimination products appearing in the urine and feces. The only identified products in the plasma are TIZ and its glucuronide (11). The product can be taken with food.

Therapeutic application

Although NTZ has only been approved for treatment of diarrhea in children caused by *Giardia lamblia* and diarrhea caused by *Cryptosporidium parvum*, the drug may soon be approved for adults suffering from diarrhea caused *Giardia lamblia*. In addition, the drug has been shown to be effective against the protozoa *Entamoeba histolytica* and *Trichomonas vaginalis*, the bacteria *Helicobacter pylori* and *Clostridium perfringens*, and various helminths, including *Ascaris lumbricoides, Enterobius vermicularis, Ancylostoma doudenale*, and *Strongyloides stercoralis* (12).

Diloxanide Furoate



Diloxanide furoate (available from the Centers for Disease Control and Prevention [CDC]) is prescribed for the treatment of asymptomatic amebiasis but is ineffective as a single agent for the extraintestinal form of the disease. The drug is

administered orally and is hydrolyzed in the gut to give diloxanide, which is considered to be the active drug. Diloxanide is the only form identified in the bloodstream. The drug is found in the urine as the glucuronide (Fig. 39.6).

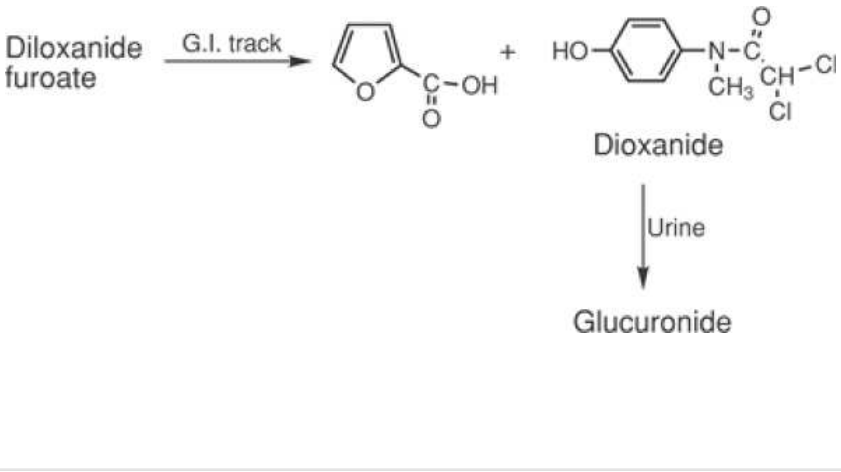


Fig. 39.6. Metabolism of diloxanide furoate.

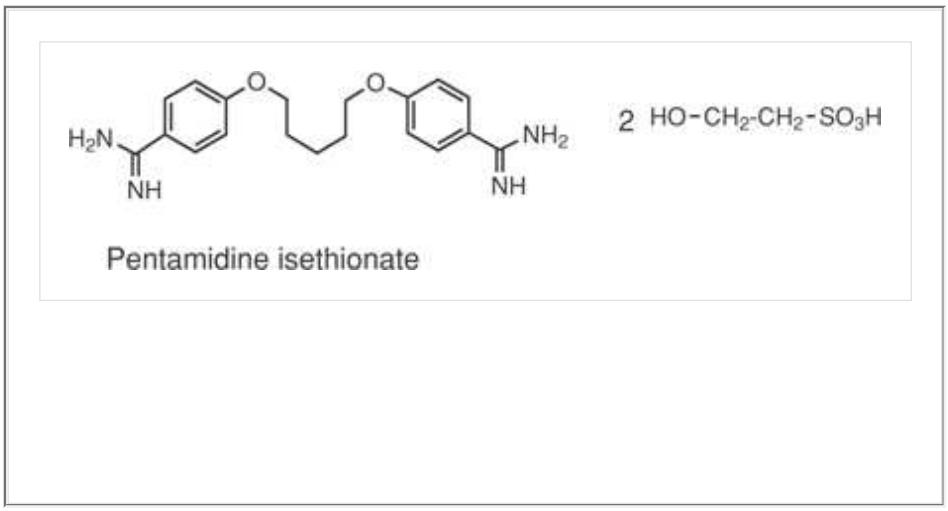
Treatment of Pneumocystis (13,14)

Sulfamethoxazole-Trimethoprim; Cotrimoxazole (Bactrim, Septra, Cotrim)

The combination of sulfamethoxazole and trimethoprim has proven to be the most successful method for treatment and prophylaxis of pneumocystis in patients with AIDS. This combination was first reported as being effective against PCP in 1975, and by 1980, it had become the preferred method of treatment, with a response rate of 65 to 94%. The combination is effective against both pneumocystic *pneumonia and the extrapulmonary disease. Pneumocystis carinii appears to be especially susceptible to the sequential blocking action of cotrimazole, which inhibits both the incorporation of p-aminobenzoic acid (PABA) into folic acid as well as the reduction of dihydrofolic acid to tetrahydrofolic acid by dihydrofolate reductase (DHFR). (A detailed discussion of the mechanism of action and the structure–activity relationship of these drugs can be found in* Chapter 38*.) Depending on the severity of the infection, the combination is administered in doses of 20 mg/kg/day of trimethoprim and 100 mg/kg/day of sulfamethoxazole in four divided doses over a period of 14 to 21 days. The incidence of side effects of this combination are high and, generally, reflects the effects of the sulfa drug component. Side effects may be significant enough to terminate treatment.*

Pentamidine Isethionate (Pentam 300, Nebupent)



Orphan Drug Product

Dapsone plus trimethoprim also has been utilized for the treatment of pneumocystis, with effectiveness nearly equal to that of cotrimazole.

Pentamidine is available as the water-soluble isethionate salt, which is used both IV and as an aerosol. The drug can be used via the intramuscular route, but significant complications have been reported and. therefore, this route of administration is not recommended. The drug has fungicidal and antiprotozoal activity, but today, it is used primarily for treatment of PCP.

Mechanism of action

The mechanism of action of pentamidine is not known with certainty, but strong evidence supports various mechanisms of action for pentamidine. Pentamidine selectively binds to the DNA in trypanosoma parasite (see below). Pentamidine has also been shown to inhibit topoisomerase in *Pneumocystis carinii*, which leads to double-strand cleavage of DNA in trypanosoma (12,13,14). It has been suggested that pentamidine's mechanism of action may be different in different organisms and, therefore, that the actions reported for trypanosoma may not carry over to pneumocystis.

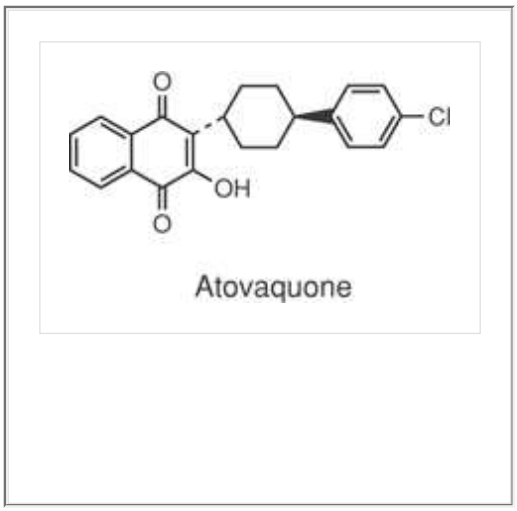
Pharmacokinetics

Pentamidine must be administered IV and, after multiple injections daily or on alternate days, accumulates in body tissue. Plasma concentrations were measured up to 8 months following a single, 2-hour IV infusion. The accumulation aids in treatment as well as in prophylaxis. The drug shows poor penetration of the CNS.

Therapeutic application

Pentamidine is used as a second-line agent either by itself or in combination for the treatment and prophylaxis of PCP. For prophylaxis, the aerosol form of the drug is indicated and has minimum toxicity. The limitation of pentamidine—that is, the need for IV administration—may be associated with the potential for severe toxicity, which includes breathlessness, tachycardia, dizziness, headache, and vomiting. These symptoms may occur in as many as 50% of the patients. These effects are thought to be associated with a too rapid IV administration, resulting in the release of histamine.

Atovaquone (Mepron)



Atovaquone, a chemical with structural similarity to the ubiquinone metabolites, was initially synthesized and investigated as an antimalarial, a use for which it has recently gained acceptance when used in combination therapy with other antimalarial agents. Today, its usefulness is primarily directed toward the treatment of PCP.

Mechanism of action

Atovaquone is thought to produce its antiparasitic action by virtue of its ability to

inhibit the mitochondrial respiratory chain. More specifically, atovaquone is a ubiquinone reductase inhibitor, inhibiting at the cytochrome bc_1 complex (15). This action leads to a collapse of the mitochondrial membrane potential. The compound shows stereospecific inhibition, with the *trans* isomer being more active than the *cis* isomer.

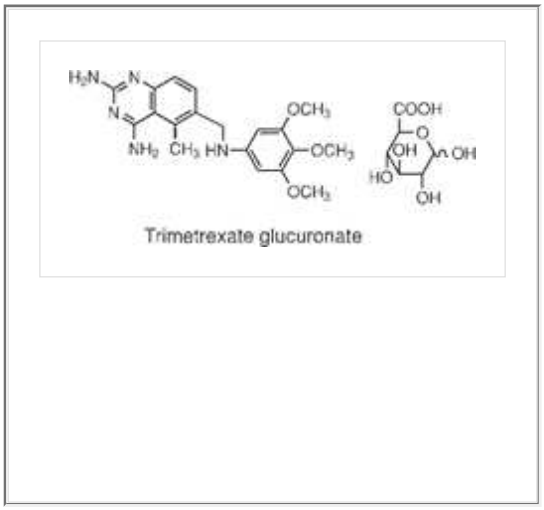
Pharmacokinetics

Atovaquone is poorly absorbed from the GI tract because of its poor water solubility and high fat solubility, but the absorption can be significantly increased if taken with a fat-rich meal. The drug is highly bound to plasma protein (94%) and does not enter the CNS in significant quantities. It is not significantly metabolized in humans and is exclusively eliminated in feces via the bile.

Therapeutic applications

With as many as 70% of patients with AIDS developing pneumocystis and, of these, nearly 60% of the patients on cotrimoxazole developing serious side effects to this combination, atovaquone is an important alternative drug (16). Atovaquone also has been reported to be effective for the treatment of toxoplasmosis caused by *Toxoplasma gondii*, although it has not been approved for this use.

Trimetrexate Glucuronate (Neutrexin)



Trimetrexate (TMQ) has been approved for the treatment of *Pneumocystis carinii* in patients with AIDS and also exhibits antiprotozoal activity against *Trypanosoma cruzi*. The drug is available as a single-ingredient medication, but it can be administered along with folinic acid in much the same way that methotrexate is administered with calcium leucovorin in cancer chemotherapy. Trimetrexate is a derivative of methotrexate.

Mechanism of action

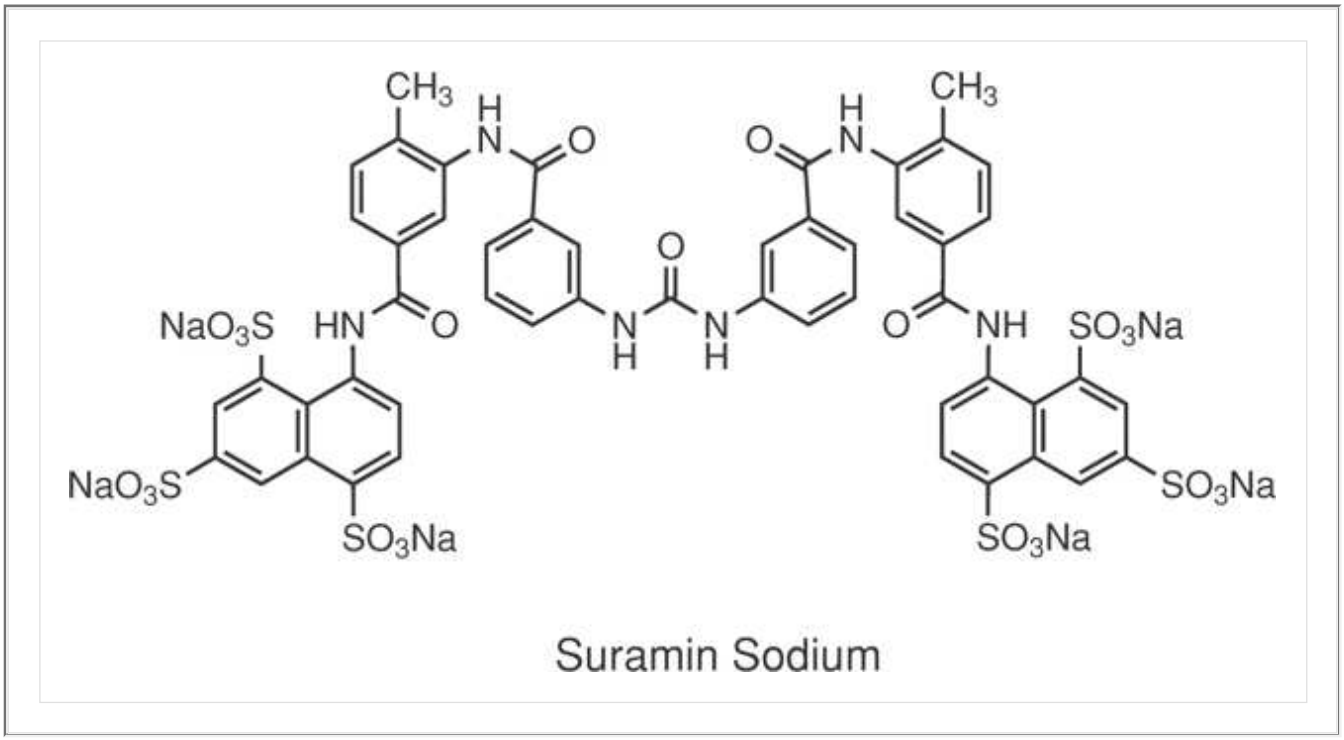
Trimetrexate is considered to be a nonclassical folate antagonist, whereas methotrexate, the structurally similar analogue of TMQ, is a classical folate antagonist. The difference between these two drugs is that methotrexate, with its polar glutamate side chain, is transported into the cell via a carrier-mediated transport system, whereas TMQ, without the glutamate moiety, is absorbed by the cell via a passive diffusion. Once in the cell, TMQ inhibits DHFR. Trimetrexate binds to *Pneumocystis carinii* DHFR 1,500 times more strongly than trimethoprim and somewhat more strongly than methotrexate. It also has been reported that TMQ readily enters the *P. carinii* cell because of the lipophilic nature of this drug (17). Methotrexate and leucovorin are not able to enter the cell, however, because the cell membrane of *P. carinii* does not possess the transporter protein (17).

Therapeutic application

Trimetrexate, when combined with the cytoprotective agent leucovorin, is more effective and better tolerated than pentamidine in the treatment of PCP (18). Because the first- and second-line agents are successful in only 50 to 75% of these cases, and because adverse reactions severely limit the use of some of the older agents, TMQ may offer some advantages in treatment. Trimetrexate is administered by IV infusion over 60 to 90 minutes and should be combined with the cytoprotective drug leucovorin. The leucovorin protects against bone marrow suppression and against renal and hepatic dysfunction. Leucovorin administration should continue for 72 hours after the last dose of TMQ. Additionally, TMQ has been reported to be effective in the treatment of Chagas' disease.

Treatment of Trypanosomiasis (19)

Suramin Sodium (Available from the CDC)



Suramin Sodium

Introduced into therapy for the treatment of early trypanosomiasis in the 1920s, suramin, a bis-hexasulfonatednaphthylurea, is still considered to be the drug of choice for treatment of non-CNS-associated African trypanosomiasis.

Mechanism of action

The mechanism of action of suramin is unproven, but the drug is known to have a high affinity for binding to a number of critical enzymes in the pathogen. Among the enzymes to which suramin has been shown to bind are several dehydrogenases and kinases. As a result of binding, suramin has been shown to be an inhibitor of DHFR, a crucial enzyme in folate metabolism, and thymidine kinase. In addition, suramin is an inhibitor of glycolytic enzymes in *Trypanosoma brucei*, with binding constants much lower than those seen in mammalian cells. Inhibition of glycolysis would be expected to block energy sources of the pathogen, leading to lysis. Whether one or more of these inhibitor actions represent the toxic action of suramin on the pathogen remains unproven.

Pharmacokinetics

Suramin sodium is a water-soluble compound that is poorly absorbed via oral administration and must be administered IV in multiple injections.

Because of it highly ionic nature, suramin will not cross the blood-brain barrier and, therefore, is ineffective for the treatment of trypanosomal infections that reach the CNS. In addition, suramin is tightly bound to serum albumin. Despite this binding, the drug is preferentially absorbed by trypanosomes through a receptor-mediated endocytosis of serum protein. Because the drug remains in the bloodstream for an extended period of time, suramin has value as a prophylactic drug.

Therapeutic application

Seramin sodium is effective against east African trypanosomiasis, but it has limited value against west African trypanosomiasis. As indicated, because the drug will not enter the CNS, the drug is only useful for the treatment of early stages of the disease. The drug exhibits a wide variety of

side effects, which can be severe in debilitated individuals, and include nausea, vomiting, and fatigue.

Pentamidine, Isethionate (Pentam 300, Nebupent)

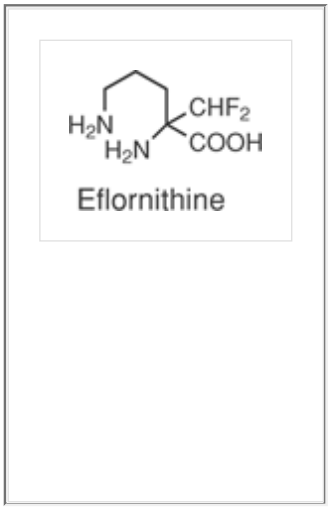
First introduced as a therapy for trypanosomiasis in 1937, pentamidine is now used in a variety of protozoal and fungal infections and, as such, finds use in the treatment of trypanosomiasis, leishmaniasis, and pneumocystis (PCP). The drug is primarily used for treatment of PCP. When used for trypanosomiasis, pentamidine is only effective against *Trypanosoma brucei rhodesiense* (east African sleeping sickness) and, even then, only during the early stage of the disease,. because the drug does not readily cross the blood-brain barrier.

Mechanism of action

As indicated above, several biochemical actions have been reported for pentamidine. The drug has been shown to bind to DNA through hydrogen-bonding of the amidine proton and AT-rich regions of DNA. More specifically, pentamidine binds to the N-3 of adenine, spans four to five base pairs, and binds to a second adenine to form interstrand cross-bonding (20). In addition to and, possibly, separate from this action, pentamidine appears to be a potent inhibitor of type II topoisomerase of mitochondria DNA (kinetoplast DNA) of the trypanosoma parasite (21). The mitochondrial DNA is a cyclic DNA. This inhibition leads to double-stand breaks in the DNA and linearization of the DNA. The relationship between binding to specific regions of the DNA and inhibition of topoisomerase is unclear.

In the case of *Trypanosoma brucei*, resistant strains are common. It is thought that resistance develops through an inability of the drug to reach the mitochondrial DNA (22). Transport into the mitochondria is a carrier-mediated process, with the absence of carrier in the resistant strains.

Eflornithine (Ornidyl)



Metcalf et al. (23) reported the synthesis of eflornithine (difluoromethyl ornithine [DFMO]) in 1978. Their interest arose from the desire to prepare ornithine decarboxylase (ODC) inhibitors as tools for studying the role of polyamines as regulators of growth processes. Ornithine decarboxylase catalyzes the conversion of ornithine to putrescine (1,4-diaminobutane), which in turn leads to the formation of the polyamines, spermine, and spermidine. It was not until 1980 that Bacchi et al. (24) demonstrated the potential of DFMO in the treatment of trypanosomiasis.

Mechanism of action

Difluoromethyl ornithine is a suicide inhibitor of ODC, a pyridoxal phosphate–dependent enzyme,

as shown in Figure 39.7. Evidence suggests that cysteine-360 in ODC is the site of eflornithine alkylation (25). Alkylation of ODC blocks the synthesis of putrescine, the rate-determining step in the synthesis of polyamines. Mammalian ODC also may be inhibited, but because the turnover of ODC is so rapid in mammals, eflornithine does not produce serious side effects.

Pharmacokinetics

Eflornithine may be administered either IV or orally. Administration IV requires large doses and frequent dosing, whereas poor oral absorption and rapid excretion because of the zwitterionic nature of the drug (an amino acid) has limited that route of administration. The drug does not bind to plasma protein and enters the CNS readily, most likely via an amino acid transport system. As a result, the drug can be used for both early and late stages of trypanosomiasis.

Therapeutic application

Eflornithine is indicated for the treatment of west African trypanosomiasis caused by

Trypanosoma brucei gambiense but has proven to be ineffective against east African trypanosomiasis. The cause of this ineffectiveness remains a mystery, although evidence suggests that in the resistant organism, endogenous ornithine plus increased activity of S-adenosylmethionine decarboxylase allows sufficient synthesis of spermidine and spermine to support cell division, thus bypassing the need for organism-synthesized ornithine (26). Side effects reported for eflornithine consist of anemia, diarrhea, and leukopenia.

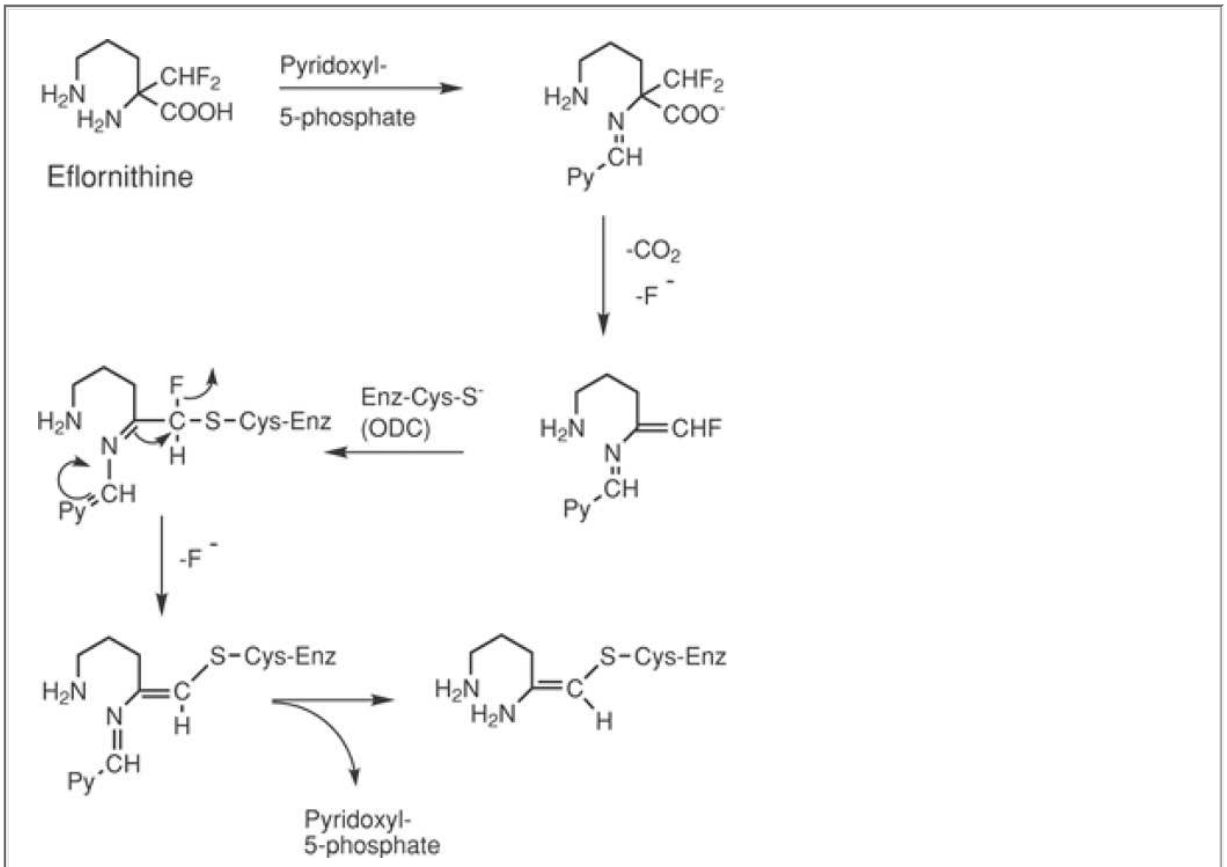


Fig. 39.7. Inhibition of ornithine decarboxylase (Enz-Cys-SH) by eflornithine.

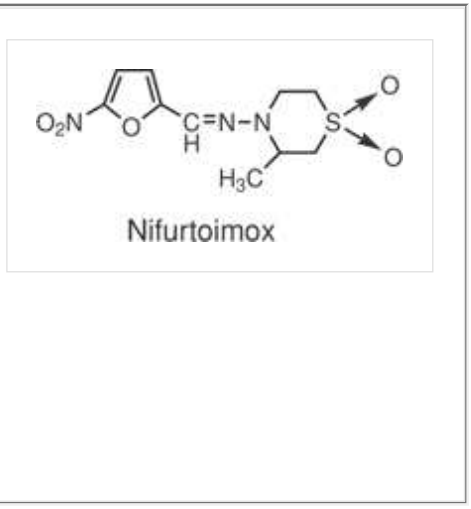
Nifurtimox (Lampit)



Another of the nitroaryl compounds, nifurtimox has proven to be useful as a drug for the treatment of trypanosomiasis. It is one of two drugs approved for use in treatment of Chagas' disease.

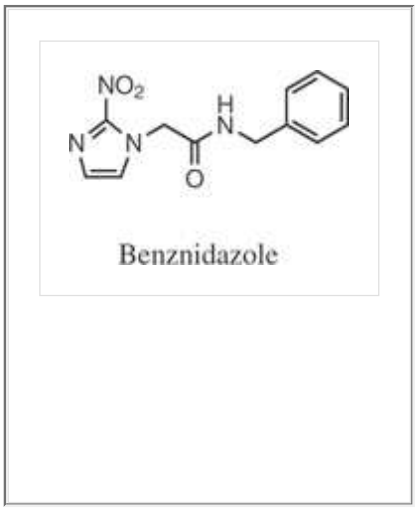
Mechanism of action

As discussed for metronidazole, nifurtimox is thought to undergo reduction followed by oxidation and, in the process, generate ROS, such as the superoxide radical anion, hydrogen peroxide, and hydroxyl radical (Fig. 39.3) (5). These species are potent oxidants, producing oxidative stress that may produce damage to DNA and lipids that may affect cellular membranes. In addition, Henderson et al. (27) have reported that nifurtimox inhibits trypanothione reductase, which results in the inhibition of trypanothione formation (93% inhibition). Trypanothione is a critical protective enzyme found uniquely in trypanosomal parasites.

Therapeutic application

Nifurtimox is the drug of choice for the treatment of acute Chagas' disease. The drug is not effective for the chronic stages of the disease. In the acute stage, the drug has an 80% cure rate. Side effects of the drug include hypersensitivity reactions, GI complications (nausea and vomiting), myalgia, and weakness.

Benznidazole (Rochagan)



Benznidazole is the second of the drugs approved for treatment of Chagas' disease. Like nifurtimox, it is effective against the circulating form of *Trypanosoma cruzi* during the acute phase of the disease, but also like nifurtimox, it is ineffective during the chronic stage of the disease.

Mechanism of action

Studies suggest that benznidazole does not catalyze the formation of ROS and, therefore, has a mechanism of action different from that of nifurtimox. It has been proposed that benznidazole undergoes an one-electron transfer to the nitro group, which in turn dismutates to give back the nitroimidazole and a nitrosoimidazole (28). The latter product may then undergo an electrophilic addition to trypanothione, which leads to depletion of trypanothione, an essential enzyme system in the *Trypanosoma cruzi* (Fig. 39.8).

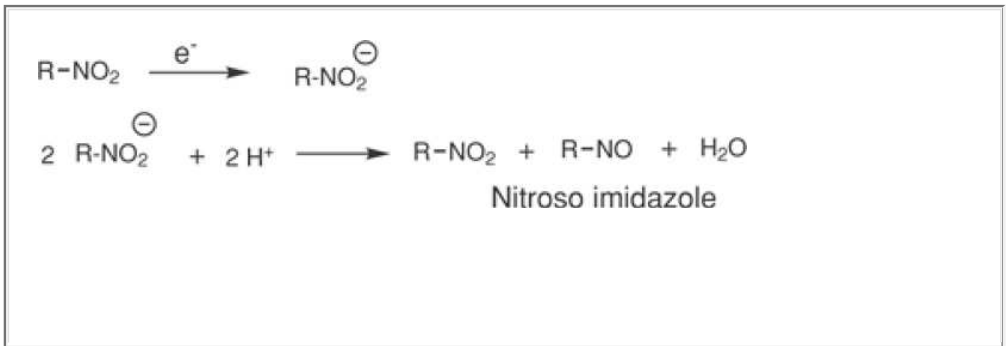


Fig. 39.8. Proposed mechanism of action of benznidazole.

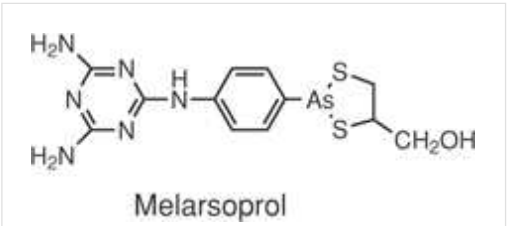
Benznidazole is not available in the United States but is available in South American countries. It is administered orally in a tablet form.

Melarsoprol (Available from the CDC)



Knowingly or unknowingly, arsenic-containing drugs have been used for treatment of parasitic conditions for thousands of years. In the late 1800s and early 1900s, Paul Ehrlich introduced the use of trivalent arsenicals. Melarsoprol, an organoarsenical, came into use in the late 1940s, and it remains the first-choice drug in the treatment of trypanosomiasis. Until 1990, it also was the only treatment for late-stage sleeping sickness.

Mechanism of action

It is known that trivalent arsenic reacts rapidly and reversibly with sulfhydryl-containing proteins, as shown in Figure 39.9. It generally is accepted that the enzyme with which melarsoprol reacts is an enzyme involved in glycolysis, and as a result, inhibition of pyruvate kinase occurs. It is argued, however, that the inhibition may not occur at pyruvate kinase but, rather, at a step before the pyruvate kinase. Blockage of glycolysis would be expected to lead to loss of motility and cell lysis. More recently, Fairlamb et al. (29) have proposed a mechanism of action that results in the inhibition of trypanothione reductase through the formation of a stable complex between melaroprol and trypanothione. Melarsoprol

reacts with the cysteine sulfhydryl of trypanothione to form the stable adduct shown in Figure 39.10. Supportive of this mechanism is the synergistic action of melarsoprol with eflornithine (DMFO). Two drugs that produce sequential blockage of the synthesis of trypanothione.

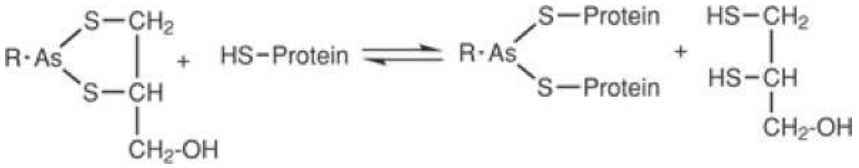


Fig. 39.9. Mechanism of action of trivalent arsenic compounds with trypanosome organism.

Pharmacokinetics

Melarsoprol is administered IV in multiple doses and multiple sessions. Its major metabolite in humans is the lipophilic melarsen oxide, which can penetrate into the CNS. This metabolite apparently is responsible for the protein-binding characteristic for melarsoprol.

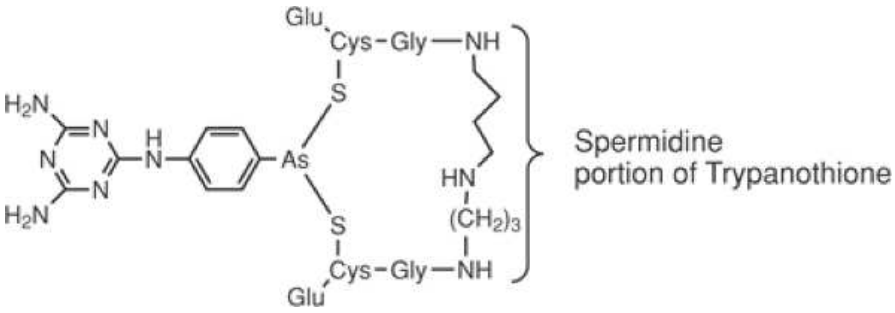

Fig. 39.10. Structure of melarsoprol trypanothione complex.

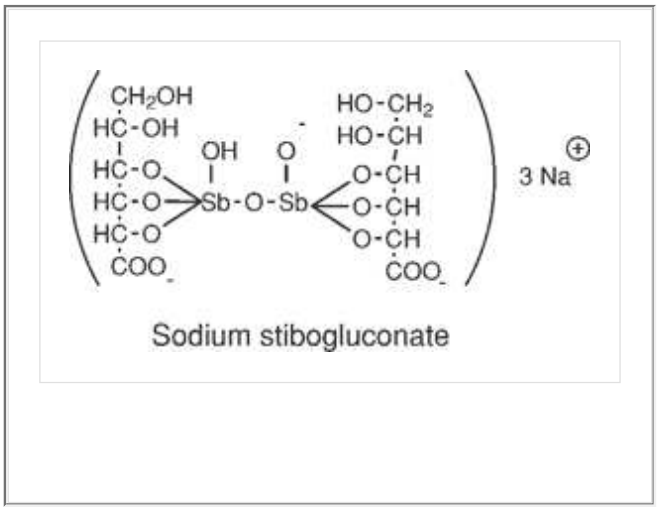
Therapeutic application

Melarsoprol is the drug of choice for the treatment of late-stage meningoencephalitic trypanosomiasis caused by the west and east African strains of the disease. Because the drug has the potential for serious nervous system toxicities (e.g., convulsions, acute cerebral edema, and coma), the drug usually is administered in a hospital setting with supervision. An additional problem with melarsoprol is the development of resistance by the parasite.

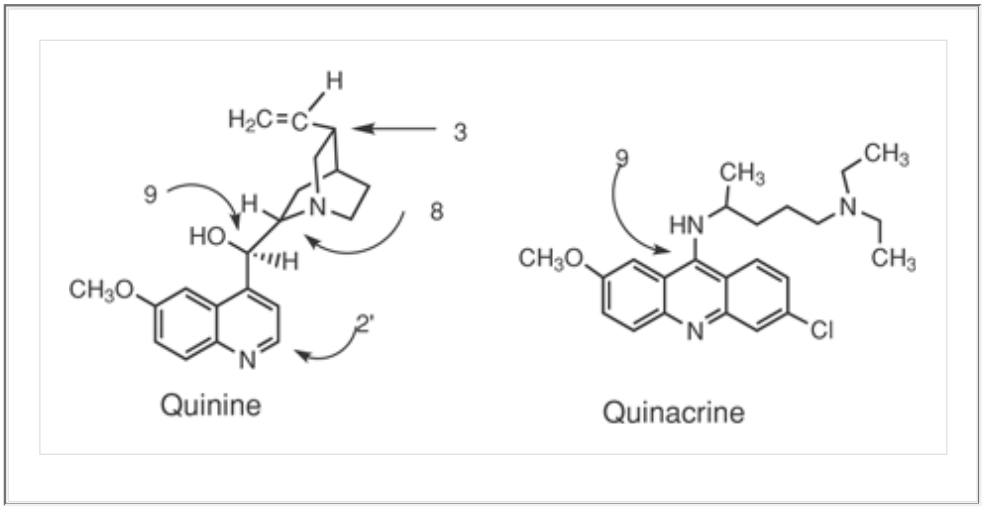
Treatment of Leishmaniasis

Sodium Stibogluconate (Pentostam, Available from the CDC)



Leishmaniasis was first described in the medical literature by Deishman and Donovan in 1903, and shortly after that, the use of antimony-based drugs were introduced as therapeutic agents to treat the condition (30). Although the structure of sodium stibogluconate is commonly drawn as shown, the actual compound probably is much more complex. The drug is a water-soluble preparation that is administered IM or IV. Pentavalent antimony compounds are thought to inhibit bioenergetic processes in the pathogen, with catabolism of glucose and inhibition of glycolytic enzymes being the primary sites of action (glucose catabolism is inhibited by 86–94%). This in turn results in inhibition of adenosine triphosphate (ATP)/guanosine triphosphate formation. Sodium sibogluconate is the drug of choice for the treatment of most forms of leishmaniasis (or meglumine antimonate, another pentavalent antimony agent). The recommended dose is 20 mg antimony/kg/day, not to exceed 850 mg antimony/day. A number of other drugs have been reported to be effective in the treatment of leishmaniasis, and these include pentamidine, amphotericin B, paromomycin, alkylphosphocholine analogues, rifampicin, and ketoconazole (31,32).

Treatment of Malaria



Quinine, was the first known antimalarial. It is a 4-quinolinemethanol derivative bearing a substituted quinuclidine ring. The use of quinine in Europe began in the seventeenth century, after the Incas of Peru informed the Spanish Jesuits about the antimalarial properties of the bark of an

evergreen mountain tree they called quinquina (later called cinchona, after Dona Franciscoa Henriquez de Ribera [1576–1639], Countess of Chinchon and wife of the Peruvian Viceroy). The bark, when made into an aqueous solution, was capable of curing most forms of malaria. It was listed in the London Pharmacopeia of 1677. The alkaloid derived from it, quinine, was isolated in the mid-1820s. Quinine, a very bitter substance, has been used by millions of malaria sufferers. Recently, it has been employed successfully to treat chloroquine-resistant strains of *Plasmodium falciparum* and is considered to be the drug of choice for these resistant strains.

A second class of chemicals that played a role in the development of synthetic antimalarials were the 9-aminoacridines. 9-Aminoacridine itself was known to exhibit antibacterial activity, whereas a derivative of 9-aminoacridine synthesized in 1934, quinacrine, was found to possess weak antimalarial activity.

With the beginning of World War II and concern about an interruption in the supply of cinchona bark from the East Indies, a massive effort was begun to search for synthetic alternatives to quinine and to develop more effective antimalarial agents than quinacrine. With a basic understanding of the structure–activity relationship of quinine (see Quinine) and the chemical similarities seen with quinacrine, it is easy to visualize the relationship between these agents and the synthetic antimalarials. The 4-aminoquinolines, chloroquine and hydroxychloroquine, are structurally similar to the right half of quinacrine (Fig. 39.11). The 8-aminoquinolines, pamaquine and

primaquine, retain the methoxyquinoline nucleus of quinine and quinacrine (Fig. 39.12). The quinoline-4-methanols, mefloquine and halofantrine, show similarity to the 4-quinolinemethanol portion of quinine (Fig. 39.12).

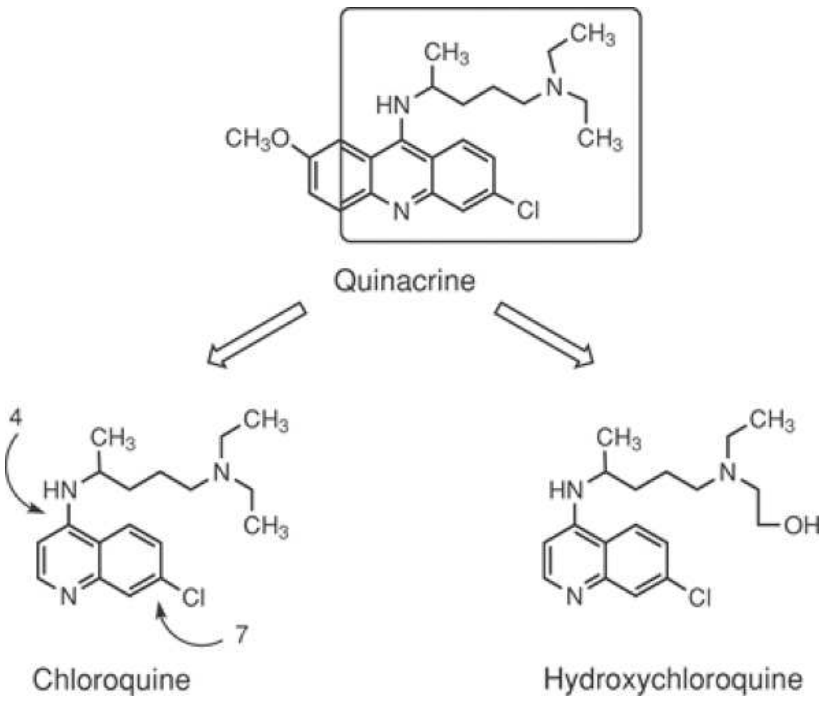


Fig. 39.11. Structural similarity between quinacrine and the 4-aminoquinolines.

4-Substituted Quinolines

Five compounds may be considered within this class of drugs: quinine, chloroquine and hydroxychloroquine, mefloquine, and halofantrine (Figs. 39.11 and 39.12). These compounds not only share a structural similarity but also are thought to have similar mechanisms of action, are effective on the same stage of the parasite, and may share similar mechanisms of resistance.

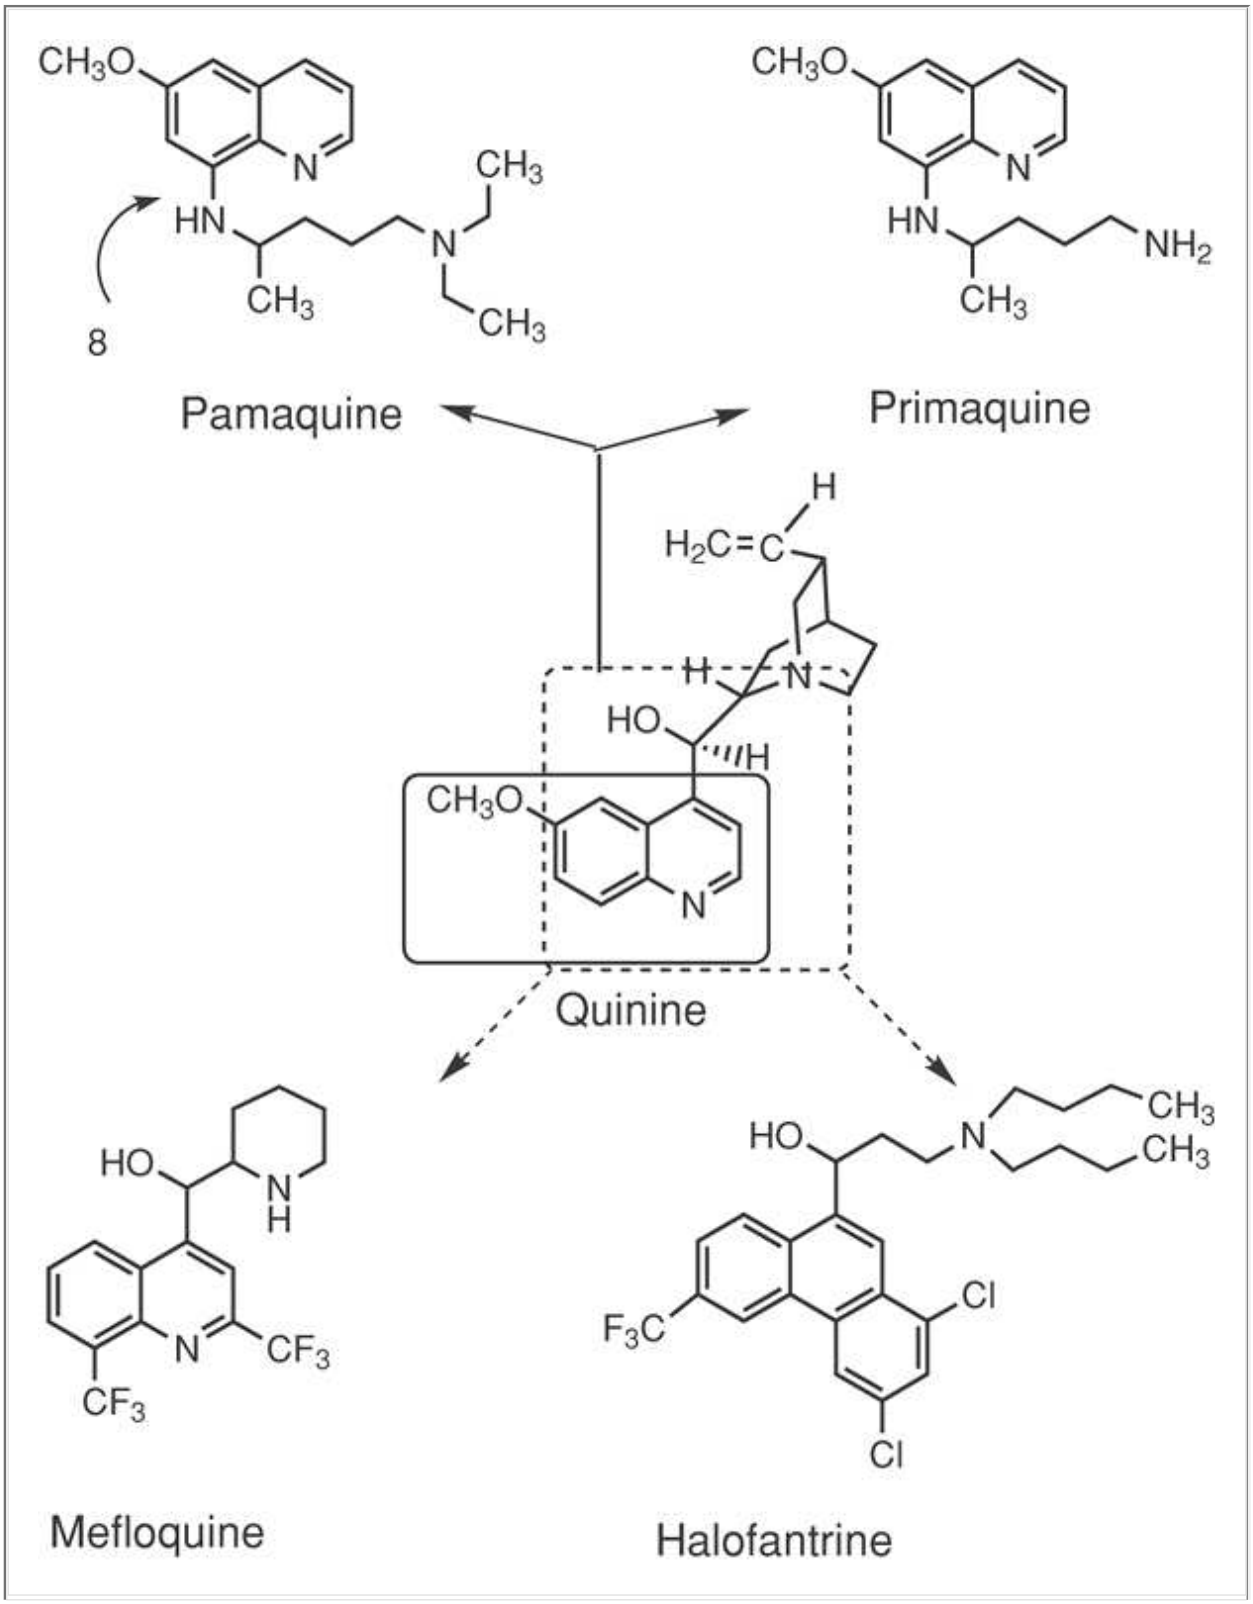

Fig. 39.12. Structural similarity between quinine and the 8-aminoquinolines () and between quinine and the quinoline-4-methanols ().

Mechanism of action

The mechanism of action of chloroquine has been studied in depth, and the results of these studies have been assumed to be applicable to the other 4-substituted quinolines (33). Various mechanisms of actions have been offered to explain the action of this class of drugs, including the DNA intercalation mechanism, the weak base hypothesis, and the ferriprotoprophyrin hypothesis. The present understanding about the mechanism of action would appear to utilize various aspects of each of these previous mechanisms. It is known that hemoglobin is transported into the food vacuoles of the plasmodium, where digestion of the hemoglobin supplies the organism with a source of amino acids. One of the products of this digestion is free heme, a substance toxic to the plasmodium cells, which in the plasmodium vacuole is polymerized to hemozoin. It has been demonstrated that the quinolines bind to hemozoin through a drug–heme complex in which the aromatic quinoline ring π-bonds to the porphyrin nucleus (34). This drug–heme complex caps the growing hemozoin polymer, thus blocking further extension of the polymer. The result of this complexation is that newly formed, free toxic heme is now present, which leads to the death of the plasmodium. The accumulation of the 4-substituted quinolines in the acidic food vacuoles (pH 4.8–5.2) is based on the fact that these drugs are weak bases, as indicated by their pK_a values. The extracellular fluid of the parasite is at pH 7.4, and as a result, the weak base will move toward the more acidic pH of the vacuoles, reaching concentrations hundreds of times those in the plasma. Additionally, the binding of the quinoline to the heme draws additional quantities into the vacuole.

Mechanism of resistance

A limiting factor for most of the antimalarial drugs is the development of resistant strains of plasmodium. It should be noted that resistance differs from region to region, and in some cases, a resistant strain may develop to a particular drug without that drug ever having been introduced to the region (possible cross-resistance). The development of resistance is thought to be a spontaneous gene mutation. Several mechanisms of resistance appear to be operating. One of these mechanisms is based on the *Plasmodium falciparium* chloroquine-resistance transporter (*pfrcrt*) mechanism, which is sufficient and necessary to impart resistance (35). A gene encodes for a transmembrane transporter protein found in the membrane of the food vacuole. Multiple mutations within a specific region this gene result in reduced accumulation of chloroquine, resulting from the increased efflux of the drug. Additional transporter proteins also may be involved in resistance.

Rapid metabolism of the antimalarials by resistant strains of plasmodium also might be considered to play a significant role in the development of resistance. It has been shown that cytochrome P450 activity parallels increased resistance to specific drugs.

Therapeutic application

The 4-substituted quinolines are referred to as rapidly acting blood schizonticides, with activity against plasmodium in the erythrocytic stage. Chloroquine is the drug of choice, but unfortunately, the incidence of chloroquine-resistance infections are extremely common today. The spread of chloroquine resistance has reached almost all malarious areas of the world. In addition, multidrug-

resistant and cross-resistant strains of plasmodium are now common. The drug of choice for the treatment of malaria caused by *Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax*, and *Plasmodium malariae* in regions infected by chloroquine-resistant *P. falciparum* is quinine, in combination with traditional antibiotics, mefloquine, or various other combinations as alternative treatment agents (Table 39.2). Of interest is the observation that after years of nonuse of chloroquine, a reemergence of chloroquine-sensitive parasites has been found.

The 4-substituted quinolines, depending on the specific drug in question, also may be used for prophylaxis of malaria. Two types of prophylaxis are possible: causal prophylaxis, and suppressive prophylaxis. The former prevents the establishment of hepatic forms of the parasite, whereas the latter eradicates the erythrocytic parasites but has no effect on the hepatic forms. Several of the 4-substituted quinolines are effective suppressive prophylactics.

Table 39.2. Guidelines for Treatment of Malaria in the United States[a]

Clinical Diagnosis	Sensitivity	Drug Recommendation
Uncomplicated malaria	Chloroquine sensitive	Chloroquine phosphate
P. falciparum	Chloroquine resistant or unknown	A. Quinine sulfate + one of the following: Doxycycline Tetracycline Clindamycin B. Atovaquone–proquanil C. Mefloquine
Uncomplicated malaria	Chloroquine sensitive	Chloroquine phosphate
P. malariae		
Uncomplicated malaria	Chloroquine sensitive	Chloroquine phosphate + Primaquine phosphate
P. vivax or *P. ovale*		
Uncomplicated malaria *P. vivax*	Chloroquine resistant	A. Quinine sulfate + doxycycline, or Tetracycline + Primaquine phosphate

		B. Mefloquine + Primaquine phosphate
Severe malaria	Chloroquine sensitive/resistant	Quinidine gluconate + one of the following: Doxycycline Tetracycline Clindamycin

[a]Information taken from CDC Guideline for Treatment of Malaria in the United States. For more details, including infectious region and dosing, see http://www.cdc.gov/malaria/pdf/treatmenttable.pdf.

Specific 4-substituted quinolines

Quinine

Quinine is the most prevalent alkaloid present in the bark extracts (~5%) of cinchona. Four stereochemical centers exist in the molecule (at C-3, C-4, C-8, and C-9) (Fig. 39-9). Quinine (absolute configuration of 3R:4S:8S:9R), quinidine (absolute configuration of 3R:4S:8R:9S), and their optical isomers all have antimalarial activity, whereas their C-9 epimers (i.e., the epi-series having either 3R:4S:8R:9R or 3R:4S:8S:9S configurations) are inactive. Modification of the secondary alcohol at C-9, through oxidation, esterification, or similar processes, diminishes activity. The quinuclidine portion is not necessary for activity; however, an alkyl tertiary amine at C-9 is important.

Quinine is metabolized in the liver to the 2′-hydroxy derivative, followed by additional hydroxylation on the quinuclidine ring, with the 2,2′-dihydroxy derivative as the major metabolite. This metabolite has low activity and is rapidly excreted. The metabolizing enzyme of quinine is CYP3A4. With the increased use of quinine and its use in combination with other drugs, the potential for drug interactions based on the many known substrates for CYP3A4 (see Chapter 10) is of concern (36).

A quinine overdose causes tinnitus and visual disturbances; these side effects disappear on discontinuation of the drug. Quinine also can cause premature contractions during the late stages of pregnancy. Although quinine is suitable for parenteral administration, this route is considered to be hazardous because of its ability to cause hemolysis. Quinidine, the (+)-isomer of quinine, has been shown to be more effective in combating the disease, but it has undesirable cardiac side effects.

Chloroquine (Aralen)

Chloroquine is the most effective of the hundreds of 4-aminoquinolines synthesized and tested during World War II as potential antimalarials. Structure–activity relationships demonstrated that the chloro at the 8-position increased activity, whereas alkylation at C-3 and C-8 diminished activity. The replacement of one of its N-ethyl groups with an hydroxyethyl produced

hydroxychloroquine, a compound with reduced toxicity that is rarely used today except in cases of rheumatoid arthritis.

Chloroquine is commonly administered as the racemic mixture, because little is gained by using the individual isomers. The drug is well absorbed from the GI tract and distributed to many tissues, where it is tightly bound and slowly eliminated. The drug is metabolized by N-dealkylation by CYP2D6 and CYP3A4 isoforms. It has been reported that the level of metabolism correlates closely with the degree of resistance. The suggestion has been made to coadminister chloroquine with CYP2D6 and CYP3A4 inhibitors to potentate activity and reduce resistance. Although this may be possible, it is not commonly practiced.

Chloroquine is an excellent suppressive agent for treating acute attacks of malaria caused by *Plasmodium vivax* and *Plasmodium ovale*. The drug also is effective for cure and as a suppressive prophylactic for the treatment of *Plasmodium malariae* and susceptible *Plasmodium falciparum*.

Chloroquine generally is a safe drug, with toxicity occurring at high doses of medication if the drug is administered too rapidly via parenteral routes. With oral administration, the side effects primarily are GI effects, mild headache, visual disturbances, and urticaria.

Mefloquine (Lariam) (37)

Mefloquine, which was synthesized with the intent of blocking the site of metabolism in quinine with the chemically stable CF_3 group, exists as four optical isomers of nearly equal activity. The drug is active against chloroquine-resistant strains of plasmodium, yet cross-resistance is not uncommon. Metabolism is cited as the possible mechanism of resistance. Mefloquine is slowly metabolized through CYP3A4 oxidation to its major inactive metabolite, carboxymefloquine (Fig. 39.13). Most of the parent drug is excreted unchanged into the urine. Its coadministration with CYP3A4 inhibitors (e.g., ketoconazole) has increased the area under the curve for mefloquine by inhibiting its metabolism to carboxymefloquine.

Mefloquine is only available in an oral dosage form, which is well absorbed. The presence of food in the GI tract affects the pharmacokinetic properties of the drug, usually enhancing absorption. The lipophilic nature of the drug accounts for the extensive tissue binding and low clearance of total drug, although the drug does not accumulate after prolonged administration. The drug has a high affinity for erythrocyte membranes.

Additional Therapeutic Indications for Chloroquine

Chloroquine also is prescribed for treatment of rheumatoid arthritis, discoid lupus erythematosus, and photosensitivity diseases.

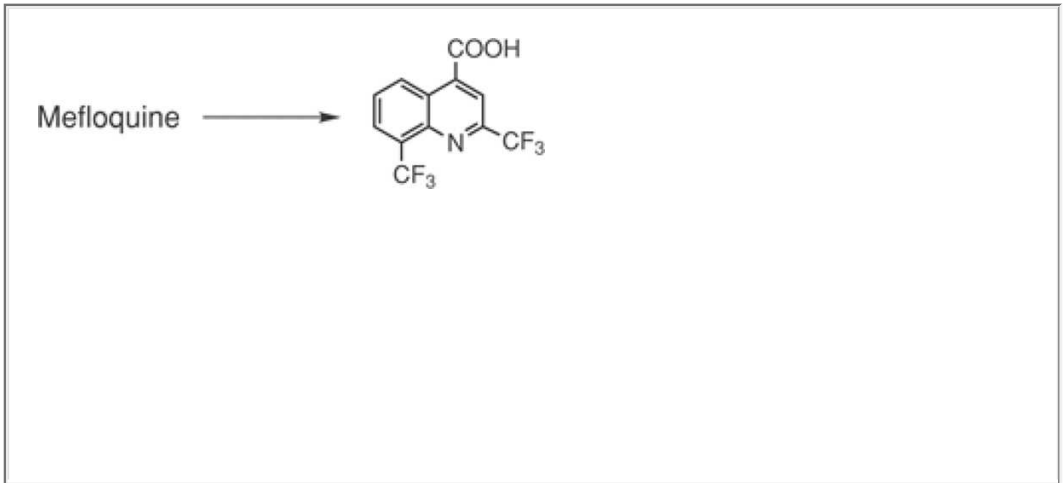

Fig. 39.13. *Plasmodium falciparum* metabolism of mefloquine.

Mefloquine is an effective suppressive prophylactic agent against *Plasmodium falciparum* both in nonimmune populations (travelers coming into regions of malaria) and in resident populations. The drug also has high efficacy against falciparum malaria, with a low incidence of recrudescence. The drug is ineffective against sexual forms of the organism.

The incidence of side effects with mefloquine is considered to be high. The effects are classified as neuropsychiatric, GI, dermatologic, and cardiovascular. The neuropsychiatric effects may be serious (e.g., suicidal tendencies or seizures) or minor (e.g., dizziness, vertigo, ataxia, and headaches). Gastrointestinal side effects included nausea, vomiting, and diarrhea, whereas the dermatologic effects include rash, pruritus, and urticaria. Finally, cardiovascular side effects may include bradycardia, arrhythmias, and extrasystoles.

Halofantrine (Hafan)

Halofantrine (38,39), a member of the 9-phenanthrenemethanol class (Fig. 39.12), originally came out of a synthesis program dating to World War II, but this particular agent was not fully developed until the 1960s. Halofantrine has one chiral center and has been separated into its enantiomers. There appears to be little difference between the enantiomers; thus, the drug is used as a racemic mixture.

Halofantrine is considered to be an alternative drug for treatment of both chloroquine-sensitive and chloroquine-resistant *Plasmodium falciparum* malaria, but its efficacy in mefloquine-resistant malaria may be questionable. The drug is metabolized via N-dealkylation to desbutylhalofantrine by CYP3A4 (Fig. 39.14). The metabolite appears to be several-fold more active than the administered drug.

At present, halofantrine is only available in a tablet form, which has significant implications as it relates to its

insolubility and drug absorption (bioavailability). Animal studies have shown that following oral administration, the drug is eliminated in feces, suggesting poor oral absorption. Its oral suspensions leads to as much as 30% lower plasma levels of the drug in comparison with the tablet. A micronized form of the drug has shown improved bioavailability. Its administration with or without food in the stomach also leads to considerable variation in plasma levels. A high lipid content in a meal taken 2 hours before dosing leads to a substantial increases in the rate and extent of absorption. Several cases of drug treatment failure appear to be related to poor absorption. Incomplete absorption and, as a result, low plasma levels, may play a role in the development of organism resistance. The elimination half-life of halofantrine and desbutylhalofantrine tend to be prolonged, which may be another factor in the development of resistance. Low levels of the drug may increase the likelihood of augmenting the emergence of halofantrine resistance.

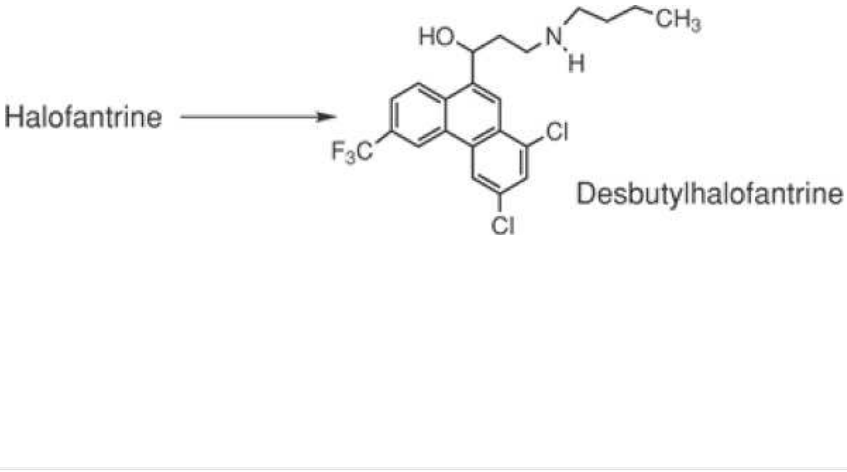

Fig. 39.14. Metabolism of halofantrine.

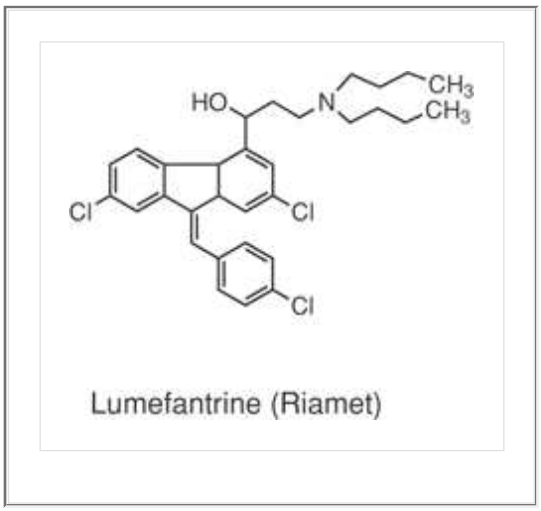
Absorption problems with halofantrine cannot be solved by increasing the dosage of halofantrine because of significant toxicity problems. Toxicity, although minimal with short-term low doses, can be severe with high doses of halofantrine. Gastrointestinal side effects include nausea, vomiting, diarrhea, and abdominal pain. Cardiovascular toxicity include orthostatic hypotension and dose-dependent lengthening of QTc intervals.

8-Aminoquinolines

Pamaquine, an 8-aminoquinoline, was first introduced for treatment of malaria in 1926 and has since been replaced with primaquine (Fig. 39.12). Primaquine is active against latent tissue forms of *Plasmodium vivax* and *Plasmodium ovale*, and it is active against the hepatic stages of *Plasmodium falciparum*. The drug is not active against erythrocytic stages of the parasite but does possess gametocidal activity against all strains of plasmodium.

Mechanism of Action

The mechanism of action of the 8-aminoquinolines is unknown, but primaquine can generate ROS via an autoxidation of the 8-amino group. The formation of a radical anion at the 8-amino group has been proposed by Augusto et al. (40). As a result, cell-destructive oxidants, such as hydrogen peroxide, superoxide, and hydroxyl radical, can be formed, as shown in Figure 39.3, leading to oxidative damage to critical cellular components.



Lumefantrine is a derivative of halofantrine that has been reported to exhibit antimalarial activity when combined with artemether in the treatment of multidrug-resistant *Plasmodium falciparium*. No evidence of cardiotoxicity has been reported with this combination, which may offer promise for successful treatment of resistant organisms.

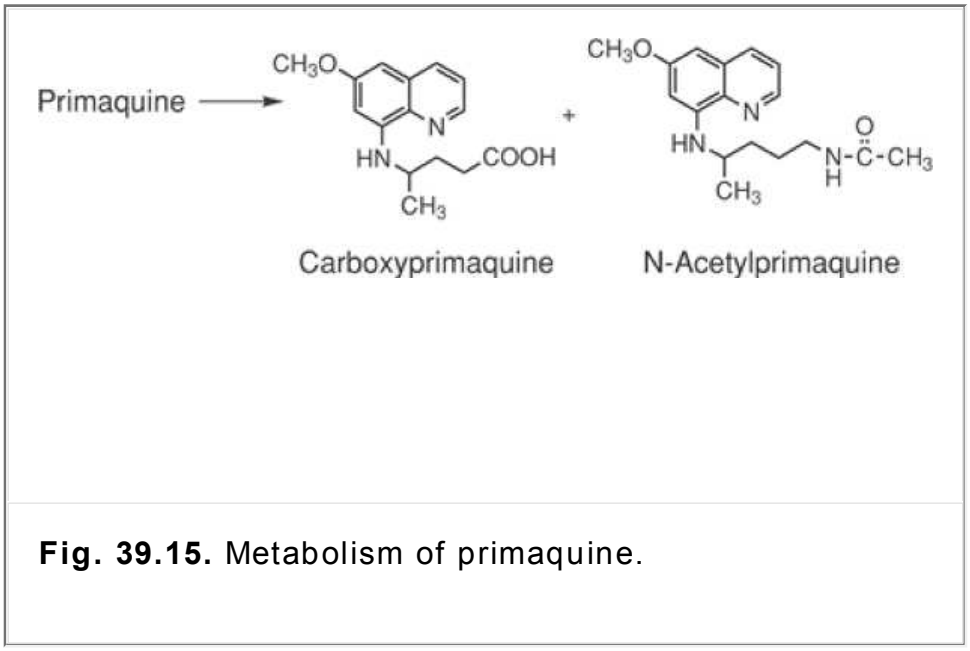


Fig. 39.15. Metabolism of primaquine.

Metabolism

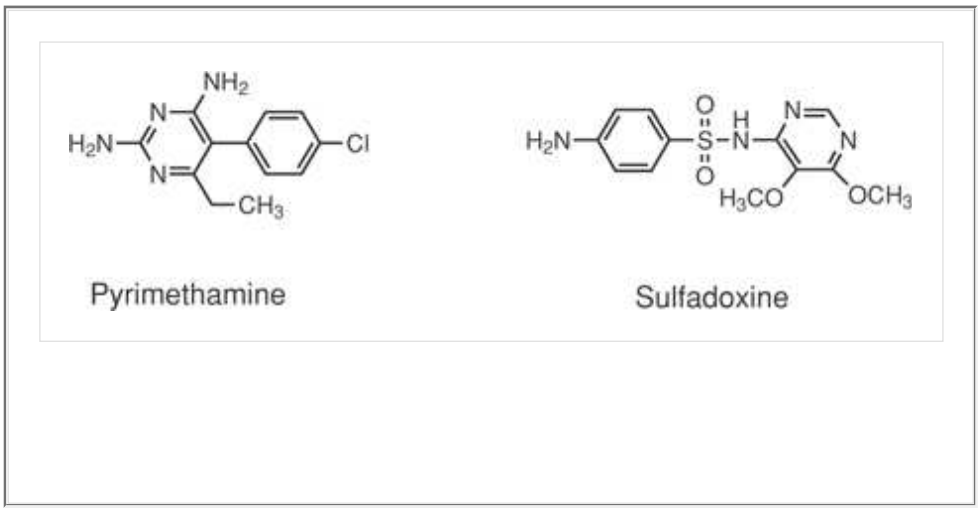
Primaquine is almost totally metabolized by CYP3A4 (99%), with the primary metabolite being carboxyprimaquine (Fig. 39.15) (41). Trace amounts of N-acetylprimaquine plus aromatic hydroxylation and conjugation metabolites also have been reported.

Therapeutic Application

Primaquine is classified as the drug of choice for the treatment of relapsing vivax and ovale forms of malaria and will produce a radical cure of the condition. It is recommended that the drug be combined with chloroquine to eradicate the erythrocytic stages of malaria. Primaquine is not given for long-term treatment because of potential toxicity and sensitization. The sensitivity appears

most commonly in individuals who have glucose-6-phosphate dehydrogenase deficiency. In these cases, hemolytic anemia may develop.

Pyrimethamine

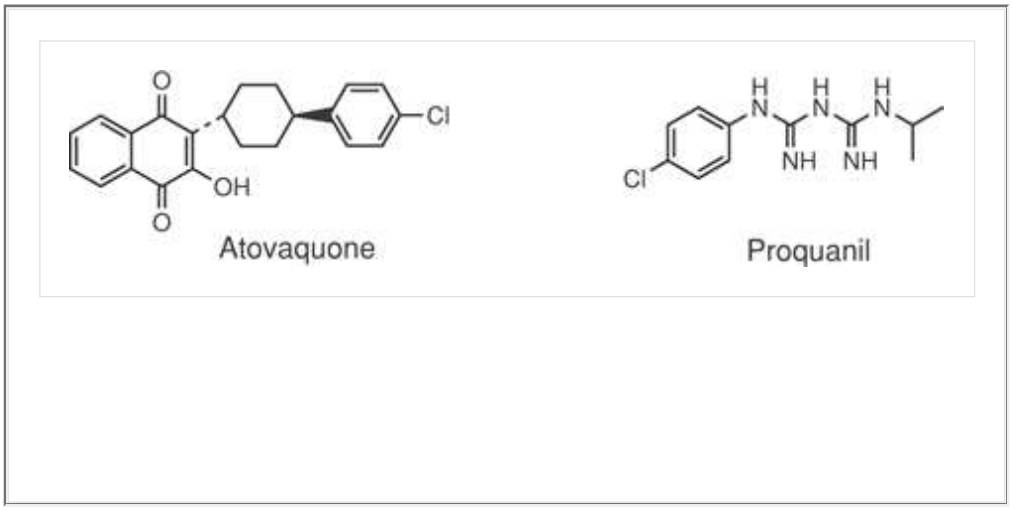


Pyrimethamine (Daraprim) is a potent inhibitor of DHFR (42). The drug has been shown to have a significantly higher affinity for binding to the DHFR of plasmodium than to the host enzyme (>1,000 times in *Plasmodium berghei*) and, as a result, has been used to selectively treat plasmodium infections. The combination of pyrimethamine with a long-acting sulfonamide, sulfadoxine, which blocks dihydrofolate synthesis by blocking incorporation of PABA into the dihydrofolate, is called Fansidar, which produces sequential blockage of tetrahydrofolate synthesis similar to that reported for treatment of bacterial infections (see Chapter 38). *Plasmodium* enzymes catalyzing folic acid synthesis differ from those enzymes found in other organisms. A single bifunctional protein present in *Plasmodium* sp. catalyzes the phosphorylation of 6-hydroxymethyl-7,8-hydropterin

(a pyrophosphokinase) and the incorporation of PABA into dihydropteroic acid. A second bifunctional enzyme catalyzes the reduction of dihydropteroic acid and thymidylic acid synthesis. As a result, the drug combination (Fansidar) appears to have improved drug-mediated disruption of folic acid in *Plasmodium* sp. (35,43). This combination has been used with quinine for the treatment and prevention of chloroquine-resistant malaria (*Plasmodium falciparum, Plasmodium ovale, Plasmodium vivax*, and *Plasmodium malaria*). The combination therapy (Fansidar) has the added advantage of being inexpensive, which is essential for successful therapy in developing countries. When used on its own, pyrimethamine is a blood schizonticide without effects on the tissue stage of the disease.

The mechanism of resistance to the folate inhibitor combination has been shown to be associated with point mutations in both DHFR and the dihydropteroate synthase enzymes (35).

Atovaquone-Proguanil



Atovaquone was originally developed as an antimalarial, but because of the high failure rate (~30%), it is not prescribed as a single chemical entity but, rather, is used to treat pneumocystis (see page 1092). More recently, however, atovaquone has been combined with proquanil as an effective prophylactic and therapeutic antimalarial (35). The two drug together (Malarone) exhibit synergy in which proguanil reduces the effective concentration of atovaquone needed to damage the mitochondrial membrane and atovaquone increases the effectiveness of proguanil but not its active metabolite (for the mechanism of action of atovaquone, see page 1091). Proguanil was developed decades earlier as a folic acid antagonist and functions as a pro-drug. The active form of proguanil is cycloguanil, which acts as a DHFR inhibitor (Fig. 39.16). Later, this discovery led to the development of pyrimethamine.

Resistance to atovaquone used as a monotherapy may have been associated with the pharmacokinetics of the drug. Atovaquone is quite lipophilic and has slow uptake, resulting in the pathogen experiencing low concentrations of the drug over an extended period of time, both of which encourage the development of resistance. A single-point mutation appears to be sufficient for resistance (44). To date, resistance to the combination has not been reported.

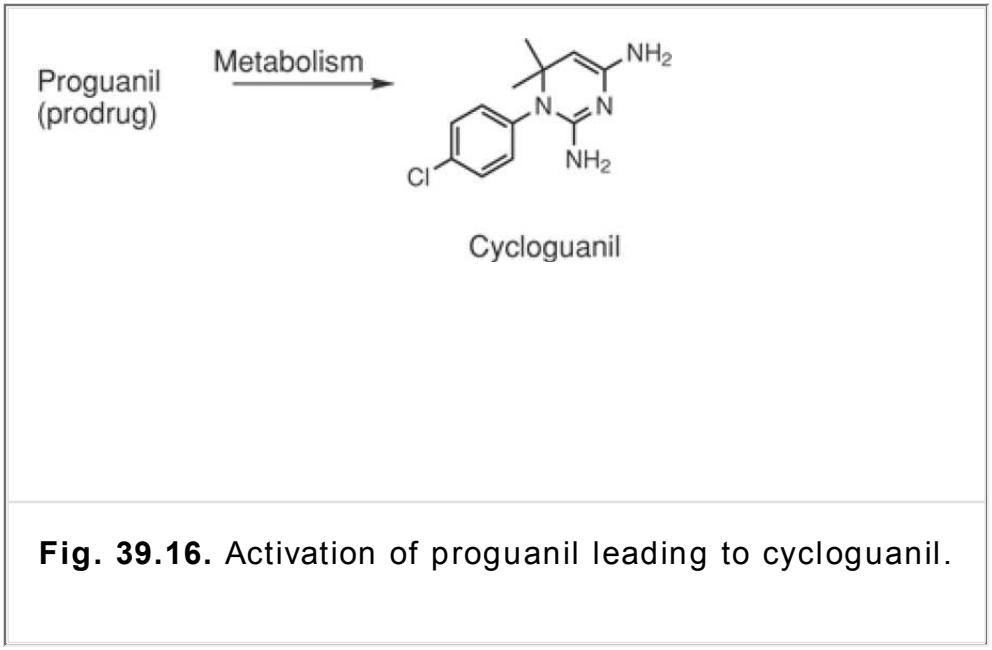


Fig. 39.16. Activation of proguanil leading to cycloguanil.

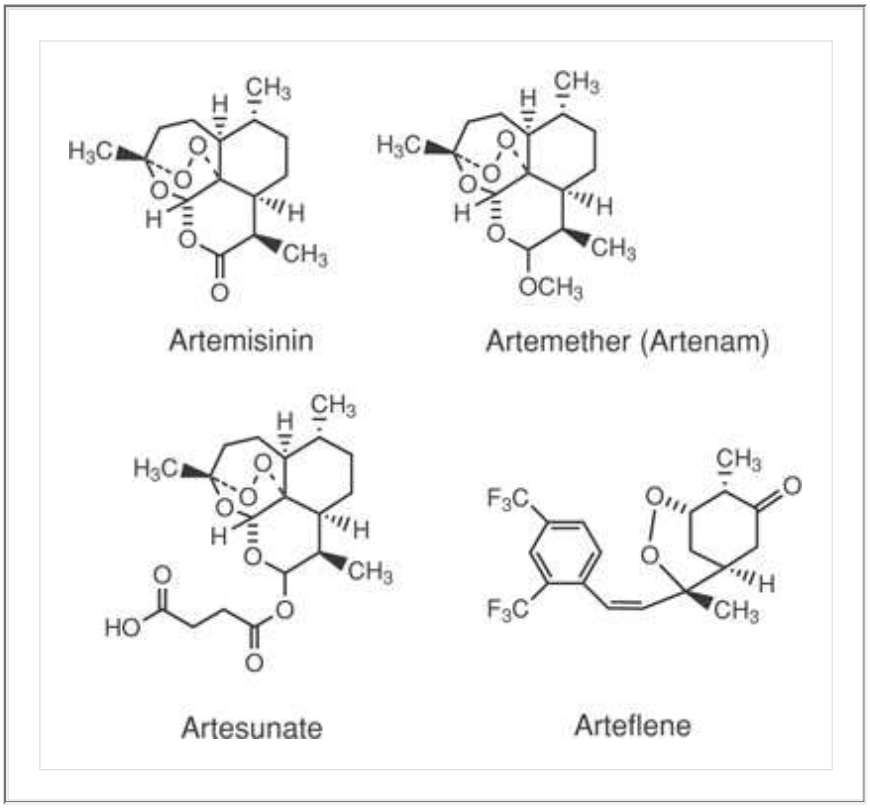
Artemisinins (45,46,47,48)



The most recent additions to the drug therapy for malaria are artemisinin and its derivatives. Isolated from *Artemisia annua* (qinghao, sweetworm wood), this material has been used by Chinese herbalists since 168 BC. Artemisinin and the synthetic and semisynthetic derivatives, artemether, arteflene, and artesunate, are active by virtue of the endoperoxide.

Mechanism of Action

The artemisinins appear to kill the parasite by a free radical mechanism—not by the generation of ROS but, rather, by virtue of a free radical associated with the endoperoxide, possibly involving a carbon radical. Evidence points toward activation of the endoperoxide via an iron-dependent mechanism. The resulting free radical selectively targets sarcoplasmic/endoplasmic reticulum Ca^{2+}-ATPase of the *Plasmodium falciparum* (PfATP6), altering calcium stores (49). The artemisinins actually may form covalent adducts to specific membrane-associated proteins after concentrating in infected erythrocytes.

Therapeutic application

The artemisinins are hydrophobic in nature with the exception of artesunate, which is available as a water-soluble hemisuccinate salt, and are partitioned into the membrane of the plasmodium. These compounds have gametocytocidal activity as well as activity against all asexual stages of the parasites. These agents are short acting, with relatively short half-lives. Little or no cross-resistance has been reported, with the drugs rapidly clearing the blood of parasites. The drugs have limited availability in the United States, but they are being utilized elsewhere as commercial or experimental agents, often in combination therapy. Combination therapy has the goal of reducing resistance with the hope for synergism and, when combined with longer-acting drugs,

an improved therapy. Among the combinations reportedly used are artesunate–fosmidomycin, artemether–lumefantrine (Coartem), amodiaquine–artesunate, chloroquine–artemisinin, and artesunate–sulfadoxine–pyrimethamine (50). These combinations are referred to as artemisinin-based combination therapy (ACT). These ACTs have been reported to show cure rates

of greater than 90%. The fixed-dose combination Coartem has been used in more than 10 million treatments, with significant increases being forecast.

Helminth Infections

Helminthiasis, or worm infestation, is one of the most prevalent diseases—and one of the most serious public health problems—in the world. Many worms are parasitic in humans and cause serious complications. Hundreds of millions (if not billions) of human infections by helminths exist worldwide, and with increased world travel and immigration from developing countries, one might expect to see this pattern of infection continue. It is estimated that one-fourth of the world population may be infected. It is interesting to note that helminths differ from many other parasites in that these organisms multiply outside of the definitive host and have the unique ability to evade host immune defenses for reasons that are not fully understood. As a result, helminth infections tend to be chronic, possibly lasting for the entire lifetime of the host (for a discussion of the uniqueness of helminth infections, see Maizels et al. in *Suggested Readings*). Helminths that infect human hosts are divided into two categories, or phyla: Platyhelminths (flatworms), and Aschelminths or nematodes (roundworms). The flatworms include the classes Cestode (tapeworms) and Trematode (flukes or schistosomes). The nematode class includes helminths common to the United States: roundworm, hookworm, pinworm, and whipworm. These worms are cylindrical in shape, with significant variations in size, proportion, and structure.

Nematode Infections

Ancylostomiasis or Hookworm Infection

The two most widespread types of hookworm in humans are the American hookworm (*Necator americanus*) and the "Old World" hookworm (*Ancylostoma doudenale*). The life cycles of both are similar. The larvae are found in the soil and are transmitted either by penetrating the skin or being ingested orally. The circulatory system transports the larvae via the respiratory tree to the digestive tract, where they mature and live for 9 to 15 years if left untreated. These worms feed on intestinal tissue and blood. Infestations cause pulmonary lesions, skin reactions, intestinal ulceration, and anemia. The worms are most prevalent in regions of the world with temperatures of 23 to 33°C, abundant rainfall, and well-drained, sandy soil.

Enterobiasis or Pinworm Infection (*Enterobius Vermicularis*)

These worms are widespread in temperate zones and are a common infestation of households and institutions. The pinworm lives in the lumen of the GI tract, attaching itself by the mouth to the mucosa of the cecum. Mature worms reach 10 mm in size. The female migrates to the rectum, usually at night, to deposit her eggs. This event is noted by the symptom of perianal pruritus. The eggs infect fingers and contaminate nightclothes and bed linen, where they remain infective for up to three weeks. Eggs resist drying and can be inhaled with household dust to continue the life cycle. Detection of the worm in the perianal region can be accomplished by means of a cellophane tape swabbed in the perianal region in the evening. The worms may be visible with the naked eye. The eggs can be collected in a similar manner but can only be seen under a microscope.

Ascariasis or Roundworm Infections (*Ascaris lumbricoides*)

These roundworms are common in developing countries, with the adult roundworm reaching 25 to 30 cm in length and lodging in the small intestine. Some infections are without symptoms, but abdominal discomfort and pain are common with heavy infestation. Roundworm eggs are released into the soil, where they incubate and remain viable for up to 6 years. When the egg is ingested, the larvae are released in the small intestine, penetrate the intestinal walls, and are carried via the blood to the lungs. The pulmonary phase of the disease lasts approximately 10 days, with the

larvae passing through the bronchioles, bronchi, and trachea before being swallowed and returning to the small intestine. Some patients have reported adult worms exiting the esophagus through the oral cavity, and it is not unusual for live ascaris to be expelled with a bowel movement. Poor or lacking sanitary facilities expose the population to infestation through contaminated foods and beverages.

Trichuriasis or Whipworm Infections (*Trichuris trichiura*)

Infections by this parasite are caused by swallowing eggs from contaminated foods and beverages. The eggs are passed with the feces from an infected individual. These eggs may live in the soil for many years. The ingested eggs hatch in the small intestine, and the larvae embed in the intestinal wall. The worms then migrate to the large intestine, where they mature. Adult worms, which reach approximately 5 cm in length, thread their bodies into the epithelium of the colon. They feed on tissue fluids and blood. Infections from this worm cause symptoms of irritation and inflammation of the colonic mucosa, abdominal pain, diarrhea, and distention. Infections can last 5 or more years if not treated. Whipworm infections are commonly seen in individuals returning from visits to the subtropics and are more common in rural areas of the southeastern United States.

Trichinosis or Trichina Infection (*Trichinella spiralis*)

Trichinella spiralis produces an infection that may be both intestinal and systemic. The worm is found in muscle

meat, where the organism exists as an encysted larvae. Traditionally, the worm has been associated with domestic pork that feeds on untreated garbage. More recently, outbreaks have occurred in individuals eating infected game, such as wild boar, bear, or walrus. Trichinosis infections are more likely to occur after consumption of homemade pork or wild-game sausages. After ingestion, the larvae are released from the cyst form and then migrate into the intestinal mucosa. After maturation and reproduction, the newly released larvae penetrate the mucosal lining and are distributed throughout the body, where they enter skeletal muscle. During the adult intestinal stage, diarrhea, abdominal pain, and nausea are the most common symptom, whereas the muscular form of the disease has symptoms that may include muscle pain and tenderness, edema, conjunctivitis, and weakness.

Filariasis

The term “filariasis” denotes infections with any of the Filarioidea, although it is commonly used to refer to lymphatic-dwelling filariae, such as *Wuchereria bancrofti, Brugia malayi*, and *Brugia timori.* Other filarial infections include *Loa loa* and *Onchocerca volvulus.* The latter two are known as the eyeworm and the river blindness worm, respectively. Elephantiasis is the most common disease associated with filariasis. These parasites vary in length from 6 cm for brugia to 50 cm for onchocerca. The incubation periods also vary from 2 months for brugia to 12 months for bancroftian filaria. It is estimated that 400 million persons are infected with human filarial parasites. Depending on the specific organism, various intermediate hosts are involved in spreading the infection. Mosquitoes are involved with the spread of *Wuchereria bancrofti, Brugia malayi*, and *Brugia timori*, whereas the female blackfly spreads river blindness. The larvae released by the female filaria are referred to as microfilariae and commonly may be found in the lymphatics.

Cestode and Trematode Infections

Cysticercosis or Tapeworm Infection

Helminths of this class that are of concern as potential parasites in humans include:

- **Beef tapeworm** (***Taenia saginata***). This worm is found worldwide and infects people who eat undercooked beef. The worm reaches a length of more than 5 m, and it contains approximately 100 segments/m. Each of these segments contains its own reproductive organs.
- **Pork tapeworm** (***Taenia solium***). Pork tapeworms sometimes are called bladder worms and occasionally are found in uncooked pork. The worm attaches itself to the intestinal wall of the human host. The adult worm reaches 5 m in length and, if untreated, survives in the host for many years.
- **Dwarf tapeworm** (***Hymenolepis nana***). This infection is transmitted directly from one human to another without an intermediate host. *Hymenolepis nana* reaches only 3 to 4 cm in length. It is found in temperate zones, and children are most frequently infected.
- **Fish tapeworm** (***Diphyllobothrium latum***). The fish tapeworm reaches a length of 10 m and contains approximately 400 segments/m. These tapeworms attach themselves to the intestinal wall and rob the host of nutrients. They especially absorb vitamin B_{12} and folic acid. Depletion of these critical nutrients, especially vitamin B_{12}, can lead to pernicious anemia. Tapeworm eggs are passed in the patient's feces, and contamination of food and drink may result in transmission of the infection.

Schistosomiasis or Blood Flukes

Three primary trematode species cause schistosomiasis in humans: *Schistosoma hematobium, Schistosoma mansoni*, and *Schistosoma japonicum.* Infections result from the penetration of normal skin by living (free-swimming) cercaria (the name given to the infectious stage of the parasite) with the aid of secreted enzymes. The cercaria develop to preadult forms in the lungs and skin. Then, these parasites travel in pairs via the bloodstream and invade various tissues. The adult worm reaches approximately 2 cm in length. The female deposits her eggs near the capillary beds, where granulomas form. Some of the eggs will move into the lumen of the intestines, bladder, or ureters and are released into the environmental surrounding, where the parasite will seek out the intermediate snail vector. Asexual reproduction occurs in the snail. After a period of time, the cercaria are again released from the snail to continue the cycle. The patients might experience headache, fatigue, fever, and GI disturbances during the early stages of the disease. Hepatic fibrosis and ascites occur during later stages. Untreated patients can harbor as many as 100 pairs of worms. Untreated worms can live 5 to 10 years within the host. It is estimated that as many as 200 million persons worldwide are infected with schistosomes. Depending on the species of schistosome, the disease is found in parts of South America, the Caribbean Islands, Africa, and the Middle East.

Drug Therapy for Helminth Infections (51)

Helminths represent a biologically diverse group of parasitic organisms differing in size, life cycle, site of infection (local and systemic), and susceptibility to chemotherapy. With such variation in infectious organisms, it is not surprising that the drugs used to control helminth infections also represent a varied group of chemical classes. As indicated in Table 39.3, the drugs may have fairly narrow spectra of activity (pyrantel pamoate) or a broad spectra of activity (benzimidazoles).

Benzimidazoles

The benzimidazoles (Table 39.4) are a broad-spectrum group of drugs discovered in the 1960s with activity against GI helminths. Several thousand benzimidazoles have been synthesized and screened for anthelmintic

activity, with albendazole, mebendazole, and thiabendazole representing the benzimidazole marketed today. The development and chemistry of this class of agents has been reviewed by Townsend and Wise (52).

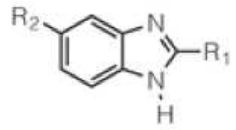
Table 39.3. Therapeutic Application of Anthelmintics for Specific Helminth Infections

Mechanism of action

Two mechanisms have been proposed to account for the action of the benzimidazoles. Fumarate reductase is an important enzyme in helminths that appears to be involved in oxidation of NADH to NAD. The benzimidazoles are capable of inhibiting fumarate reductase (53). Inhibition of fumarate reductase ultimately uncouples oxidative phosphorylation, which is important in ATP production.



Drugs	Trade name	R_1	R_2
Thiabendazole	Mintezol		—H
Mebendazole	Vermox		Albendazole	Zental		—$SCH_2CH_2CH_3$
Oxibendazole			—$OCH_2CH_2CH_3$
Parbendazole			—$CH_2CH_2CH_2CH_3$
Ciclobendazole			
Table 39.4. Benzimidazole Anthelmintics

A second mechanism and, probably, the primary action of the benzimidazoles is associated with the ability of these drugs to bind to the protein tubulin and, thus, prevent tubulin polymerization to microtubules (54,55). Tubulin is a dimeric protein that is in dynamic equilibrium with the polymeric microtubules. Binding to the tubulin prevents the self-association of subunits and creates a "capping" of the microtubule at the associating end of the microtubule. The microtubulin continues to dissociate from the opposite end, with a net loss of microtubule length. What is interesting is the unique selectivity of the benzimidazoles. It has been shown that benzimidazole also can bind to mammalian tubulin, but when used as anthelmintics, these drugs are destructive to the helminth, with minimal toxicity to the host. It has been suggested that the selectivity is associated with differing pharmacokinetics between binding to the two different tubulin proteins.

Metabolism

The benzimidazoles have limited water solubility and, as a result, are poorly absorbed from the GI tract (a fatty meal will increase absorption). Poor absorption may be beneficial, because the drugs are used primarily to treat intestinal helminths. To the extent that the drugs are absorbed, they undergo rapid metabolism in the liver and are excreted in the bile (Fig. 39.17) (56,57). In most cases, the parent compound is rapidly and nearly completely metabolized with oxidative and hydrolytic processes predominating. The Phase I oxidative reaction commonly is a cytochrome P450–catalyzed reaction, which may then be followed by a Phase II conjugation.

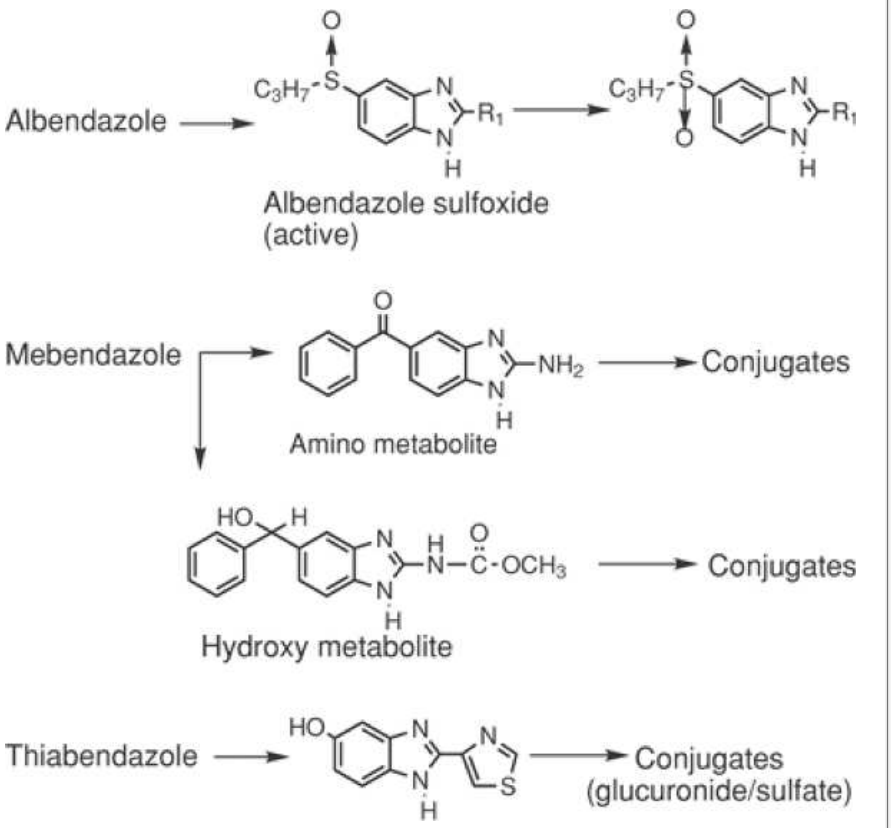

Fig. 39.17. Metabolism of benzimidazoles.

Albendazole is unique in two ways. First, the presence of a thioether substituent at the five position increases the likelihood of sulfur oxidation. Second, the initial metabolite, albendazole sulfoxide, is a potent anthelmintic. This initial oxidation is catalyzed principally (70%) by CYP3A4 and CYP1A2 and(30%) by flavin-containing monooxygenase, giving rise to a compound that is bound to plasma protein. This intermediate has an expanded utility in that it has been shown to be active against the hydatid cyst found in echinococciasis, a tapeworm disease (58). Further oxidation by cytochrome P450 leads to the inactive sulfone. Additional metabolites of the sulfone have been reported that include carbamate hydrolysis to the amine and oxidation of the 5-propyl side chain. These reactions occur only to a minor extent.

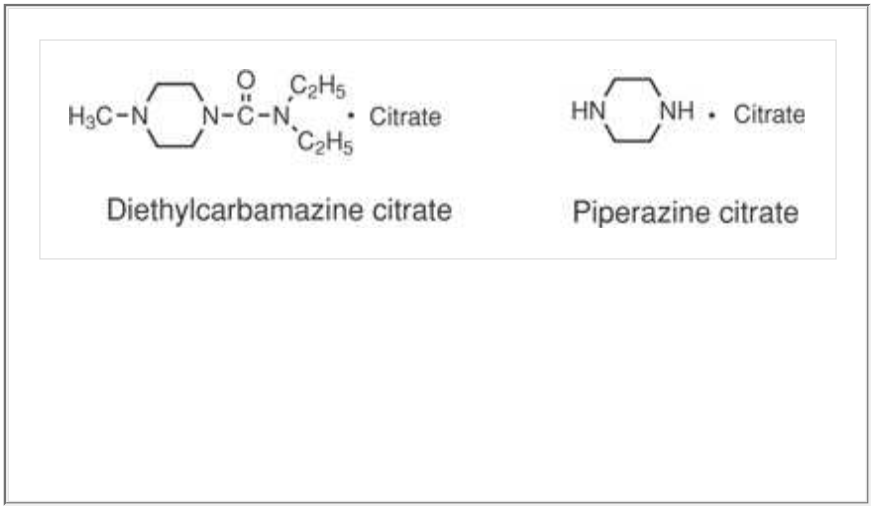
Metabolism of mebendazole occurs primarily by reduction of the 5-carbonyl to a secondary alcohol, which greatly increases the water solubility of this compound. An additional Phase I metabolite resulting from carbamate hydrolysis has been reported as well. Both the secondary alcohol and the amine are readily conjugated (a Phase II metabolism). Evidence would suggest that the anthelmintic activity of mebendazole resides in the parent drug and none of the metabolites.

Thiabendazole is metabolized through aromatic hydroxylation at the five position catalyzed by CYP1A2. The resulting phenol is conjugated to 5-hydroxythiabendazole glucuronide and 5-hydroxythiabendazole sulfate, respectively. The initial metabolite, along with minor amount of N_1-methylthiabendazole (from a methylation Phase II reaction), have been reported to be teratogenic in mice and rats.

Therapeutic application

As indicated in Table 39.3, mebendazole and albendazole have a wide spectrum of activity against intestinal nematodes. The drugs are useful and effective against mixed infections. The adverse reactions commonly are GI in nature (nausea, vomiting, and diarrhea). Both drugs have been reported to be teratogenic in rats and, therefore, should not be used during the first trimester of pregnancy. A third drug of this class is thiabendazole, which remains of some value in treatment of strongyloidiasis, as an alternate drug, and cutaneous larva migrans (creeping eruption), for which it is the drug of choice. Thiabendazole commonly is used in veterinary medicine. The drug is less commonly used because of associated toxicity. Thiabendazole has been reported to cause Stevens-Johnson syndrome and has the potential for hepatotoxicity and crystalluria.

Diethylcarbamazine (Hetrazan)



Discovered in the 1940s, diethylcarbamazine (DEC) has proven to be especially effective as a filaricidal agent. The incidence of filariasis among American troops during World War II necessitated a search for drugs with an antifalarial spectrum of activity. The once-popular piperazine also was discovered during these initial screenings. Although chemically similar, the activity again helminths is quite different. Piperazine is active against nematodes, whereas DEC is active against falaria and microfalaria (59).

Mechanism of action

Although studied extensively, the mechanism of action of DEC remains unknown. Diethylcarbamazine appears to be the active form of the drug, with a very rapid onset of action (within minutes), but of interest is the fact that the drug is inactive in vitro, suggesting that activation of a cellular component is essential to the filaricidal action. Three mechanisms have been suggested. The first is involvement of blood platelets triggered by the action of filarial excretory antigens. A complex reaction is thought to occur between the drug, the antigen, and platelets (60). Although these authors were unable to show a direct action of the drug on the microfalaria, a more recent study showed that DEC produced morphological damage to the microfalaria. The damage consisted of the loss of the cellular sheath, exposing antigenic determinants to immune defense mechanisms. Severe damage then occurred to microfalaria organelles, leading to death (61). The second is inhibition of microtubule polymerization and disruption of preformed microtubules (62). The third is interference with arachidonic acid metabolism (63). Diethylcarbamazine is known to have anti-inflammatory action, which appears to involve blockage at cyclooxygenase and leukotriene A_4 synthase (leukotriene synthesis). This action appears to alter vascular and cellular adhesiveness and cell activation. This latter action would suggest a possible relationship between the first and third mechanism.

Metabolism

The metabolism of DEC leads to the compounds shown in Figure 39.18 plus trace amounts of methylpiperazine and piperazine. Nearly all of the metabolites appear in the urine. As much as 10 to 20% of the drug is excreted unchanged. As indicated by the rapid action of the drug, it would appear that none of the metabolites are involved in the therapeutic action of DEC.

Therapeutic application

Diethylcarbamazine citrate is freely soluble in water, is rapidly absorbed, and is effective against microfalariae. The drug does not appear to be effective against the adult worm. In general, the drug has mild adverse effects, but under some conditions, it

may produce serve adverse reactions, including anaphylactic reactions, intense pruritus, and ocular complications (64). The severe anaphylactic reaction is known as the Mazzotti reaction, and it appears to be an immune response related to the presence of dead microfilariae. This reaction is more common in individuals who have a high-load microfilarial infection, and it may preclude the use of DEC in some patient populations (51).

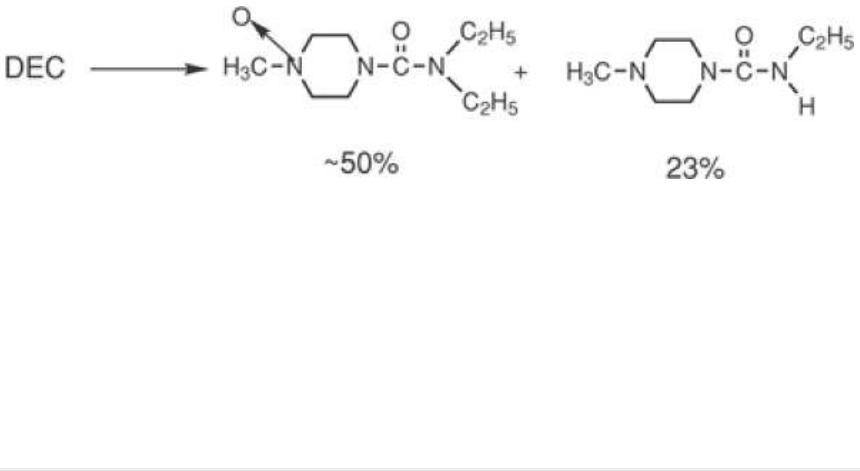


Fig. 39.18. Metabolism of diethylcarbamazine (DEC).

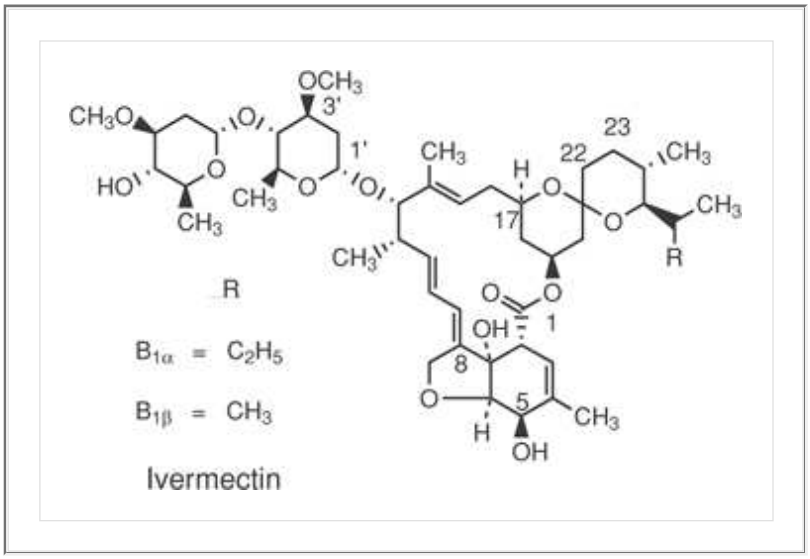
Ivermectin (Mectizan)



Extracted from the soil actinomycete *Streptomyces avermitilis*, the natural avermectins are 16-membered macrocyclic lactones that, on reduction of the $C_{22\text{-}23}$ double bond, give rise to ivermectin (IVM), which is an 80:20 mixture of dihydroavermectin $B_{1\alpha}$ and $B_{1\beta}$, respectively. The natural avermectins have minimal biological activity, but IVM has proven to be quite beneficial in the treatment of various nematode infections.

Mechanism of action

Two mechanisms of action are thought to be involved in the action of IVM (51,65). The first is an indirect action in which motility of microfalaria is reduced, which in turn allows cytotoxic cells of the host to adhere to the parasite, resulting in elimination from the host. This action may occur by virtue of the ability of IVM to act either as a γ-aminobutyric acid (GABA) agonist or as an inducer of chloride ion influx, leading to hyperpolarization and muscle paralysis. The chloride ion influx appears to be the more plausible mechanism (66). Recently, it has been shown that IVM binds irreversibly to the glutamate-gated chloride channel of the nematode *Haemonchus contortus*, whereas the channel is in an open conformation. The binding then remains locked in the open conformation, allowing ions to cross the membrane, leading to the paralytic action of IVM (67). The result of this action is a rapid decrease in microfilarial concentrations.

A second action of IVM leads to the degeneration of microfilariae in utero. This action would result in fewer microfilariae being released from the female worms, and it occurs over a longer period of time. The presence of degenerated microfilariae in utero prevents further fertilization and production of microfilariae.

Metabolism

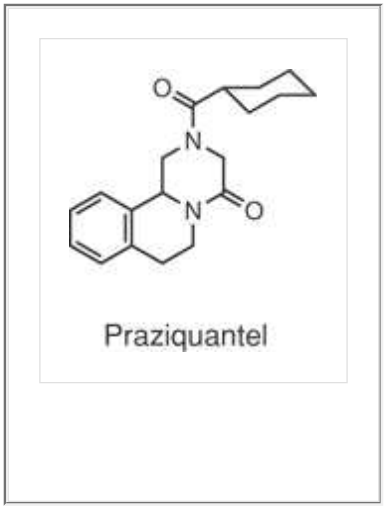
Ivermectin is rapidly absorbed, is bound to a great extent to plasma protein, and is excreted in the urine or feces either unchanged or as the 3′-O-demethyl-22,23-dihydroavermectin $B_{1\alpha}$ or as the dihydroavermectin $B_{1\alpha}$ monosaccharide. The absorption of IVM is significantly affected by the presence of alcohol. Administration of IVM as an alcoholic solution may result in as much as a 100% increase in absorption.

Therapeutic application

Although IVM has activity against a variety of microfalaria, including *Wuchereria bancrofti, Brugia malayi, Loa loa*, and *Mansonella ozzardi*, as well as activity against *Strongyloides stercoralis*, the drug is used primarily in the treatment of onchocerciasis (African river blindness) caused by *Onchocerca volvulus.* It is estimated that 20 million people are affected by this condition and an

additional 123 million are at risk of the infection. The drug is effective against both the eyeworm as well as skin infections of *O. volvulus*. Ivermectin has the distinct advantage over DEC in that IVM can be used as a single dose (150 µg/kg) once a year (although there is support for dosing every 6 months), has far less likelihood of causing the potentially fatal anaphylactic reaction (Mazzotti reaction), and can be used for mass treatment programs.

Praziquantel (Biltricide)



Praziquantel (PZQ) is an isoquinoline derivative with most of the biological activity found in the levo enantiomer. The compound has no activity against nematodes, but it is highly effective against cestodes and trematodes.

Mechanism of action

More than one mechanism of action may exist for PZQ, possibly depending on the type of parasite being treated. The mechanism of action appears to involve Ca^{2+} redistribution either directly or indirectly. In the case of helminths found in the lumen of the host (cestode infection), the drug leads to muscle contraction and paralysis, leading in turn to worm expulsion. Additionally, PZQ has been shown to inhibit phosphoinositide metabolism, which by an undetermined mechanism leads to the worm paralysis (68). With intravascular-dwelling schistosomes, PZQ leads to drug-induced damage of the tegument of the worm. As a result, antigens in the helminth are subject to attack by immune antibodies of the host (69,70). An antigen–antibody immunological reaction leads to the death of the parasite. Finally, PZQ affects glycogen content and energy metabolism (71,72).

Metabolism

Praziquantel is rapidly absorbed and undergoes hepatic first-pass metabolism. The metabolites are

either less active or inactive and consist of hydroxylated compounds. In the serum, the major metabolite appears to be the monohydroxylated 4-hydroxycyclohexylcarboxylate, whereas in the urine, 50 to 60% of the initial PZQ exists as dihydroxylated products (Fig. 39.19) (73). These hydroxylation reactions are catalyzed by CYP2B6 and CYP3A4. The metabolites would be expected to exist in the conjugated form in the urine.

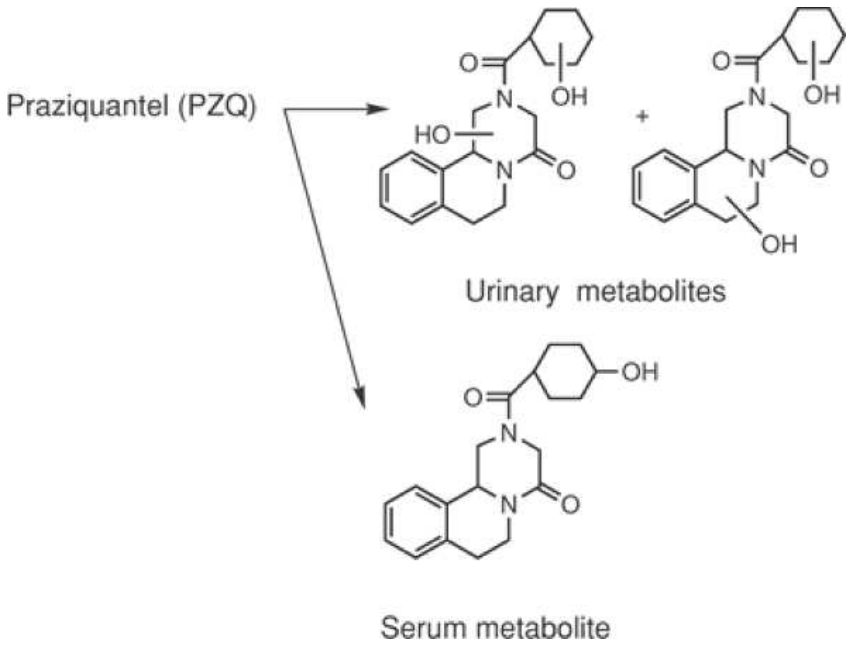


Fig. 39.19. Metabolism of praziquantel (PZQ).

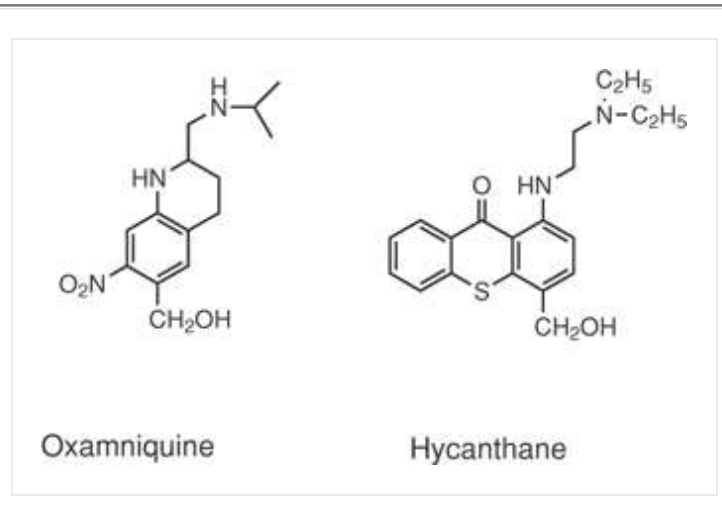
Therapeutic application

PZQ is the drug of choice for treatment of schistosomiasis and liver flukes (trematode and cestode infections). The drug is stage specific, with activity against the invasive stages, which includes the cercariae and young schistosomula and the mature worms, but not against the liver stages. Although an approved drug, PZQ is considered to be an investigational drug by the U.S. FDA in the treatment of schistosomiasis and liver flukes. The drug has a bitter taste and, therefore, should not be chewed. The side effects usually are not severe and consist of abdominal discomfort (pain and diarrhea). Mounting evidence suggests that resistance may become a significant problem.

Oxamniquine (Mansil, Vansil)



Oxamniquine was originally investigated in the 1960s and was found to have limited antiprotozoal activity, with activity against *Schistosoma mansoni* but no activity against the other two schistosomal organisms. In addition, the drug is stage specific, with activity against cercariae and very young schistosomula and adult worms. For reasons that remain unknown, the drug is more effective against adult male worms than against female worms. The drug has structural similarity to hycanthone, which is no longer used because of severe toxicity and teratogenic effects.

Mechanism of action

Oxamniquine is activated via esterification to a biological ester that spontaneously dissociates to an electrophile, which alkylates the helminth DNA, leading to irreversible inhibition of nucleic acid metabolism (Fig. 39.20) (72). Resistant helminths do not esterify oxamniquine; therefore, activation does not occur. Other metabolic reactions consist of oxidative reactions, leading to inactivation (Fig. 39.20). The metabolites are excreted primarily in the urine.

Therapeutic application

Oxamniquine is readily absorbed following oral administration and has a relatively short half-life. The drug has been highly effective against *Schistosoma mansoni* native to Brazil, where it is marketed under the trade name Mansil. It also is beneficial against West African *S. mansoni* and is supplied under the trade name Vansil. Side effects are minimal, with transient dizziness being reported. The major drawback is high cost. Encouraging outcomes have been reported with the combination of oxamniquine and PZQ.

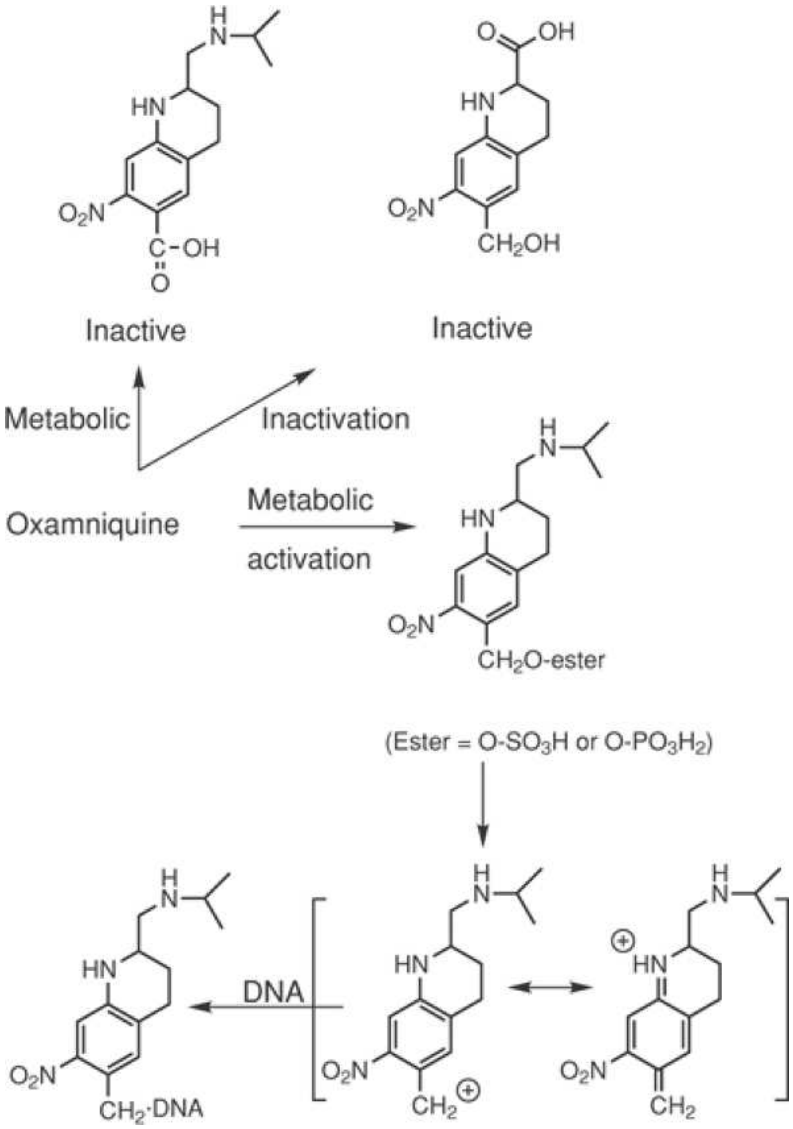


Fig. 39.20. Metabolism of oxamniquine accounting for the mechanism of action and inactivation.

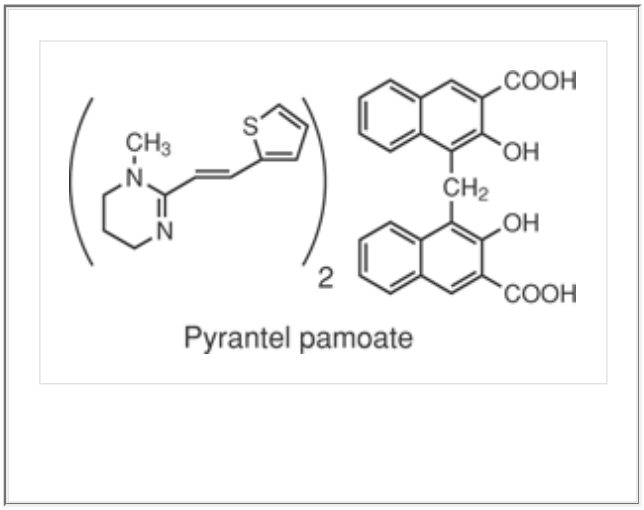
Pyrantel Pamoate (Antiminth)



Pyrantel pamoate

Pyrantel was first reported for its anthelmintic activity in 1966 (74). Although it has activity against most intestinal roundworm infections, it has not been approved by the U.S. FDA for several of these infestations. It is considered to be the drug of choice in the treatment of pinworms. The drug is used as the pamoate salt, which is quite insoluble and, as a result, is not readily absorbed. This property improves the usefulness of the drug for treatment of intestinal helminths. In addition to its value in treating enterobiasis, the drug is effective for hookworm and roundworm (ascariasis) infections. Pyrantel acts as a depolarizing neuromuscular blocking agent that activates nicotinic receptors and inhibits cholinesterase, ultimately leading to worm paralysis.

Ectoparasitic Infections

Two parasitic organisms that cause common topical infections are *Sarcoptes scabiei*, which is responsible for scabies, and *Pediculus humanus*, which is responsible for lice infections.

Scabies

Scabies, commonly referred to as the "seven year itch," is a condition caused by *Sarcoptes scabiei*, or the itch mite. The condition commonly is spread by direct, person-to-person contact, although the organism is capable of living for 2 to 3 days in clothing, bedding, or house dust. Sharing of clothing is a common means whereby the condition spreads. The organism burrows into the epidermis, usually in the folds of the skin of the fingers, the elbows, female breast, penis, scrotum, and buttocks. The female parasite lays eggs in the skin, which then hatch and mature to adults. The itch mite can live for 30 to 60 days. The infections are most common in children, but they also may be found in adults in institutional settings. The primary symptom of severe itching may foster secondary infections at the site of scratching. Because of the potential for spread to other members of a family, it is common to treat all members of the family. This will prevent reinfection from a second family member after successful therapy of the first family member.

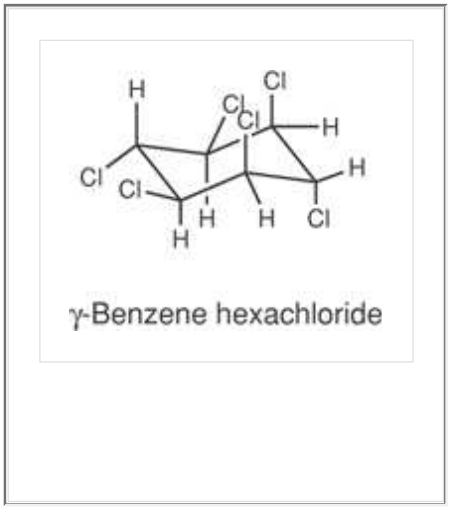
Lice

Pediculosis or lice is caused by any of the parasites *Pediculus humanus capitis*, the head louse; *Pediculus humanus corporis*, the body louse; or *Phthirius pubis*, the crab louse (found in the genital area). Lice are bloodsucking insects that live for 30 to 40 days on the body of the host. The organisms reproduce, and the female lays her eggs, the nits, which become attached to hair. The nits are white in color and hatch in 8 to 10 days. For the parasite to live, it must feed on blood, which it sucks through punctures in the skin. A hypersensitivity reaction occurs at these puncture sites, which then leads to pruritus, host scratching, and possible secondary infection. In addition to the scalp and skin, the eyebrows, eyelids, and beard may become sites of infection. The transfer of infection can occur through person-to-person contact and from infected clothing,

on which the organism can survive for up to 1 week. The sharing of clothing is a common means for the spread of body lice. Head lice are quite common among children in grade school, whereas crab lice are common among individuals who are sexually active. Treatment of family members is recommended, and clothing and bed linen should be removed and washed in very hot water.

Drug Therapy for Scabies and Pediculosis

Lindane (Kwell)



Chlorination and reduction of benzene leads to a mixture of hexachlorocyclohexanes. The insecticidal activity resides primarily in the γ-isomer of hexachlorocyclohexane (γ-benzene hexachloride). The compound is thought to produce its insecticidal action by virtue of a CNS stimulatory action that occurs by blockage of GABA. The compound is readily absorbed through the chitinous exoskeleton of the parasite. Unfortunately, lindane also is readily absorbed through intact human skin, especially the scalp, and has the potential for systemic neurotoxicity in the host. Infants and children and, possibly, the elderly are most prone to the neurotoxic effects of the drug. Because the lindane is quite lipophilic and, is applied to the scalp as a shampoo, it may be absorbed where upon it can readily enter the CNS of the patient producing signs of neurotoxicity (convulsions, dizziness, clumsiness, and unsteadiness).

The drug is available in a lotion and a shampoo and is recommended for the treatment of both pediculosis and scabies. When using the lotion topically, it should be applied to dry skin, covering the entire surface and being left in place for 8 hours. The lindane then should be removed by washing thoroughly. If the shampoo is used for *Pediculosis capitis*, the hair should be cleaned of oil and dried before application of the lindane shampoo. The shampoo is then worked into the hair and scalp, being applied in such a way as to prevent other parts of the body from coming into contact with the drug. After approximately 4 minutes, the drug is removed by washing with

water, and the hair is dried and then combed with a fine-toothed comb to remove nits.

Pyrethrum and Pyrethroids

The naturally occurring pyrethrums have been used as insecticides since the 1800s. These compounds are extracted from the flowering portion of the Chrysanthemum plant. The flowers produced in Kenya have, on average, 1.3% pyrethrins. These pyrethrum extracts are a major agricultural product for that country.

Chemistry

The Chrysanthemum extract is a mixture of ester consisting of the acids chrysanthemic and

pyrethric and the alcohols pyrethrolone and cinerolone (Fig. 39.21). The esters are prone to hydrolysis and oxidation and, as a result, should be stored in the cold and protected from light. Because of the high cost, limited availability, and rapid degradation, synthetic derivatives have been investigated. The result has been the preparation of pyrethroids, the synthetic derivatives of pyrethrins. The compound used therapeutically is permethrin, which exists as a 60:40 mixture of *trans:cis* isomers.

Mechanism of action (75,76,77,78)

The pyrethrins and pyrethroids (permethrin) are nerve membrane sodium channel toxins that do not affect potassium channels. The compounds bind to specific sodium channel proteins and slow the rate of inactivation of the sodium current elicited by membrane depolarization and, as a result, prolong the open time of the sodium channel. At low concentrations, the pyrethroids produce repetitive action potentials and neuron firing; at high concentrations, the nerve membrane is depolarized completely and excitation blocked.

The receptor interaction of the pyrethrums with the sodium channel complex is stereospecific and dependent on the stereochemistry of the carboxylic acid. In the case of the pyrethroids, the most active isomers are the 1R,3-*cis*- and 1R,3-*trans*-cyclopropanecarboxylates. The 1S-*cis*- and -*trans*-isomers are inactive and actually are antagonists to the action of the 1R-isomers.

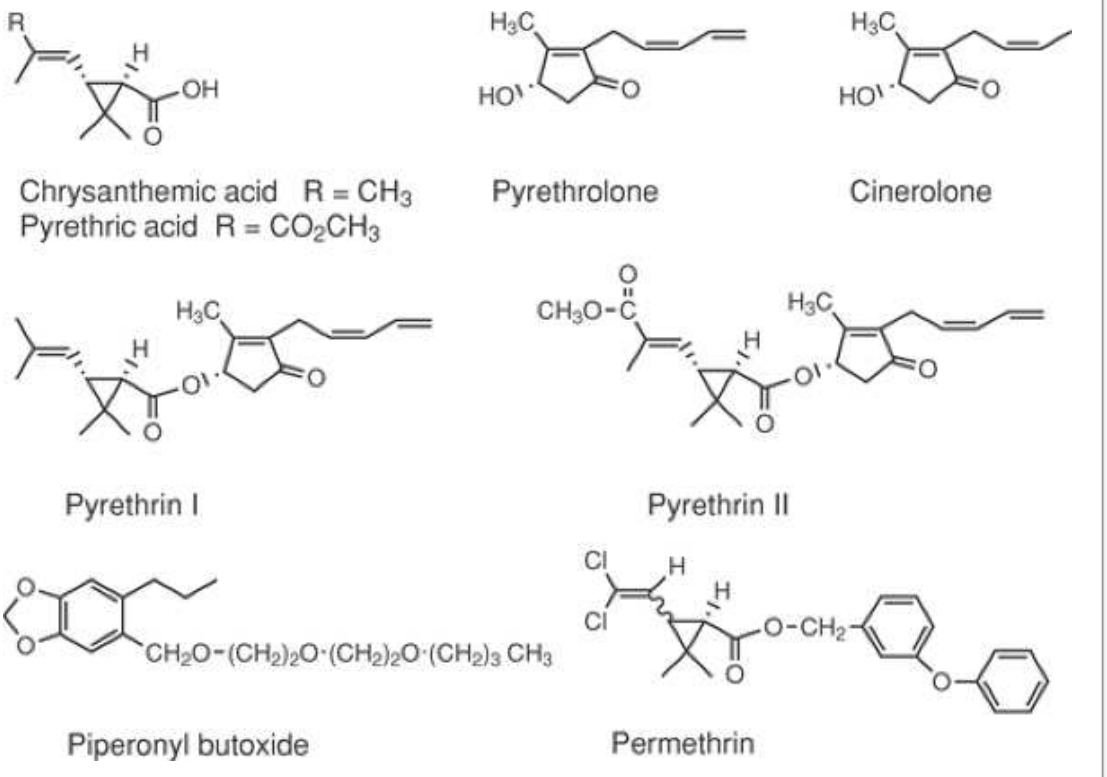


Fig. 39.21. Structures of pyrethrum and pyrethroid.

Metabolism

A property that enhances the usefulness of the pyrethrums and pyrethroids is that these compounds are highly toxic to the ectoparasites but relatively nontoxic to mammals if absorbed. The apparent lack of toxicity is associated with the rapid metabolism of these drugs through

hydrolysis and or oxidation (Fig. 39.22) (79,80). The nature of the metabolism (i.e., hydrolysis versus oxidation) is dependent on the structure of the pyrethrins or pyrethroids. Oxidation of the *trans*-methyl of the isobutylene in the carboxyl moiety initially gives an alcohol, which then proceeds to the carboxylic acid, whereas epoxidation of the terminal alkene of the alcohol portion of pyrethrin I gives either the 1,2-diol or the 1,4-diol. No ester hydrolysis is reported. Permethrin is hydroxylated on the terminal aromatic ring at either the 4- or 2-position, is oxidized on the methyl group of the dimethylcyclopropane, and is hydrolyzed at the ester moiety. The rapid breakdown of these agents also accounts for their low persistence in the environment.

Therapeutic application

Pyrethrins (A-200, RID)

Because of the high cost and rapid degradation of the pyrethrins, they usually are combined with piperonyl butoxide, a synergist (Fig. 39.21). Piperonyl butoxide has no insecticidal activity in it own right but is thought to inhibit the cytochrome P450 enzyme of the insect, thus preventing an oxidative inactivation of the pyrethrins by the parasite. The combination is used in a 10:1 ratio of piperonyl butoxide to pyrethrins. The mixture is used for treatment of *Pediculus humanus capitis*, *Pediculus humanus corporis*, and *Phthirius pubis.* Various dosage forms are available, including a gel, shampoo, and topical solution.

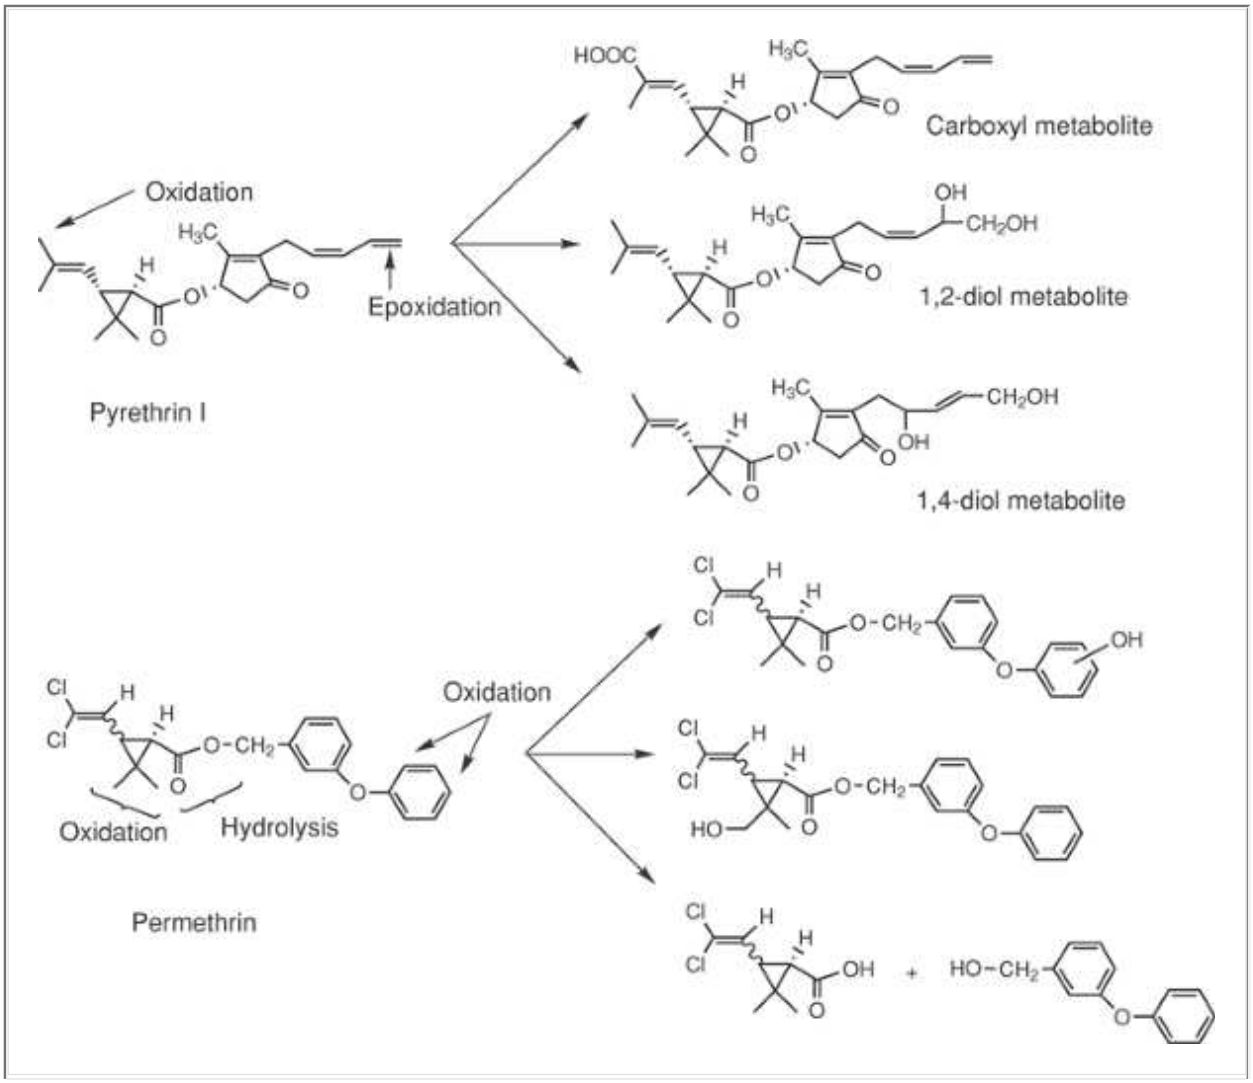

Fig. 39.22. Metabolism of pyrethrin I and permethrin.

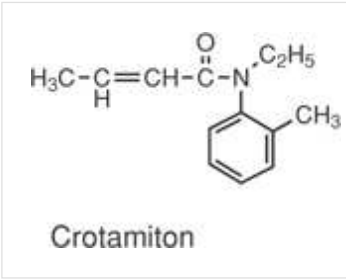
Permethrin (Nix-1% lotion, Elimite-5% Cream)

Permethrin, because of its increased stability and its availability synthetically, is not used with a synergist. The compound is used in a 1% lotion for the treatment of pediculosis capitis and in a 5% cream as a scabicide.

Crotamiton



Crotamiton is available as a 10% cream for the treatment of scabies, although it is less effective than pyrethrins or permethrin (81,82). Because crotamiton may need to be applied a second time for successful treatment of scabies but the pyrethrins or permethrin require a single application, poor patient compliance with crotamiton may reduce its effectiveness. The advantage of crotamiton over lindane comes from the fact that lindane has potential neurotoxicity if absorbed especially in infants and children, whereas crotamiton has less systemic neurotoxicity. The most common side effect reported for crotamiton is skin irritation.

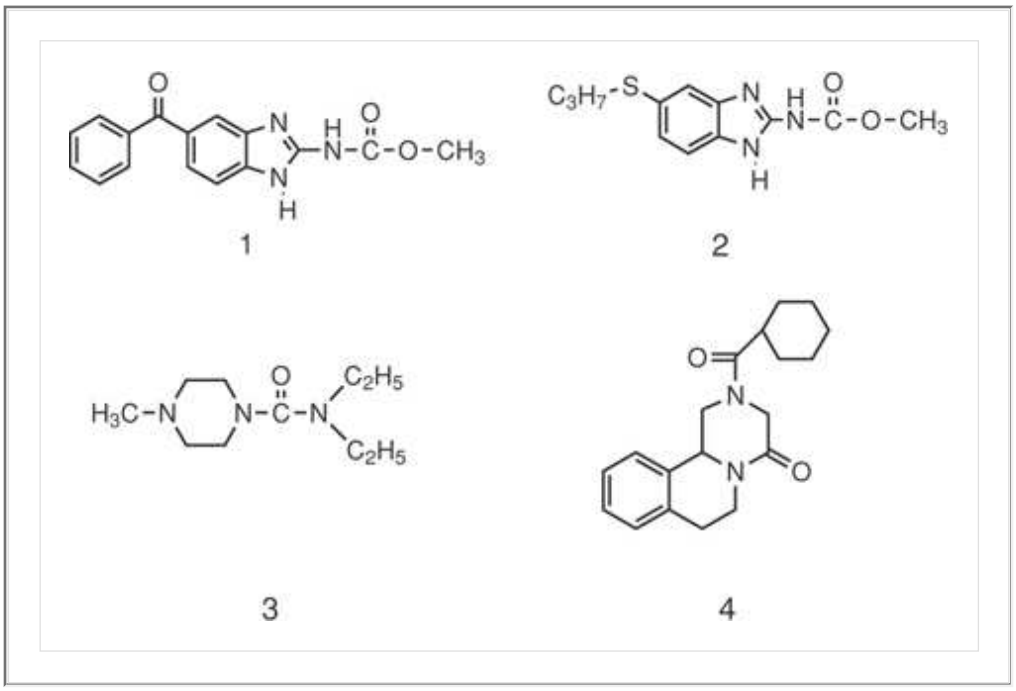
Case Study

Victoria F. Roche

S. William Zito

CQ is a strapping, 6-foot, 62-year-old, Caucasian male who presents to the emergency room with complaints of abdominal distention, flatulence, intermittent abdominal cramping, and diarrhea. In addition, he says he has not had his customary energy ever since he came back from a fishing trip to the Great Lakes. On further inquiry, CQ reveals that he is an avid fly fisherman and has had great success in catching a “trophy” salmon on light tackle. Although he generally practices conservation by releasing the fish he catches, he recalls that on one occasion, he kept a fish so that the cook at the resort he was staying at could teach him how to make his specialty of Scandinavian fish balls. To get the taste just right, CQ recalls that he had to taste the mixture before he cooked it. Hearing this, the physician suspects that CQ may have ingested a fish tapeworm, which was subsequently confirmed by finding operculate eggs (eggs with a lid) of the cestode, *Diphyllobothrium latum*, in the patient's feces on microscopic examination. You have the following antiparasitic agents in

your hospital formulary. Which would be the best choice for this case?



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 40

Antifungal Agents

Robert K. Griffith

Drugs covered in this chapter:

Polyenes

- Amphotericin B
- Natamycin
- Nystatin

Azoles

- Fluconazole
- Itraconazole
- Ketoconazole
- Posaconazole
- Terconazole
- Voriconazole

Allyl amines

- Butenafine
- Naftifine
- Terbinafine

Eschinocandins

- Anidulafingin
- Caspofungin
- Micafungin

- Ciclopirox
- Flucytosine
- Griseofulvin
- Halogrogin
- Tolnaftate
- Undecylenic acid

Introduction

Until recently, chemotherapy of fungal infections has lagged far behind chemotherapy of bacterial infections. This lack of progress has resulted, in part, because the most common fungal infections in humans have been relatively superficial infections of the skin and mucosal membranes and potentially lethal deep-seated infections have been quite rare. Because most humans with a normally functioning immune system are able to ward off invading fungal pathogens with little difficulty, the demand for improvements in antifungal therapy has been small. Immunocompromised patients, however, are very susceptible to invasive fungal infections. The onset of the AIDS epidemic, combined with the increased use of powerful immunosuppressive drugs for organ transplants and cancer chemotherapy, has resulted in a greatly increased incidence of life-threatening fungal infections and a corresponding increase in demand for new agents to treat these infections. The number of effective antifungal agents available is quite small compared to those available to treat bacterial infections, but research in this area is quite active. Several new agents have been introduced in the last few years.

Fungal Diseases

The fungal kingdom includes yeasts, molds, rusts, and mushrooms. Most fungi are saprophytic, which means that they live on dead organic matter in the soil or on decaying leaves or wood. A few of these fungi can cause opportunistic infections if they are introduced into a human through wounds or by inhalation. Some of these infections can be fatal. There are relatively few

obligate animal parasites (i.e., microorganisms that can only live on mammalian hosts) among the fungi, although *Candida albicans* is commonly found as part of the normal flora of the gastrointestinal tract and vagina. The obligatory parasites are limited to dermatophytes that have evolved to live on/in the keratin-containing hair and skin of mammals, where they cause diseases such as ringworm and athletes foot. (Ringworm is not caused by a parasitic worm but, rather, is named for the ring-like appearance of this fungal infection of the skin.) A detailed description of fungal infections is beyond the scope of this book, but comprehensive treatises are available (1).

Most fungal infections are caused primarily by various yeasts and molds. Yeasts, such as the opportunistic pathogen *Candida albicans* and the bakers' yeast *Saccharomyces cerevisiae*, typically grow as single oval cells and reproduce by budding. *Candida albicans* and some other pathogenic yeasts also can grow in multicellular chains called hyphae. Infection sites may contain both yeast and hyphal forms of the microorganism. Molds, such as *Trichophyton rubrum*, one of the causative agents of ringworm, grow in clusters of hyphae called a mycelium. All fungi produce spores, which may be transported by direct contact or through the air. Although most topical fungal infections are readily treated, the incidence of life threatening systemic fungal infections, including those caused by yeasts such as *Candida albicans* and molds such as *Aspergillus fumigans* are increasing, and mortality remains high (2).

Dermatophytes

Dermatophytes are fungi causing infections of skin, hair, and nails (3). The dermatophytes obtain nutrients from attacking the cross-linked structural protein keratin, which other fungi cannot use as a food source. Dermatophytic infections, known as tinea, are caused by various species of three genera (*Trichophyton, Microsporum*, and *Epidermophyton*) and are named for the site of infection rather than for the causative organism. Tinea capitis is a

fungal infection of the hair and scalp. Tinea pedis refers to infections of the feet, including athlete's foot, tinea manuum to fungal infection of the hands, tinea cruris to infection of the groin (jock itch), and tinea unguium to infection of the fingernails. Athlete's foot in particular may be an infection involving several different fungi, including yeasts. Tinea unguium, also known as onychomycosis, whether of the fingernails or toenails, can be particularly difficult to treat, because the fungi invade the nail itself. Appropriate drug therapy prevents the fungus from spreading to the newly formed nail. Penetration of drugs into previously existing nail is problematic, however, and with some drug regimens, the infection is not cured until an entirely new, fungus-free nail has grown in. Because this can take months, patient compliance with a lengthy drug regimen can be a problem.

Clinical Significance

Antifungal agents include diverse compounds with varied actions. A few key examples can highlight the importance of medicinal chemistry to clinical practice. Knowledge regarding the molecular structure of polyene antifungal agents, such as amphotericin B, is essential in understanding how they work. These agents are macrocyclic lactones with distinct hydrophilic and lipophilic regions. One of the putative mechanisms of polyene action involves the formation of pores in the fungal cell membrane. The lipophilic regions of the polyene molecules facilitate the binding to the cell membrane sterols. The hydrophilic portions of the molecule align to create a hydrophilic pore in the sterol-containing cell membrane. As a result, there is membrane depolarization and increased membrane permeability and, eventually, fungal cell death. The lipophilic regions of amphotericin B also contribute to its poor solubility in aqueous solutions. The traditional intravenous formulation of amphotericin B includes a dispersing agent, deoxycholate, which facilitates formation of the required micellular dispersion when administered in a 5% dextrose in water solution.

5-Flucytosine (5-FC) is an analogue of the natural pyrimidine cytosine that is converted to 5-fluorouracil (5-FU) in susceptible fungi. Formation of 5-FU is essential to the antimycotic effect of 5-FC; 5-FU acts as a pyrimidine antimetabolite and is phosphorylated to the cytotoxic agent 5-fluorodeoxyuridine monophosphate. All of these facts are commonly emphasized in a medicinal chemistry sequence, and readers probably are aware that 5-FU is a chemotherapeutic agent that causes myelosuppression as its major toxicity. Therefore, it should not be surprising that the same side effect can be seen in patients receiving 5-FC.

The newest antifungals, the echinocandins, are macromolecular structures with high molecular weights (>1,000 dalton), which a student can easily visualize by looking at the chemical structure. Their relatively low volume of distribution in the body can be partially explained by their size. Clinically, these agents have not achieved high concentrations in the central nervous system and the vitreous chamber of the eye, two compartments that are subject to fungal invasion.

Yeasts

The most common cause of yeast infections is *Candida albicans*, which is part of the normal flora in a significant portion of the population where it resides in the oropharynx, gastrointestinal tract, vagina, and surrounding skin (4). It is the principal cause of vaginal yeast infections and oral yeast infections (thrush). These commonly occur in mucosal tissue when the normal population of flora has been disturbed by treatment of a bacterial infection with an antibiotic or when growth conditions are

changed by hormonal fluctuations, such as occur in pregnancy. *Candida albicans* can cause infections of the skin and nails, although the latter are not common. In persons with healthy immune systems, *Candida* infections are limited to superficial infections of the skin and mucosa. In persons with impaired immune systems, however, *Candida albicans* also may cause deep-seated systemic infections, which can be fatal. Several other infections with *Candida* species occur, including *C. tropicalis, C. krusei, C. parapsilosis*, and *C. glabrata* (also known as *Torulopsis glabrata*). These organisms are becoming more common and often do not respond to antifungal therapy as readily as *Candida albicans.*

Cryptococcus neoformans is a yeast commonly found in bird droppings, particularly pigeon droppings (5). When dust contaminated with spores is inhaled by persons with a competent immune system, the organism causes a minor, self-limiting, lung infection. Such infections frequently are mistaken for a cold, and medical treatment is not sought. In immunocompromised persons, however, the organism can be carried by the circulatory system from the lungs to many other organs of the body, including the central nervous system (CNS). Infection of the CNS is uniformly fatal unless treated.

Although most yeast infections are caused by various species of *Candida* or *Cryptococcus*, other yeasts also can cause infections in humans, including *Malassezium furfur*, *Trichosporon beigelii*, and *Blastoschizomyces capitatus* (6). These infections are relatively rare, and they are difficult to treat.

Thermally Dimorphic Fungi (Endemic Mycoses)

Thermally dimorphic fungi are saprophytes that grow in one form at room temperature and in a different form in

a human host at 37°C (7). The most common infectious agents are *Blastomyces dermatitidus, Paracoccidiodes brasiliensis, Coccidioides immitus*, and *Histoplasma capsulatum*, the causative agents of blastomycosis, paracoccidiomycosis, coccidiomycosis (valley fever), and histoplasmosis, respectively. All these organisms live in soil and cause disease through inhalation of contaminated dust. The resulting lung infections are often mild and self-limiting, but they may progress on to a serious lung infection. The circulatory system may transport the organisms to other tissues, where the resulting systemic infection may be fatal. *Blastomyces dermatitidus* is endemic to southcentral United States and *P. brasiliensis* to Central and South America, where it is the most common cause of fungal pulmonary infections. *Coccidioides immitus* is endemic to the dry areas of the southwestern United States and northern Mexico. It is particularly prevalent in the San Joaquin Valley of California, hence the name valley fever. *Histoplasma capsulatum* is endemic to the Mississippi and Ohio River valleys of the United States, where nearly 90% of the population tests positive for exposure to the organism.

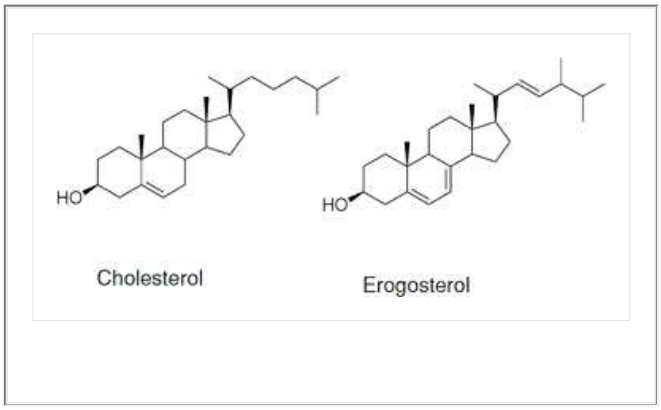
Molds

Various *Aspergillus* species are found worldwide and are virtually ubiquitous in the environment. The most common organisms causing disease are *A. fumigatus, A. niger*, and *A. flavus.* Several other *Aspergillus* species are known to cause infection, and some, such as *A. nidulans*, are becoming more common. *Aspergillus* spp. very rarely cause disease in persons with normal immune systems but are very dangerous to persons with suppressed immune systems. Because *Aspergillus* spores are everywhere, inhalation is the most common route of inoculation, but infection through wounds, burns, and implanted devices (e.g., catheters) also is possible. Nosocomial (hospital-derived) aspergillosis is a major source of infection in persons with leukemia and in those receiving organ or bone marrow transplants. Aspergillosis of the lungs may be contained, but systemic aspergillosis has a high mortality rate.

Zygomycosis (mucormycosis) is a term used to describe infections caused by the genera *Rhizopus, Mucor*, and *Absidia* of the fungal order Mucorales (8). As with several other opportunistic fungal pathogens, these soil microorganisms generally are harmless to those with a competent immune system but can cause rapidly developing, fatal infections in an immunosuppressed patient. These organisms can infect the sinus cavity, from which they spread rapidly to the CNS. Blood vessels also may be attacked and ruptured. Zygomycoses spread rapidly and are often fatal.

Biochemical Targets for Antifungal Chemotherapy

Antifungal chemotherapy depends on biochemical differences between fungi and mammals (9,10). Unlike bacteria, which are prokaryotes, both fungi and mammals are eukaryotes, and the biochemical differences between them are not as great as one might expect. At the cellular level, the greatest difference between fungal cells and mammalian cells is that fungal cells have cell walls but that mammalian cells do not. Inhibitors of bacterial cell wall biosynthesis, such as penicillins and cephalosporins, have provided many powerful antibacterial agents with little toxicity to humans. The fungal cell wall therefore is a logical target for a similar class of drugs, which would be expected to be potent antifungals yet have little human toxicity. Only recently, however, have a few potent inhibitors of fungal cell wall biosynthesis become available for clinical use (11). Other targets for antifungal agents include inhibitors of DNA biosynthesis, disruption of mitotic spindles, and general interference with intermediary metabolism. The difference between fungal and mammalian cells that is most widely exploited, however, is that the cell membranes of fungi and mammals contain different sterols. Sterols are important structural components of fungal and mammalian cell membranes and are critical to the proper functioning of many cell membrane enzymes and ion-transport proteins. Mammalian cell membranes contain cholesterol as the sterol component, whereas fungi contain ergosterol (12).

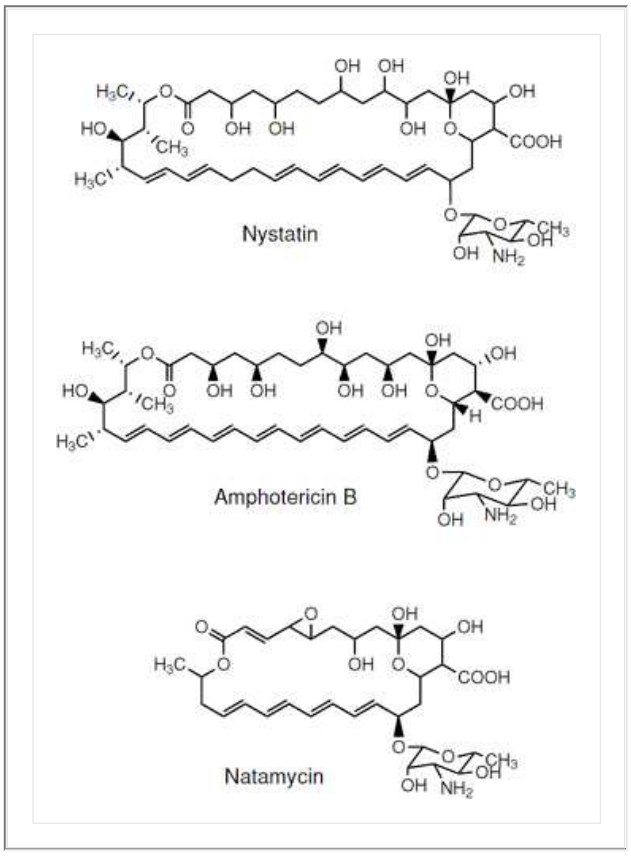


Although the two sterols are quite similar, the side chains are slightly different, and when three-dimensional models are constructed, the ring system of ergosterol is slightly flatter because of the additional double bonds in the B ring. Nevertheless, with only a few exceptions, this difference in sterol components provides the biochemical basis of selective toxicity for most of the currently available antifungal drugs.

Polyene Membrane Disruptors—Amphotericin B, Nystatin, and Congeners

Before the mid-1950s, effective antifungal therapy was limited to topical applications of undecylenic acid derivatives, mixtures of benzoic acid and salicylic acid, and a few other agents of modest efficacy. No reliable treatments existed for the few cases of deep-seated systemic fungal infections that did occur. The discovery of the polyene antifungal agents, however, provided a breakthrough into both a new class of antifungal agents and the first drug to be effective against deep-seated fungal infections. The polyenes are macrocyclic lactones with distinct hydrophilic and lipophilic regions. The hydrophilic region contains several alcohols, a carboxylic acid, and usually, a sugar. The

lipophilic region contains, in part, a chromophore of four to seven conjugated double bonds. The number of conjugated double bonds correlates directly with antifungal activity in vitro and, inversely, with the degree of toxicity to mammalian cells. That is, not only are the compounds with seven conjugated double bonds, such as amphotericin B, approximately 10-fold more fungitoxic, they are the only ones that may be used systemically.



Mechanism of Action

The polyenes have an affinity for sterol-containing membranes, insert into the membranes, and disrupt membrane functions.

The membranes of cells treated with polyenes become leaky, and eventually, the cells die because of the loss of essential cell constituents, such as ions and small organic molecules. Polyenes have a demonstrably higher affinity for membranes containing ergosterol over cholesterol-containing membranes. This is the basis for their greater toxicity to fungal cells. Some evidence suggests that the mechanism of insertion differs between the types of cells. Polyene molecules may insert individually into ergosterol-containing membranes but require prior formation of polyene micelles before inserting into cholesterol-containing membranes.

Specific Drugs

Nystatin

Nystatin, the first clinically useful polyene antifungal antibiotic, is a conjugated tetraene isolated from cultures of the bacterium *Streptomyces noursei* in 1951. Nystatin is an effective topical antifungal against a wide variety of organisms and is available in a variety of creams and ointments. Nystatin is too toxic to be used systemically, but because very little drug is absorbed following oral administration, it may be administered by mouth to treat fungal infections of the mouth and gastrointestinal tract (Table 40.1). Although nystatin itself was not a breakthrough in systemic antifungal therapy, the search for other polyenes led to the discovery of a polyene that can be used systemically.

Amphotericin B

Amphotericin B, which as a heptaene has low enough toxicity to mammalian cells to permit intravenous (IV) administration, was discovered in 1956. Amphotericin B is, nevertheless, a very toxic drug and must be used with caution. Adverse effects include fever, shaking chills, hypotension, and severe kidney toxicity. Despite its toxicity, amphotericin B is considered to be the drug of choice for many systemic, life-threatening fungal infections. The drug cannot cross the blood-brain barrier and must be administered intrathecally for treatment of fungal infections of the CNS. Closely related heptaenes are candicidin, hamycin, and trichomycin.

The nephrotoxicity of amphotericin B has been a serious drawback to the use of this drug since its introduction. Recently, however, the toxicity of the drug has been decreased substantially by changes in formulation (Table 40.2). The polyenes are only sparingly soluble in water, and amphotericin B has long been formulated as a complex with deoxycholic acid for IV administration. More recently developed formulations of amphotericin B, such as liposomal encapsulation and lipid complexes, have dramatically decreased the toxicity of the drug to humans, which permits higher plasma levels to be employed. The mechanisms by which the new formulations decrease the toxicity are not entirely clear, but altered distribution is clearly a factor. Because the blood vessels at the site of infection are more permeable than those of normal tissue, the large suspended particles of the lipid formulations can penetrate the site of infection more readily than they can penetrate healthy tissue. The result is selective delivery of drug to the site of infection. Some evidence also indicates that the newer formulations transfer amphotericin B to ergosterol-containing fungal cells more efficiently than to cholesterol-containing mammalian cells.

Natamycin

Natamycin, a tetraene, is available in the United States as a 5% suspension applied topically for the treatment of fungal infections of the eye (Table 40.1).

Ergosterol Biosynthesis Inhibitors

A schematic of fungal ergosterol biosynthesis starting from squalene is shown in Figure 40.1. The biosynthetic pathway has been simplified to emphasize steps important to the action of currently employed antifungal drugs. The last nonsteroidal precursor to both ergosterol and cholesterol is the hydrocarbon squalene. Squalene is converted to squalene epoxide by the enzyme squalene epoxidase. Squalene epoxide is then cyclized to lanosterol, the first steroid in the biosynthetic pathway. The

steps involved in converting the side chain of lanosterol to the side chain of ergosterol, and the steps in removal of the geminal dimethyl groups on position 4, are not shown, because none of these reactions is targeted by clinically employed antifungal agents.

Table 40.1. Topical Antifungals

Chemical Class	Generic Name	Trade Name	Dosage Form
Allylamine	Butenafine	Lotrimin Ultra Mentax	1% cream
	Naftifine	Naftin	1% cream, gel
	Terbinafine	Lamisil	1% cream

		Lamisil DermGel	10 mg/g gel
	Tolnaftate (thiocarbamate)	Various	1% cream, solution
		Absorbine Athletes' Foot Cream	1% cream
		Genaspor	1% cream
		Tinactin	1% cream, solution, powder, spray powder, spray liquid
		Aftate	1% gel, spray powder, spray liquid
Imidizole	Clotrimazole	Cruex	1% cream
		Lotrimin AF	1% cream, lotion, solution
		Desenex	1% cream
	Econazole	Various	1% cream
		Spectazole	1% cream
	Sertaconazole	Ertaczo	2% cream
	Ketoconazole	Nizoral	2% cream, shampoo
	Miconazole	Micatin	2% cream, powder, spray powder, spray liquid
		Monistat-Derm	2% cream
		Maximum Strength Desenex	2% cream
		Fungoid Creme	2% cream
		Lotrimin AF	2% powder, spray powder
		Zeasorb AF	2% cream
		Prescription Strength Desenex	2% spray liquid

		Fungoid Tincture	2% solution
	Oxiconazole	Oxistat	1% cream, lotion
	Sulconazole	Exelderm	1% cream, solution
Triazole	Terconazole	Terazol	Topical 0.4–0.8% cream, suppository
Polyene	Nystatin	Mycostatin	100,000 U/g cream, ointment, powder
		Nilstat	100,000 U/g cream, ointment
		Nystex	100,000 U/g cream, ointment
	Natamycin	Alcon	5% ophthalmic suspension
Misc.	Ciclopirox	Loprox	0.77% cream, gel, suspension 1% shampoo
		Penlac	8% nail lacquer
	Haloprogin	Halotex	1% cream, solution
	Undecylenic Acid	Protectol Medicated	15% powder
		Caldesene	10% powder
		Cruex	10% powder
		Cruex Aerosol	19% powder
		Desenex	25% powder
		Phicon F	8% cream
		Various	2–25% creams, powders, ointments

A key step in conversion of lanosterol to both cholesterol and ergosterol is removal of the 14α-methyl group. This reaction is carried out by a cytochrome P450 (CYP450) enzyme, 14α-demethylase. The mechanism of this reaction involves three successive hydroxylations of the 14α-methyl group, converting it from a hydrocarbon through the alcohol, aldehyde, and carboxylic acid oxidation states (Fig. 40.2). The methyl group is eliminated as formic acid to afford a double bond between C-14 and C-15 of the D ring. This enzyme is the primary target of the azole antifungal agents discussed below.

Eventually, either before or after modification of the side chain, the Δ^{14} double bond is reduced by a Δ^{14}-reductase to form a

trans ring juncture between the C and D rings. Several steps later, the double bond between C-8 and C-9 is isomerized to a Δ^7 double bond by the enzyme Δ^8,Δ^7-isomerase. Many of the steps are identical to those involved in mammalian cholesterol biosynthesis, and the basis for selective toxicity to fungal cells will be discussed under the specific agents.

Azoles—Imidazoles and Triazoles

Azole antifungal agents are the largest class of antimycotics available today, with more than 20 drugs on the market. Some are primarily used topically to treat superficial dermatophytic and yeast infections (Table 40.1), whereas others are administered orally for the treatment of systemic fungal infections (Table 40.2). The oral

bioavailability of some azoles, in contrast to amphotericin B, combined with their generally broad-spectrum of activity has led to their widespread use in treating a variety of serious infections. The characteristic chemical feature of azoles from which their name is derived is the presence of a five-membered aromatic ring containing either two or three nitrogen atoms. Imidazole rings have two nitrogens and triazoles three. In both cases, the azole ring is attached through N_1 to a side chain containing at least one aromatic ring. Imidazole-containing agents are shown in Figure 40.3 (for triazoles, see Fig. 40.6).

Table 40.2. Systemic Antifungal Agents

Chemical Class	Generic Name	Trade Name	Dosage Form
Allylamine	Terbinafine	Lamisil	250-mg tablets
Imidazole	Ketoconazole	Various	200-mg tablets
		Nizoral	200-mg tablets
Triazole	Fluconazole	Diflucan	50-, 100-, 150-, and 200-mg tablets; 350-mg (10 mg/mL reconst.) powder for oral suspension; 100- and 200-mL (2 mg/mL) solution for injection
	Voriconazole	Vfend	50- and 200-mg tablets; 200-mg powder for injection; 45-g (40 mg/mL reconst.) powder for oral suspension
	Itraconazole	Various	100-mg capsules
		Sporanox	100-mg capsules; 10 mg/mL injection solution; 10 mg/mL oral solution
Echinocandins	Caspofungin	Cancidas	50- and 70-mg powder for injection
	Anidulafungin	Eraxis	50-mg powder for injection
	Micafungin	Mycamine	50-mg powder for injection
Polyene	Amphotericin B	Amphocin (desoxycholate)	50-mg powder for injection
		Fungizone (desoxycholate)	50-mg powder for injection

		Abelcet (lipid complex)	100 mg/20 mL suspension, single-use vials
		Amphotec (cholesteryl)	50 mg/20 mL and 100 mg/50 mL powder, single-use vials
		AmBisome (liposomal)	Powder, single-use vials
Misc.	Flucytosine	Ancobon	250- and 500-mg capsules
	Griseofulvin	Fulvicin, Grifulvin, Grisactin	250- and 500-mg microsize tablets; 125- to 330-mg ultramicrosize tablets

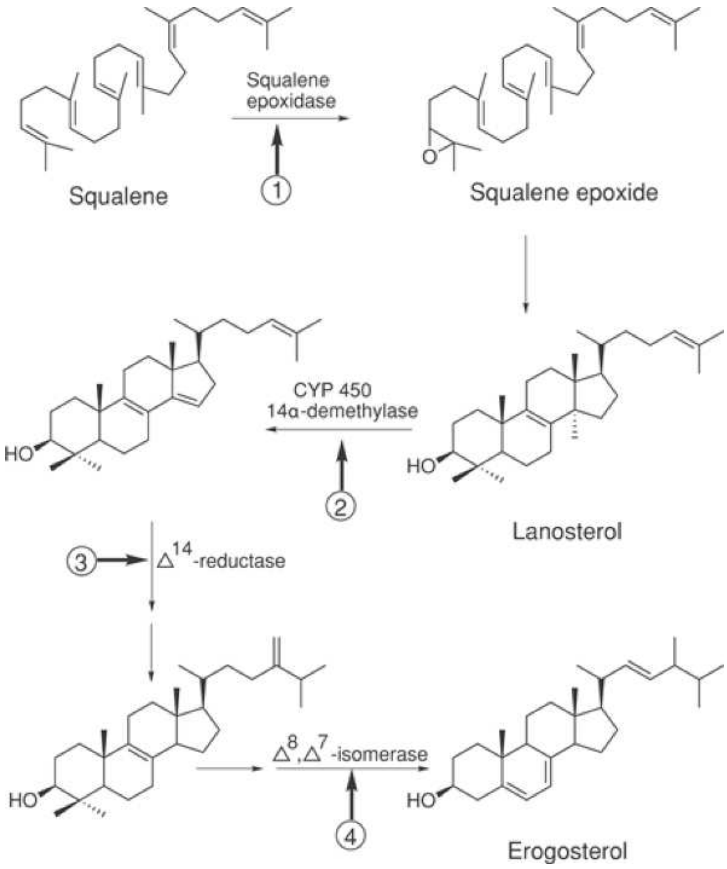


Fig. 40.1. Ergosterol biosynthesis from squalene, with key steps shown in the simplified figure. Enzymatic steps known to be the site of action of currently employed antifungal agents are indicated by a heavy black arrow and a number.

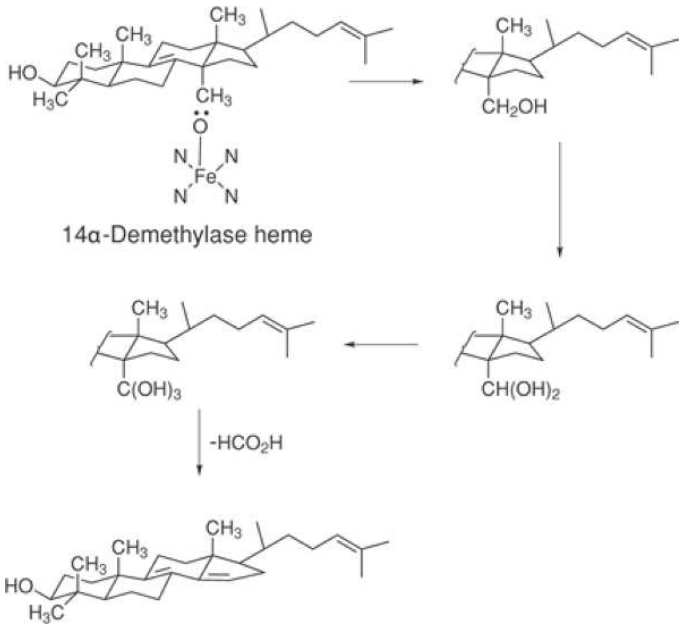

Fig. 40.2. Demethylation of the 14α-methyl group from lanosterol carried out by the cytochrome P450 enzyme sterol 14α-demethylase (CYP51). The mechanism involves three successive heme-catalyzed insertions of activated oxygen into the three carbon-hydrogen bonds of the 14α-methyl group, which raises the oxidation state of the methyl group to a carboxylic acid. The group is finally eliminated as formic acid to create a double bond between carbons 14 and 15.

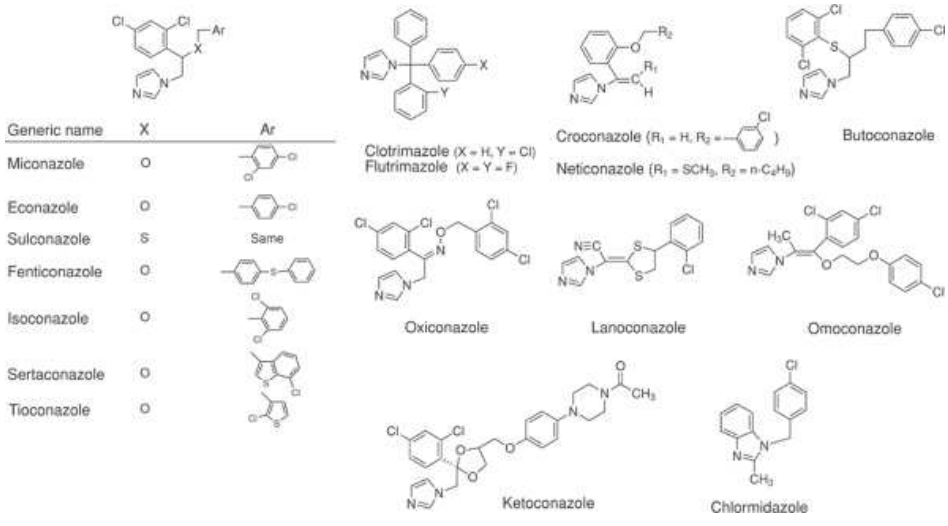

Fig. 40.3. Imidazole antifungal agents.

Mechanism of Action

All the azoles act by inhibiting ergosterol biosynthesis through inhibition of the 14α-demethylase discussed above under ergosterol biosynthesis (Fig. 40.1, Site 2). The basic N3 atom of the azole forms a bond with the heme iron of the CYP450 prosthetic group in the position normally occupied by the activated oxygen (Fig. 40.4). The remainder of the azole antifungal forms bonding interactions with the apoprotein in a manner that determines the relative selectivity of the drug for the fungal

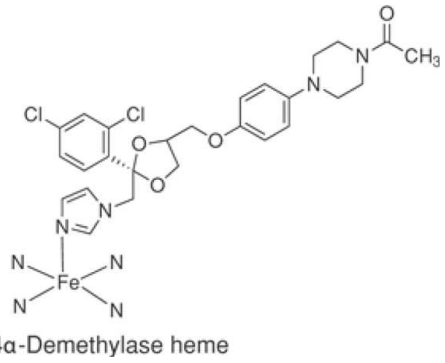
demethylase versus other CYP450 enzymes.

Inhibition of the 14α-demethylase results in accumulation in the fungal cell membrane of sterols still bearing a 14α-methyl group. These sterols do not have the exact shape and physical properties of the normal membrane sterol ergosterol. This results in permeability changes, leaky membranes, and malfunction of membrane-imbedded proteins. These effects taken together lead to fungal cell death. Because biosynthesis of the mammalian membrane sterol cholesterol also employs a CYP450 14α-demethylase, why do 14α-methyl sterols not accumulate in human cell membranes? The reason is in the relative strength of inhibition of the same enzyme from different species. For example, the median inhibitory concentration (IC_{50}) for ketoconazole against the enzyme from *Candida albicans* is approximately 10^{-9} M versus approximately 10^{-6} M for the human enzyme. This three orders of magnitude difference in strength of inhibition provides the therapeutic index with respect to this particular enzyme. As discussed below, however, many of the azoles are powerful inhibitors of other mammalian CYP450 enzymes.

The early azole antifungal drugs were all either extensively and rapidly degraded by first-pass metabolism or

P.1119

too toxic for systemic use. As a result, only those drugs with reduced or slow first-pass metabolism (ketoconazole, fluconazole, itraconazole, voriconazole, and posaconazole) are used systemically. The other azoles (clotrimazole, tioconazole, terconazole, butoconazole, econazole, oxiconazole, sulconazole, miconazole, and ketoconazole) are available in a variety of creams and ointments for topical treatments of dermatophytic infections and intravaginal use for vaginal yeast infections. (Table 40.1).



14α-Demethylase heme

Fig. 40.4. Mechanism of azole/CYP450 binding. The basic nitrogen of azole antifungal agents forms a bond to the heme iron of CYP450 enzymes, preventing the enzyme from oxidizing its normal substrates. Ketoconazole is representative of the azole antifungals.

Specific drugs

Ketoconazole

Ketoconazole (Fig. 40.3), an imidazole, was the first orally active antifungal azole to be discovered and, as a consequence, has been widely studied and employed for the treatment of systemic fungal infections, primarily candidiasis. Ketoconazole has little effect on *Aspergillus* or *Cryptococcus*. Ketoconazole is highly dependent on low stomach pH for absorption, and antacids or drugs that raise stomach pH will lower the bioavailability of ketoconazole. As with other azoles, it is extensively metabolized by microsomal enzymes (Fig. 40.5). All the metabolites are inactive. Evidence that CYP3A4 plays a significant role in metabolism of ketoconazole is that coadministration of CYP3A4 inducers, such as phenytoin, carbamazepine, and rifampin, can cause as much as a 50% reduction in levels of ketoconazole (13). Ketoconazole also is a powerful inhibitor of human CYP3A4 and, as a consequence, has many serious interactions with other drugs. For example, coadministration of ketoconazole with the hypnotic triazolam results in a 22-fold increase in triazolam's area under the curve (AUC) and a sevenfold increase in half-life. Interestingly, CYP3A4 also is present in the gut and may contribute substantially to the metabolism of many drugs, such as the immunosuppressant agent cyclosporine, thus the potential for drug–drug

P.1120

interaction (see box). Ketoconazole is a weak inhibitor of CYP2C9, which is the enzyme responsible for the metabolism of several narrow therapeutic index drugs, such as warfarin and phenytoin. As better systemic agents have become available, ketoconazole's clinical use has become limited to topical applications in a variety of dosage forms, including creams, lotions, suppositories, and shampoos.

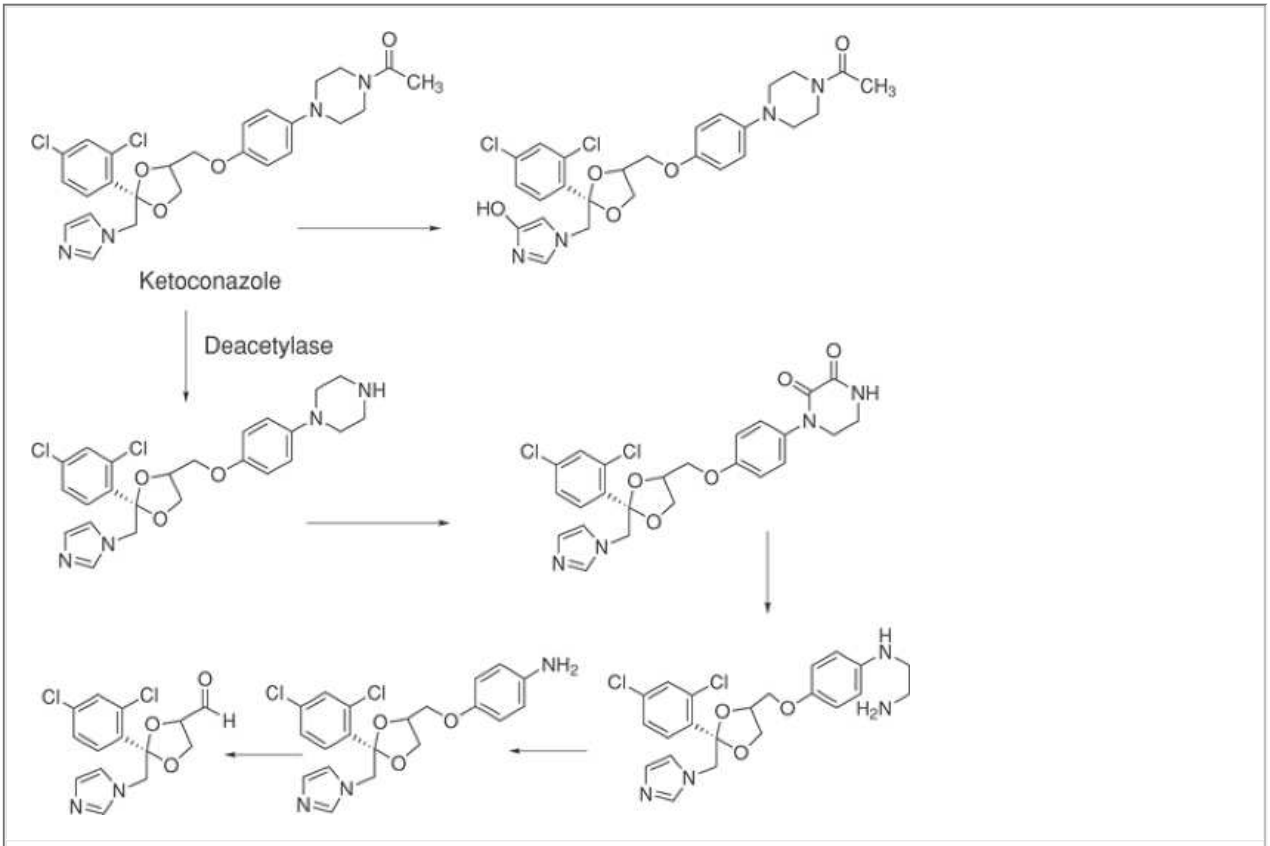


Fig. 40.5. Extensive metabolism of ketoconazole involving hydrolysis of the N-acetyl by a deacetylase. The oxidation reactions are catalyzed by CYP3A4 and a flavin-linked mixed-function oxidase. All metabolites are inactive.

Ketoconazole and Cyclosporine—A Clinical Useful Drug Interaction

Cyclosporine is an immunosuppressive agent used in transplant patients to help prevent organ rejection. Although effective, cyclosporine therapy is extremely expensive and the drug appears to be approximately 20% bioavailable following an oral dose. This low bioavailability results from the metabolism of cyclosporine by the CYP450 system to a number of metabolites. Early reports of coadministration of ketoconazole with cyclosporine described excessive adverse effects attributable to cyclosporine toxicity. From this and knowledge about the effects of ketoconazole on CYP450-mediated metabolism, investigators hypothesized that a much lower dose of cyclosporine could be given concomitantly with ketoconazole, producing blood levels of cyclosporine equivalent to those seen with the higher dose at a fraction of the cost. In fact, it appears that ketoconazole given concurrently with cyclosporine may allow up to an 80% reduction in cyclosporine dose.

Itraconazole

Itraconazole was, along with fluconazole, one of the first triazoles introduced into clinical use (Fig. 40.6) (14). Itraconazole's oral bioavailability is variable and is influenced by food and stomach pH, a strongly acidic pH being required for good absorption. Like ketoconazole, itraconazole is extensively metabolized by CYP3A4 following oral administration, and levels are markedly reduced by coadministration of the CYP3A4-inducers phenytoin, carbamazepine. and rifampin (13). Additionally, like ketoconazole, itraconazole has been demonstrated to be a strong inhibitor of CYP3A4 (15). This interaction has proven to be of clinical significance because the risk of developing rhabdomyolysis following lovastatin or simvastatin therapy with coadministration of itraconazole (16,17,18). Itraconazole therefore is likely to have serious interactions with any other drug metabolized by CYP3A4. Again like ketoconazole, itraconazole appears to have little or no effect on CYP2C9-mediated metabolism of warfarin and phenytoin.

Terconazole

Terconazole (Fig. 40.6) is a close analogue of ketoconazole and itraconazole. It is approved only for the treatment of vaginal candidiasis and is not used systemically (Table 40.1) (19,20).

Fluconazole

Fluconazole (Fig. 40.6), which was introduced at the same time as itraconazole, differs from ketoconazole and itraconazole in that it is equally bioavailable when given orally or IV. Two major advantages of fluconazole over other antifungal agents are that it can cross the blood-brain barrier and has efficacy against *Cryptococcus neoformans* (21). Fluconazole also differs in that it is only a weak inhibitor of CYP3A4 but a strong inhibitor of CYP2C9 (22). For instance, fluconazole doubles the AUC of (*S*)-warfarin (the active enantiomer) and greatly prolongs the prothrombin time in patients receiving warfarin anticoagulant therapy (23). Because warfarin has such a narrow therapeutic index and excessive anticoagulation can be extremely harmful, this interaction is considered to be of major clinical significance. Fluconazole also decreases the metabolism of the CYP2C9 substrate phenytoin, an antiepileptic agent that also has a narrow therapeutic index (24). Depending on the dose of fluconazole, coadministration with phenytoin can result in a 75 to 150% increase in the phenytoin AUC, and numerous case reports have documented substantial adverse effects following this regimen. Fluconazole also will inhibit CYP3A4, though not to the same degree as ketoconazole and itraconazole. Fluconazole exhibits a dose-dependent inhibition of triazolam metabolism (a CYP3A4 reaction) causing as much as a fourfold increase in triazolam AUC.

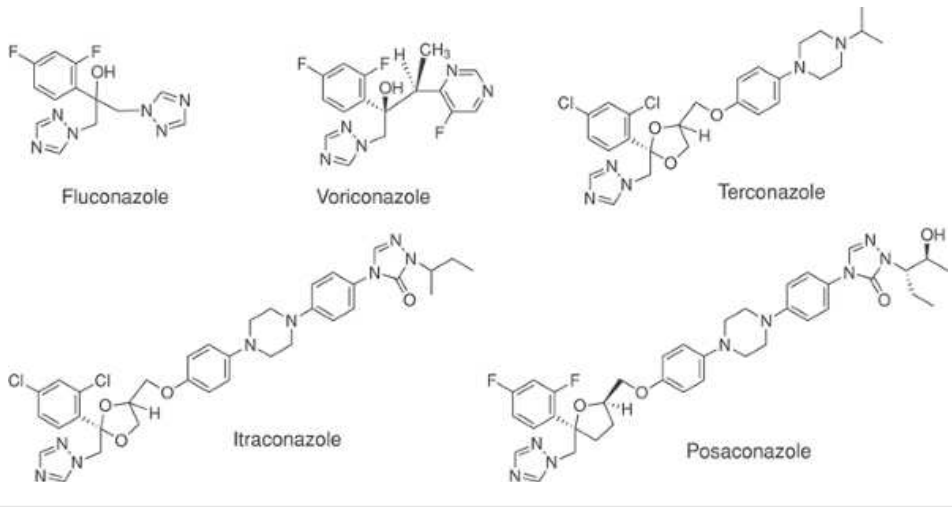

Fig. 40.6. Triazole antifungal agents.

Voriconazole

Voriconazole (Fig. 40.6) is a fluconazole analogue that was developed to overcome some of the limitations of fluconazole (25) and does, indeed, have a broader spectrum of activity than fluconazole, having activity against *Aspergillus* and fluconazole-resistant strains of *Candida* and *Cryptococcus* (26). Voriconazole is orally absorbed and penetrates the blood-brain barrier. Unfortunately, voriconazole is extensively metabolized CYP450 enzymes (Fig. 40.7) and is an inhibitor of CYP2C19, CYP2C9, and CYP3A4, leading to many drug interactions (27,28). Voriconazole exhibits nonlinear, saturable kinetics, and because CYP2C19 exhibits genetic polymorphisms, plasma levels can be higher in poor metabolizers versus extensive metabolizers (29,30).

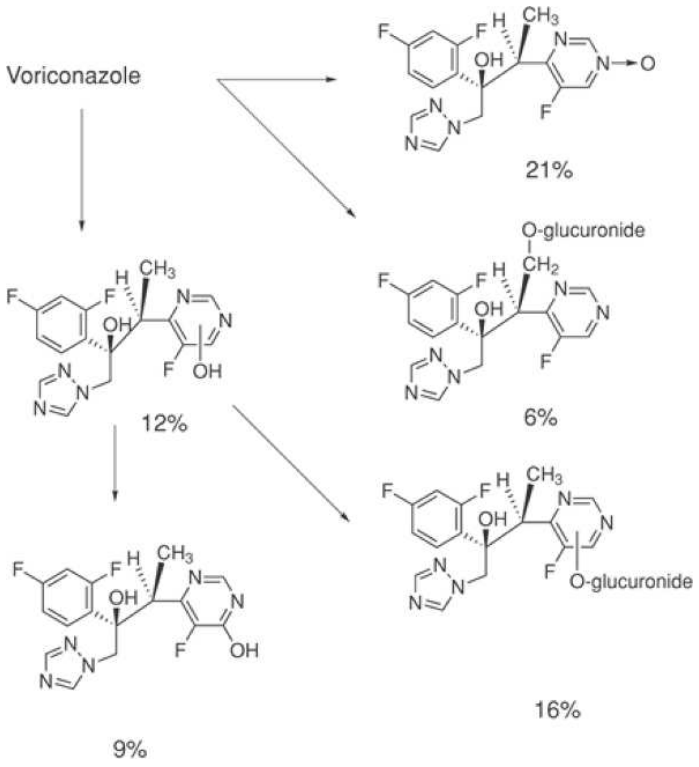

Fig. 40.7. Major metabolic products resulting from CYP450 metabolism of voriconazole.

Posaconazole

Posaconazole (Fig. 40.6), a recently introduced triazole, has a number of advantages over previous agents (31,32). Posaconazole has a wide spectrum of activity compared to other azoles, particularly against *Aspergillus* and other increasingly common nosocomial infections resistant to treatment by other antifungal drugs (32). Posaconazole is metabolized primarily by Phase II glucuronide conjugation and has little interaction with the oxidative CYP450 enzymes (33). Thus, posaconazole should have far fewer drug interactions than the other azole antifungal agents. Posaconazole is structurally similar to itraconazole and saperconazole, but it contains a tetrahydrofuran ring in place of the dioxolan ring of those agents, which may account for some of its unique properties.

Allyl Amines and Other Squalene Epoxidase Inhibitors

The group of agents generally known as allyl amines[34] strictly includes only naftifine and terbinafine, but because butenafine and tolnaftate function by the same mechanism of action, they are included in this class and are shown in Figure 40.8. One can, of course, consider the benzyl group of butenafine to be bio-isosteric with the allyl group of naftifine and terbinafine. Tolnaftate, a much older drug, is chemically a thiocarbamate but has the same mechanism of action as the allyl amines. These drugs have a more limited spectrum of activity than the azoles and are effective only against dermatophytes. Therefore, they are employed in the treatment of fungal infections of the skin and nails (35).

Mechanism of action

All of the drugs in Figure 40.8 act through inhibition of the enzyme squalene epoxidase (Fig. 40.1, Site 1). Inhibition of this enzyme has two effects, both of which appear to be involved in the fungitoxic mechanism of this class (36). First, inhibition of squalene epoxidase results in a decrease in total sterol content of the fungal cell membrane. This decrease alters the physicochemical properties of the membrane, resulting in malfunctions of membrane-imbedded transport proteins involved in nutrient transport and pH balance. Second, inhibition of squalene epoxidase results in a buildup within the fungal cell of the hydrocarbon squalene, which is itself toxic when present in abnormally high amounts. Mammals also employ the enzyme squalene epoxidase in the biosynthesis of cholesterol, but a desirable therapeutic index arises from the fact that the fungal squalene epoxidase enzyme is far more sensitive to the drugs than the corresponding mammalian enzyme. Terbinafine has a K_i of 0.03 μM versus squalene epoxidase from *Candida albicans* but only 77 μM versus the same enzyme from rat liver—a 2,500-fold difference (37).

Specific drugs

Naftifine

Naftifine (Fig. 40.8) was the first allyl amine to be discovered and marketed (34). It is subject to extensive first-pass metabolism to be orally active and, consequently, is only available in topical preparations (Table 40.1). The widest use of naftifine is against various tinea infections of the skin.

Terbinafine

Terbinafine (Fig. 40.8) is available in both topical and oral dosage forms (Tables 40.1 and 40.2) and is effective against a variety of dermatophytic

infections when employed topically or systemically (38). A unique property of terbinafine is its effectiveness in the treatment of onychomycoses (nail infections) (39). Given orally, the highly lipophilic drug redistributes from the plasma into the nail bed and into the nail itself, where the infection resides (40), making terbinafine superior to other agents for treating this particular type of infection. Terbinafine is extensively metabolized by several CYP450 enzymes, including CYP1A2, CYP2C19, CYP2C9, CYP2C8, CYP3A4, and CYP2B6 (41). Because there are so many pathways for terbinafine metabolism, inhibition of any one has very little effect on overall clearance of the drug, although drugs that inhibit several CYP450 enzymes, such as cimetidine, can increase terbinafine plasma levels. Although not a substrate for the enzyme, terbinafine is a strong inhibitor of CYP2D6 and can have significant interactions with drugs that are metabolized by this enzyme, such as codeine and desipramine (22,42).

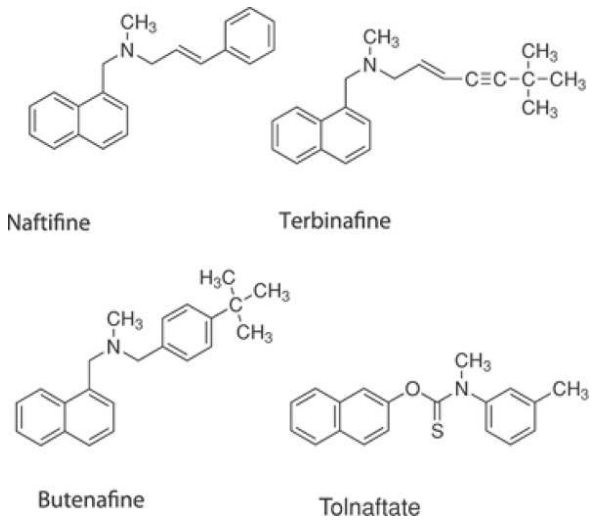

Fig. 40.8. The squalene epoxidase inhibitors, allyl amines. Naftifine was the first drug shown to act by inhibition of squalene epoxidase, as does the much older thinocarbamate, tolnaftate.

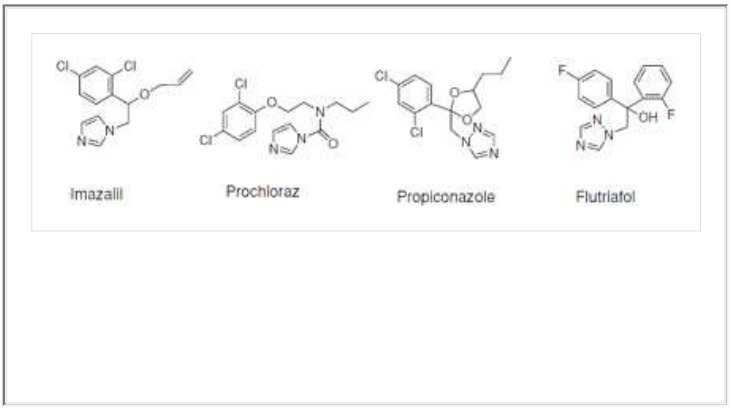
Azole Antifungals in Agriculture



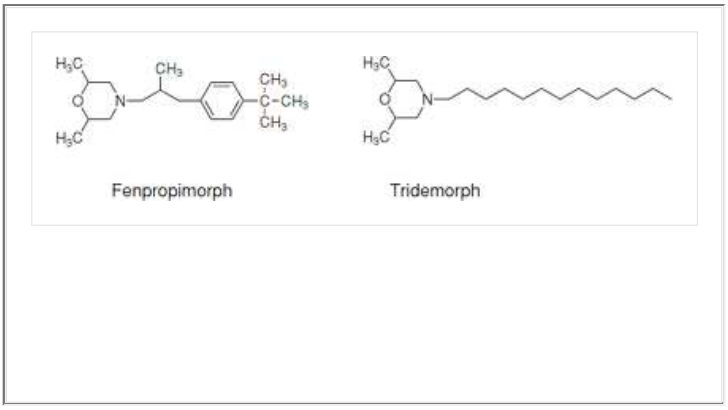
Every year, fungal infections of crops causes hundreds of millions of dollars worth of damage to a wide variety of food and other crops. Before the development of effective agricultural antifungals, crop diseases were the cause of several major famines. The infamous Irish Potato Famine of the nineteenth century was caused by a pathogenic fungus, *Phytophera infestans*. Tens of thousands of people starved to death, and thousands more emigrated to the United

States to escape the famine. Today, both imidazole and triazole antifungal agents, such as imazalil and propiconazole, are among the most effective crop-protection agents known. More than 20 azole antifungals are used for crop protection, and a representative sample is shown. The mechanism of action of the agricultural antifungals is identical to that of the agents used for mammalian infections. In fact, they bear a remarkable resemblance to antifungal drugs employed in treating human disease.

Butenafine and Tolnaftate

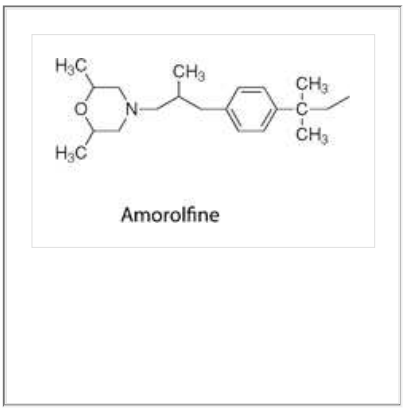
Butenafine and tolnaftate, like naftifine (Fig. 40.8), are only available in topical preparation for the treatment of dermatophytic infections (Table 40.1). Tolnaftate has been marketed in a variety of nonprescription drug preparations for decades. Butenafine, discovered more recently, has a somewhat wider spectrum of activity than tolnaftate. For example, butenafine is active against superficial *Candida albicans* infections, which are not affected by tolnaftate (43).

Agricultural Antifungal Morpholines



Just as there are several classes of drugs to treat human fungal infections, there are several classes of “drugs” to treat fungal phytopathogens. The morpholines, fenpropimorph and tridemorph, are not used to treat human disease but have wide utility in protecting crops from phytopathogenic fungi.

Morpholines



Amorolfine is the only drug in this class that is employed clinically in the treatment of human fungal infections. Amorolfine is not currently available in the United States, but it is marketed in Europe and Asia for the topical treatment of dermatophytic infections (44).

Morpholine antifungals inhibit ergosterol biosynthesis by acting on the enzymes Δ^{14}-reductase and Δ^{8},Δ^{7}-isomerase (Fig. 40.1, Site 3 and 4) (45). Inhibition of these enzymes results in incorporation into fungal cell membranes of sterols retaining either a Δ^{14} double bond, a Δ^{8} double bond, or both. None of these will have the same overall shape and physicochemical properties as the preferred sterol, ergosterol. As with the antifungals already discussed, this results in membranes with altered properties and malfunctioning of membrane-embedded proteins.

Inhibitors of Cell Wall Biosynthesis—Echinocandins

The most notable difference between fungal and mammalian cells is that fungi have a cell wall and mammals do not. Drugs interfering with cell wall biosynthesis would be expected to be relatively nontoxic to mammals. Such drugs have been the foundation of antibacterial therapy since the discovery of penicillin and the development of dozens of effective penicillins and

cephalosporins. Only recently, however, have a few drugs affecting fungal cell wall biosynthesis become available. Echinocandins, a group of cyclic peptides with long lipophilic side chains and sometimes called lipopeptides, have been under investigation for a number of years (Fig. 40.9) (46). Echinocandins interfere with cell wall biosynthesis through inhibition of the enzyme β-1,3-glucan synthase. β-Glucan is an important polymer component of many fungal cell walls, and reduction in the glucan content severely weakens the cell wall, leading to rupture of the fungal cell.

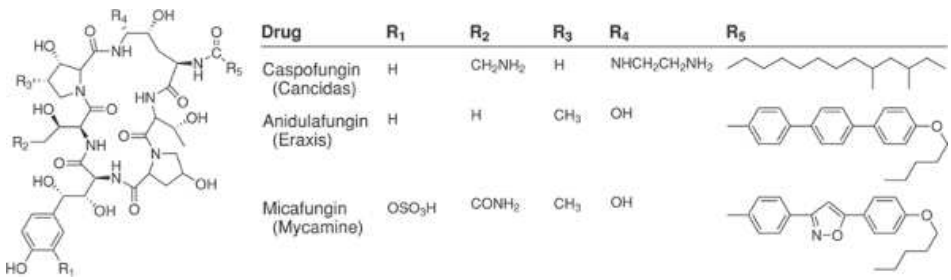


Fig. 40.9. Echinocandins.

Caspofungin, Anidulafungin, and Micafungin

Recently, three semisynthetic echinocandins have been approved for use in treating life-threatening systemic fungal infections (47). These are caspofungin, anidulafungin, and micafungin (Fig. 40.9). These drugs represent the first class of antifungal agents with a novel mechanism of action to be marketed in more than 30 years and are a very valuable contribution to therapy for systemic fugal infections. They are effective against a variety of *Candida* species that have proven to be resistant to other agents as well as effective against azole-resistant *Aspergillus*. Therefore, these drugs are truly life-saving for those afflicted with these previously resistant fungi. Unfortunately these echinocandins are not effective against *Cryptococcus neoformans*. None of these drugs is orally active, and all must be administered by IV infusion. Because of limited hepatic metabolism, drug–drug interactions are not a problem. Caspofungin is metabolized by hydrolysis in two portions of the hexapeptide ring (Fig. 40.10) (48), whereas anidulafungin does not appear to be actively metabolized but rather slowly degrades (49). Micafungin is metabolized by a sulfotransferase and by catechol-O-methyltransferase (COMT), but no significant drug interactions are known (50).

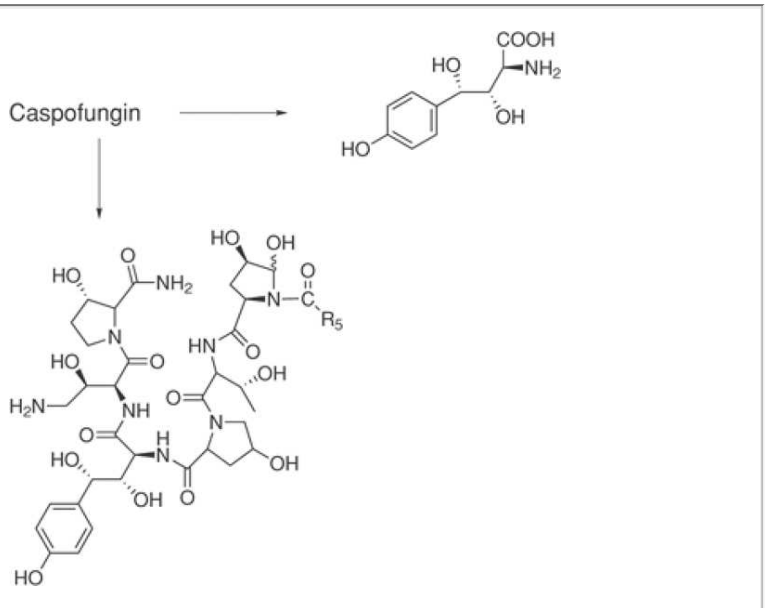

Fig. 40.10. Metabolic products formed from caspofungin.

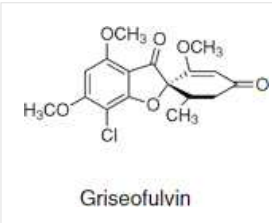
Drugs Acting Through Other Mechanisms

Flucytosine

Flucytosine is a powerful antifungal agent used in the treatment of serious systemic fungal infections, such as *Cryptococcus neoformans* and *Candida* spp (Table 40.2). Flucytosine itself is not cytotoxic but, rather, is a pro-drug that is taken up by fungi and metabolized to 5-fluorouracil (5-FU) by fungal cytidine deaminase (Fig. 40.11) (51). Then, 5-FU is converted to 5-fluorodeoxyuridine, which as a thymidylate synthase inhibitor interferes with both protein and RNA biosynthesis. 5-Fluorouracil is cytotoxic and is employed in cancer chemotherapy (see Chapter 42). Human cells do not contain cytosine deaminase and, therefore, do not convert flucytosine to 5-FU. Some intestinal flora, however, do convert the drug to 5-FU, so human toxicity does result from this metabolism. Resistance rapidly develops to flucytosine when used alone, so it is almost always used in conjunction with amphotericin B. Use of flucytosine has declined since the discovery of fluconazole.

Griseofulvin



Griseofulvin is an antifungal antibiotic produced by an unusual strain of *Penicillium* (52). It is used orally to treat

superficial fungal infections, primarily fingernail and toenail infections, but it does not penetrate skin or nails if used topically (Table 40.2). When given orally, however, plasmaborne griseofulvin becomes incorporated into keratin precursor cells and, ultimately, into keratin, which cannot then support fungal growth. The infection is cured when the diseased tissue is replaced by new, uninfected tissue, which can take months. The mechanism of action of griseofulvin is through binding to the protein tubulin, which interferes with the function of the mitotic spindle and, thereby, inhibits cell division. Griseofulvin also may interfere directly with DNA replication. Griseofulvin is gradually being replaced by newer agents (53).

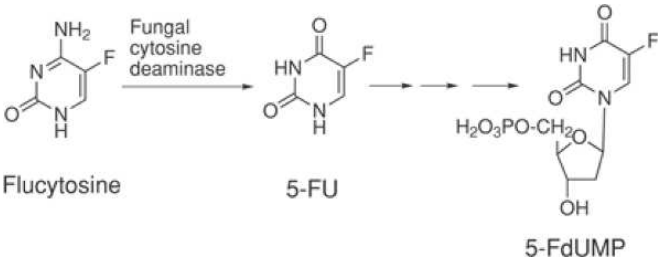


Fig. 40.11. Flucytosine, a pro-drug, is converted by fungal cytosine deaminase to 5-fluorouracil (5-FU). This reaction does not occur in mammalian cells. A further transformation of 5-FU to the actual cytotoxic agent, 5-fluorodeoxyuridine monophosphate (5-FdUMP), also occurs.

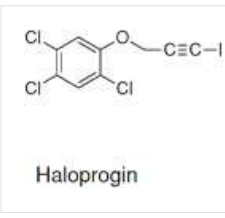
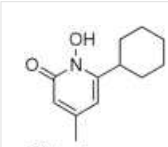
Haloprogin



Haloprogin

Haloprogin is an iodinated acetylene active against dermatophytes (54). Haloprogin is only used for topical applications (Table 40.1). The mechanism of haloprogin is not clear, but it appears to lead to nonspecific metabolic disruption. It has been demonstrated to interfere with DNA biosynthesis and cell respiration.

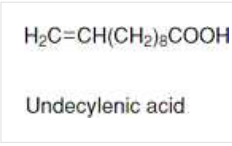
Ciclopirox



Ciclopirox

Ciclopirox is a hydroxylated pyridinone that is employed for superficial dermatophytic infections, principally onychomycosis. Ciclopirox has a unique mechanism of action through chelation of polyvalent cations, such as Fe^{3+}, which causes inhibition of a number of metal-dependent enzymes within the fungal cell. Although ciclopirox has been available for more than 30 years, a new formulation of an 8% lacquer has been recently introduced for treating nail infections (55).

Undecylenic Acid



Undecylenic acid

Undecylenic acid is widely employed, frequently as the zinc salt, in over-the-counter preparations for topical treatment of infections by dermatophytes (Table 40.1) (56). Undecylenic acid is fungistatic that acts through a nonspecific interaction with components in the fungal cell membrane.

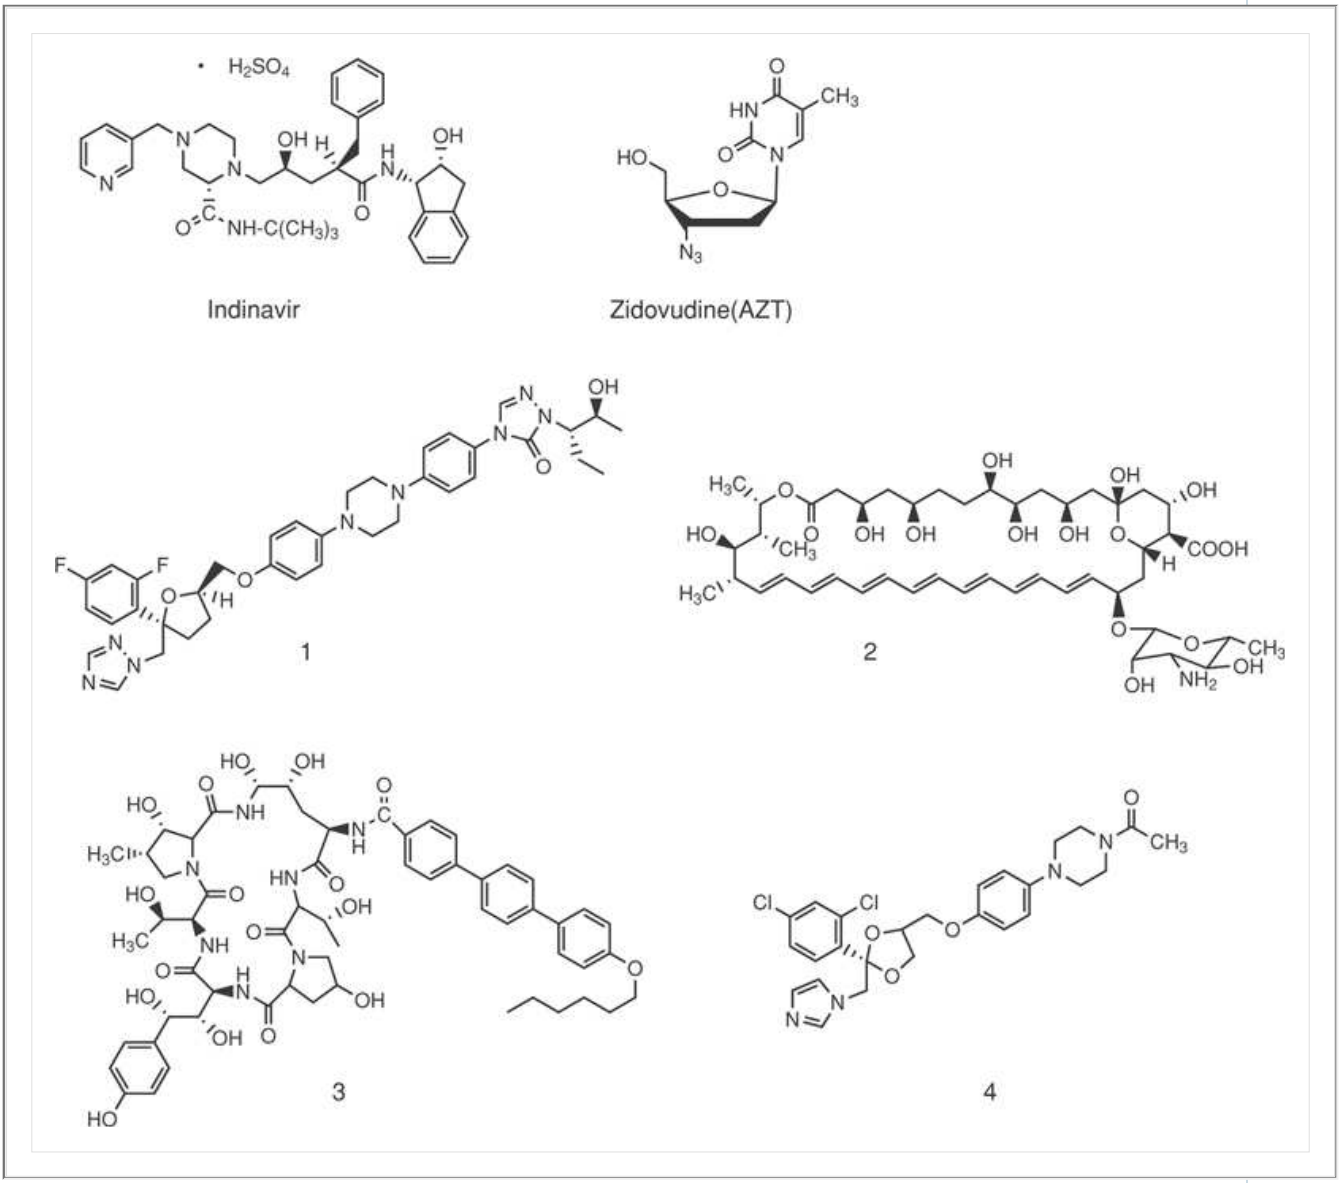
Case Study

Victoria F. Roche

S. William Zito

KK is a 42-year-old, Brazilian-born executive who works for Ronald Stump, an internationally famous investment mogul and entrepreneur who mentors (and generously rewards) go-getters like KK. KK's career potential seemed unlimited until he acquired AIDS from a previous partner who was unaware of his HIV-positive status at the time of their relationship. The last year has been tough for KK, who has always been athletic, adventurous, and seemingly indestructible, but he has fallen ill several times in the past 12 months with bacterial and viral infections, including a particularly nasty case of poststreptococcal nephritis. He is currently on antiviral therapy that includes indinavir sulfate (Crixivan, 800 mg every 8 hours) and zidovudine (Retrovir, 300 mg b.i.d.). Although he is still able to work and is managing fairly well, he is fearful about the anticipated final outcome of his disease and is employing spiritual and nontraditional strategies in an attempt to heal.

As part of this holistic approach to healing, KK flew to the Amazon and spent two nights alone on the edge of the jungle, seeking insight and peace through reflection and prayer. All he took in with him was his medication and a sufficient amount of food and water to last for 48 hours. He felt safe, however, because he was within a 20-minute walk of a tribal community and could sound an alarm that would alert people in case of danger or an emergency. He slept under the stars, pulling up ground vegetation into a “natural” bed each night. He felt emotionally restored after the experience—until it became known that he had inhaled dust contaminated with the soil fungus *P. brasiliensis* and a species of *Aspergillus* mold. He is now in the critical care wing of your hospital with a disseminated fungal infection. The therapeutic plan is to start him on an appropriate IV antifungal agent supplemented with oral therapy. Consider the structures of the antifungal agents drawn below, and identify suitable parenteral and oral antifungal drug products for KK.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives

provided in the case.

4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 41

Antimycobacterial Agents

Thomas L. Lemke

Drugs covered in this chapter:

Antimycobacterial agents

Antituberculin drugs

- Capreomycin
- Cycoserine
- Ethambutol
- Ethionamide
- Isoniazid
- Kanamycin
- Para aminobenzoic acid
- Pyrazinamide
- Rifampin
- Rifapentine
- Streptomycin

MAC therapy

- Azithromycin
- Clarithromycin

Leprostatic drugs

- Clofazimine
- Dapsone
- Rifampin
- Thalidomide

General Considerations

Mycobacteria are a genus of acid-fast bacilli belonging to the Mycobacteriaceae, which include the organisms responsible for tuberculosis and leprosy as well as a number of other, less common diseases. Characteristic of mycobacteria is the fact that these organisms tend to be slow-growing, difficult to stain, and when they are stained with basic dye, can resist decolorization with acid alcohol. The staining characteristics relate to the abnormally high lipid content of the cell wall. In fact, the cell wall or cell envelope of the mycobacterium holds the secret to many of the characteristics of this genus of organisms. The cell envelope is unique in both structure and complexity. It has been suggested that the cell envelope is responsible for

mycobacterium pathogenicity or virulence, multiple drug resistance, cell permeability, immunoreactivity and inhibition of antigen responsiveness, as well as disease persistence and recrudescence. In addition, several of the successful chemotherapeutic agents are know to inhibit the cell envelope synthesis as their mechanism of action. It is no wonder that significant effort has been put forth to define the chemical structure of the mycobacterium cell envelope.

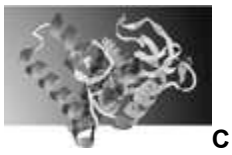
A series of papers were presented and reported in 1991 dealing with the topic of the structure and functions of the cell envelope of mycobacterium (1). As illustrated in Figure 41.1, the mycobacterial cell envelope contains, on the interior surface, a plasma membrane similar to that found in most bacteria. A conventional peptidoglycan layer affording the organism rigidity appears next. This layer is composed of alternating N-acetyl-D-glucosamines (Glu) linked to N-glycoyl-D-muramic acids (Mur) through 1–4 linkages that, in turn, is attached to the peptido chain of D-alanine (A), D-glutamine (G), meso-diaminopimelic acid (DP), and L-alanine (A). A novel disaccharide phosphodiester linker made up of N-acetyl-D-glucosamine and rhamnose connects the muramic acid to a polygalactan and polyarabinose chain. The latter polysaccharides are referred to as the arabinogalactan (AG) portion of the cell envelope. The manner in which the arabinosyl and galactosyl resides are arranged is still under investigation. It is known that the arabinosyl chains terminate in mycolic acid residues. (The mycolates will be discussed in more detail later in this chapter.) Noncovalently bound to the mycolates are a number of free nonpolar and polar lipids (the phthiocerol lipids and the glycopeptidolipids, respectively). Finally, spanning from the interior, embedded in the plasma membrane, to the exterior is the lipoarabinomannan (LAM) polymer. As indicated, this unit is composed of polyarabinose, polymannan, and various lipids attached through a phosphatidylinositol moiety (2,3).

Specific Diseases

Leprosy (Hansen's Disease)

Throughout the Bible, one finds reference to the condition of leprosy, such as that described in *Leviticus*: “[I]s there any flesh in the skin of which there is a burn by fire, and the quick flesh of the burn becomes a bright spot, reddish white or white,...and if the hair in the bright spot is turned white, and it appears deeper than the skin, it is leprosy broken out in the burn.” Associated with the disease was a belief that individuals suffering from this disease were unclean. Today, leprosy (Hansen's disease) is recognized as a chronic granulomatous infection caused by *Mycobacterium leprae*. The disease may consist of lepromatous leprosy, tuberculoid leprosy, or a condition with characteristics between these two poles and referred to as borderline leprosy. The disease is more common in tropical countries but is not limited to warm climate regions. It is thought to afflict some 10 to 20 million individuals. Children appear to be the most susceptible population, but the signs and symptoms usually do not occur until much later in life. The incubation period usually is

three to five years. The disease is contagious, but the infectiousness is quite low. Person-to-person contact appears to be the means by which the disease is spread, with entrance into the body occurring through the skin or the mucosa of the upper respiratory tract. Skin and peripheral nerves are the regions most susceptible to attack.



Clinical Significance

Diseases caused by mycobacteria, such as tuberculosis and *Mycobacterium avium–intracellulare* complex, are of great concern to both health care workers and the public. Understanding the infectivity and pathophysiology of mycobacteria and the medicinal

chemistry of the antimicrobials in the complex treatment of mycobacterial infections can help to facilitate a clinician's pharmacotherapy decisions. Mycobacteria are very-slow-growing organisms that grow both intracellularly and extracellularly. Because of their growth, the treatment of mycobacterial infections, especially tuberculosis, requires long-term treatment with a combination of agents to effectively eradicate the disease and prevent resistance. In addition, many of these agents are associated with significant side effects and drug interactions. A good understanding about the medicinal chemistry of the antimycobacterial agents helps the clinician to determine the most effective and safe combination for an individual patient.

The continuing interest in the study of the medicinal chemistry of antimycobacterial agents is prudent in the development of newer and safer agents. Researchers are continuously looking for agents that have more rapid antimycobacterial activity as well as lower resistance and fewer side effects. The discovery of such agents would have a significant effect on increasing the eradication of this worldwide epidemic. Shorter-course therapies would lead to an increase in patient compliance and possible decrease in mycobacterial resistance. As newer and more effective therapies are developed, clinicians will need to stay informed of these therapies, such as their pharmacokinetic and pharmacodynamic profiles, so that their patients can get the most optimal and effective treatment.

Elizabeth Coyle, Pharm.D.
Clinical Assistant Professor, Department of Clinical Sciences & Administration, University of Houston College of Pharmacy

The first signs of the disease consist of hypopigmented or hyperpigmented macules. Additionally, anesthetic or paresthetic patches may be experienced by the patient. Neural involvement in the extremities ultimately leads to muscle atrophy, resorption of small bones, and spontaneous amputation. When facial nerves are involved, corneal ulceration and blindness may occur. The identification of *M. leprae* in skin or blood samples is not always possible, but the detection of the antibody to the organism is an effective diagnostic test, especially for the lepromatous form of the disease.

Tuberculosis

Tuberculosis (TB) is a disease that has been known from the earliest of recorded history. It is characterized as a chronic bacterial infection caused by *Mycobacterium*

tuberculosis, an acid-fast, aerobic bacillus with the previously discussed, unusual cell wall. The cell wall has a high lipid content, resulting in a high degree of hydrophobicity and resistance to alcohol, acids, alkali, and some disinfectants. After staining with a dye, the *M. tuberculosis* cell wall cannot subsequently be decolorized with acid wash, thus the characteristic of being an acid-fast bacillus. It is estimated that today, one-third to one-half of the world population is infected with *M. tuberculosis*, leading to approximately 6% of all deaths worldwide (~2 million deaths) (4,5). Tuberculosis is the leading worldwide cause of mortality resulting from an infectious bacterial agent. A steady decline in the reported cases of TB had been occurring in the United States from the 1950s until 1985. From 1985 until 1988, however, this decline leveled off, but beginning in 1989, an increase was noted. In 1991, the Centers for Disease Control and Prevention (CDC) reported 25,701 new cases of TB. Today, the press and professional publications announce the “epidemic” spread of TB. The resurgence has been linked to urban crowding, homelessness, immigration, drug abuse, the disappearance of preventive-medicine health clinics, crowded prisons, and the AIDS epidemic. “Most alarming is the emergence of multidrug-resistant TB” (MDR-TB) (6). Before 1984, only 10% of the organisms isolated from patients with TB were resistant to any drug. In 1984, 52% of the organisms were resistant to at

least one drug, and 32% were resistant to more than one drug. MDR-TB may have a fatality rate as high as 50%. As a result of MDR-TB, isolates of *M. tuberculosis* should be tested for antimicrobial susceptibility. In fact, drug resistance is encountered in patients who have never been treated with any of the TB drugs.

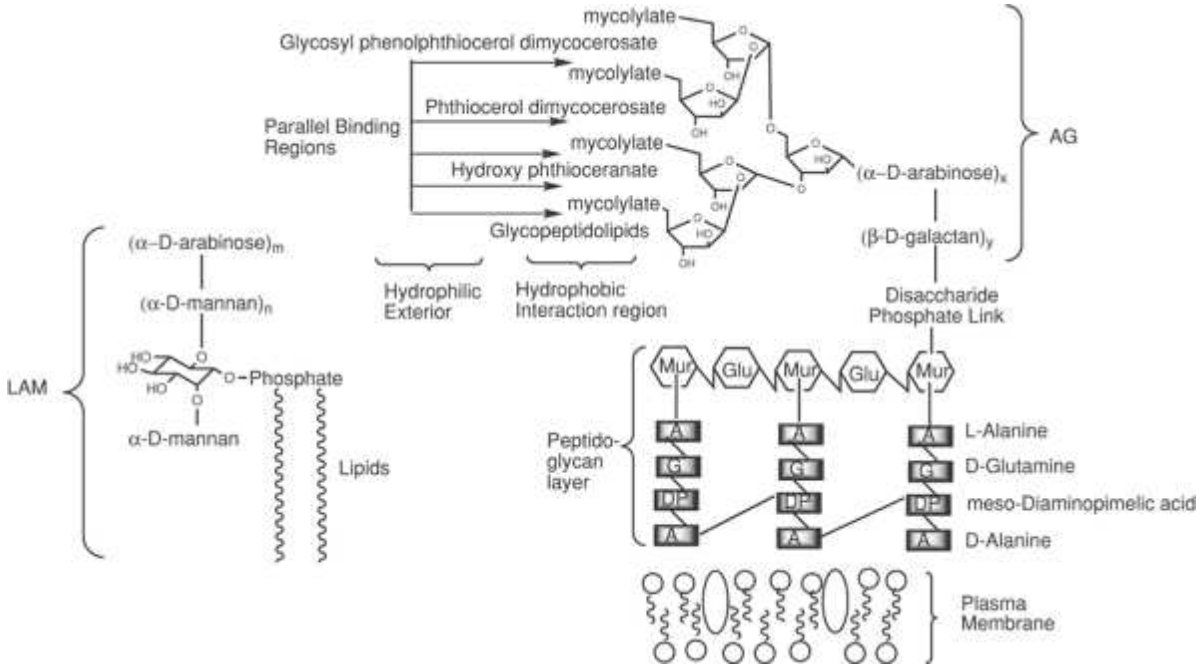


Fig. 41.1. Diagrammatic representation of the cell wall/cell envelope of mycobacterium.

Mycobacterium tuberculosis is transmitted primarily via the respiratory route. The organism appears in water droplets expelled during coughing, sneezing, or talking. Either in the droplet form or as the desiccated airborne bacilli, the organism enters the respiratory tract. The infectiousness of an individual will depend on the extent of the disease, the number of organisms in the sputum, and the amount of coughing. Usually, within 2 weeks of beginning therapy, the infected individual will no longer be infectious. TB is a disease that mainly affects the lungs (80–85% of the cases), but *M. tuberculosis* can spread through the bloodstream and the lymphatic system to the brain, bones, eyes, and skin (extrapulmonary TB). In pulmonary TB, the bacilli reach the alveoli and are ingested by pulmonary macrophages. Substances secreted by the macrophages stimulate surrounding fibroblasts to enclose the infection site, leading to formation of granulomas or tubercles. The infection, thus contained locally, may lie dormant, encapsulated in a fibrotic lesion, for years and then reappear later. Extrapulmonary TB is much more common in HIV-infected patients (40–75%).

Because of the effect of the AIDS virus on the immune system, all HIV-infected individuals should be screened for TB, and if infected, the patient should be treated for TB before an active infections develops. Patients with HIV infection and TB are 100-fold more likely of developing an active infection than noninfected patients. Individuals diagnosed with active TB should be counseled and tested for HIV, because the TB may have developed in conjunction with the weakened immune system seen in the patient with HIV infection.

Mycobacterium Avium–Intracellulare Complex

Mycobacterium avium and *Mycobacterium intracellulare* are atypical acid-fast bacilli that are ubiquitous in the environment and usually considered to be nonpathogenic in healthy individuals. Unfortunately, in immune-compromised individuals, these and possibly other, unidentified mycobacteria cause severe, life-threatening infections. Disseminated *Mycobacterium avium–intracellulare* complex (MAC) is the most common bacterial opportunistic infection seen in patients with AIDS and the third most common opportunistic infection behind candidal esophagitis and primary *Pneumocystis carinii* pneumonia reported in patients with AIDS. Between 1981 and 1987, and before the availability of effective antiretroviral medication, the incidence of MAC was reported as 5%. Today, approximately half of all patients with AIDS develop an infection caused by MAC. The lungs are the organs most commonly involved in patients without AIDS, but the infection may involve bone marrow, lymph nodes, liver, and blood in patients with AIDS. The CD4 T-lymphocyte count is used as a predictor for risk of disseminated MAC; a count of less than 50 cells/mm^3 in an HIV-infected person (adult or adolescent) is an indication of a potential infection and a recommendation for chemoprophylaxis. The MAC organisms grow within macrophages; therefore, the drug must be capable of penetration of the macrophage. Treatment of MAC, both prophylactically and for diagnosed infections, requires the use of multidrug therapy, and for disseminated MAC, this treatment is for the life of the patient.

General Approaches to Drug Therapy

The mycobacteria have a number of characteristics in common, but it is important to recognize that the species vary widely in their susceptibility to the different drugs and that, in turn, this may relates to significant differences in the organisms. Some species, such as *M. tuberculosis*, are very slow-growing, with a doubling time of approximately 24 hours, whereas others, such as *Mycobacterium smegmatis*, doubles in 2 to 3 hours. The pathogenic mycobacterial organism can be divided into organism that are actively metabolizing and rapidly growing; semidormant bacilli, which exhibit spurts of metabolism bacilli in acid pH; and dormant or persisters. The latter characteristic is the most problematic and responsible for treatment failures. Most current TB drugs are those that are effective against actively metabolizing and rapidly growing bacilli. Thus,

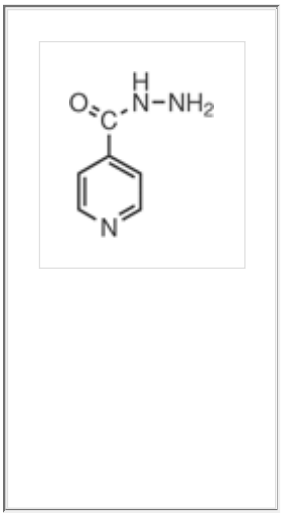
successful chemotherapy calls for drugs with bactericidal action against all stages of the organisms—but especially against the persisters. The use of combination therapy over an extended period of time is one answer to successful treatment.

Drug Therapy for Tuberculosis

Drug therapy for the treatment of TB has been greatly hampered by the development of MDR-TB and the lack of new classes of drugs. In fact, no new drugs have been developed in the last 40 years. The only change in the treatment of TB has been the strategy of using direct observed treatment (DOT), with an emphasis on patient-centered care (7). Additionally, whereas the course of treatment has been reduced, through the use of drug combinations, to 6 months, patient compliance continues to be a serious problem, which in turn may be associated with the development of bacterial resistance.

First-Line Agents

Isoniazid (Isonicotinic Acid Hydrazide, Nydrazid, Laniazid)



Isoniazid (INH) is a synthetic antibacterial agent with bactericidal action against *M. tuberculosis*. The drug was discovered in the 1950s as a beneficial agent effective against intracellular and extracellular bacilli, and it generally is considered to be the primary drug for treatment of *M. tuberculosis*. Its action is bactericidal against replicating organisms, but it appears to be only bacteriostatic at best against semidormant and dormant populations. After treatment with INH, *M. tuberculosis* loses its acid fastness, which may be interpreted as indicating that the drug interferes with cell wall development.

Mechanism of action

Although extensively investigated, the mechanism of action of INH has remained unknown until recently. New investigations into mechanisms of bacterial resistance have shed light on the molecular mechanism of action of INH (8). It generally is recognized that INH is a pro-drug that is activated through an oxidation reaction catalyzed by an endogenous enzyme (9). This enzyme, katG, which exhibits catalase-peroxidase activity, converts INH to a reactive species capable of acylation of an enzyme system found exclusively in *M. tuberculosis*. Evidence in support of the activation of INH reveals that INH-resistant isolates have decreased catalase activity and that the loss of catalase activity is associated with the deletion of the catalase gene, *katG*. Furthermore, reintroduction of the gene into resistant organisms results in restored sensitivity of the organism to the drug. Reaction of INH with catalase-peroxidase results in formation of isonicotinaldehyde, isonicotinic acid, and isonicotinamide, which can be accounted for through the reactive intermediate isonicotinoyl radical or isonicotinic peroxide, as shown in Figure 41.2 (10). Evidence has been offered both for and against the reaction of catalase-peroxidase activated INH with a portion of the enzyme inhA, which is involved in the biosynthesis of the mycolic acids (Fig. 41.3) (11,12,13). The mycolic acids are important constituents of the mycobacterial cell wall in that they provide a permeability barrier to hydrophilic solutes. The enzyme inhA, produced under the control of the *inhA* gene, is an NADH-dependent, enoyl reductase protein thought to be involved in double-bond reduction during fatty acid elongation (Fig. 41.4). Isoniazid specifically inhibits long-chain fatty acid synthesis (>26 carbon atoms). It should be noted that the mycolic acids are α-branched lipids having a “short” arm of 20 to 24 carbons and a “long” arm of 50 to 60 carbons. It has been proposed that INH is activated to an electrophilic species that acylates the four position of the NADH (Fig. 41.5, on page 1132). The acylated NADH is no longer capable of catalyzing the reduction of unsaturated fatty acids, which are essential for the synthesis of the mycolic acids (14,15,16).

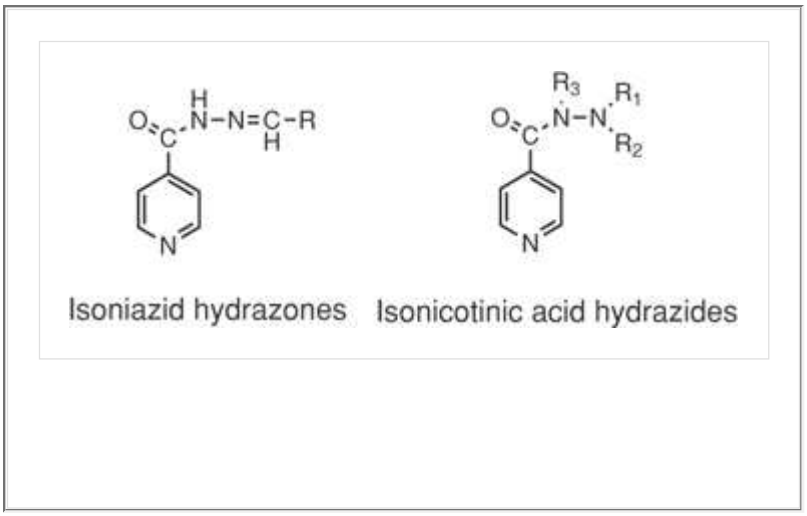
Structure–activity relations

An extensive series of derivatives of nicotinaldehyde, isonicotinaldehyde, and substituted isonicotinic acid hydrazide have been prepared and investigated for their tuberculostatic activity. Isoniazid hydrazones were found to possess activity, but these compounds were shown to be unstable in the gastrointestinal (GI) tract, releasing the active isonicotinic acid hydrazide (i.e., INH). Thus, it would appear that their activity resulted from the INH and not from the derivatives (17,18). Substitution of the hydrazine portion of INH with alkyl and aralkyl substituents resulted in a series of active and inactive derivatives (19,20,21,22).

Substitution on the N-2 position resulted in active compounds (R1 and/or R2 = alkyl; R3 = H), whereas any substitution of the N-1 hydrogen with alkyl groups destroyed the activity (R1 and R2 = H; R3 = alkyl). None of these changes produced compounds with activity superior to that of INH.



Metabolism

Isoniazid is extensively metabolized to inactive metabolites (Fig. 41.6, on page 1132) (23,24). The major metabolite is N-acetylisoniazid. The enzyme responsible for acetylation, cytosolic N-acetyltransferase, is produced under genetic control in an inherited autosomal fashion. Individuals who possess high concentrations of the enzyme are referred to as rapid acetylators, whereas those with low concentrations are slow acetylators. This may result in a need to adjust the dosage for fast acetylators. The N-acetyltransferase is located primarily in the liver and small intestine. Other metabolites include isonicotinic acid, which is found in the urine as a glycine conjugate, and hydrazine. Isonicotinic acid also may result from hydrolysis of acetylisoniazid, but in this case, the second product of hydrolysis is acetylhydrazine. Acetylhydrazine is acetylated by N-acetyltransferase to the inactive diacetyl product. This reaction occurs more rapidly in rapid acetylators. The formation of acetylhydrazine is significant in that this compound has been associated with the hepatotoxicity, which may occur during INH therapy. Acetylhydrazine has been postulated to serve as a substrate for microsomal P450, resulting in the formation of a chemical that is capable of acetylating liver protein, in turn resulting in the liver necrosis (25). It has been suggested that a hydroxylamine intermediate is formed that results in an active acetylating agent (Fig. 41.7, on page 1132). The acetyl radical/cation acylates liver protein.

Pharmacokinetics

Isoniazid is readily absorbed following oral administration. Food and various antacids, especially aluminum-containing antacids, may interfere with or delay the absorption; therefore, it is recommended that the drug be taken on an empty stomach. The drug is well distributed to body tissues, including infected tissue. A long-standing concern about the use of INH during

preventive therapy for latent TB has been the high incidence of hepatotoxicity. Recent studies have concluded that, excluding patients over 35 years of age, if relevant clinical monitoring is employed, the rate of hepatotoxicity is quite low (26). The risk of hepatotoxicity is associated with increasing age and appears to be higher in women than in men.

Rifamycin Antibiotics

The rifamycins are members of the ansamycin class of natural products produced by *Streptomyces mediterranei*. This chemical class is characterized as molecules with an

aliphatic chain forming a bridge between two nonadjacent positions of an aromatic moiety. While investigating the biological activity of the naturally occurring rifamycins (B, O, and S), a spontaneous reaction gave the biologically active rifamycin SV, which was later isolated from natural sources. Rifamycin SV was the original rifamycin antibiotic chosen for clinical development (27). Semisynthetic derivatives are prepared via conversion of the natural rifamycins to 3-formylrifamycin, which is derivatized with various hydrazines to give products such as rifampin (RIF) and rifapentine. Rifampin and rifapentine have significant benefit over previously investigated rifamycins in that they are orally active, are highly effective against a variety of both Gram-positive and Gram-negative organisms, and have high clinical efficacy in the treatment of TB. The rifamycin antibiotics are active against both growing and slow-metabolizing, nongrowing bacilli.

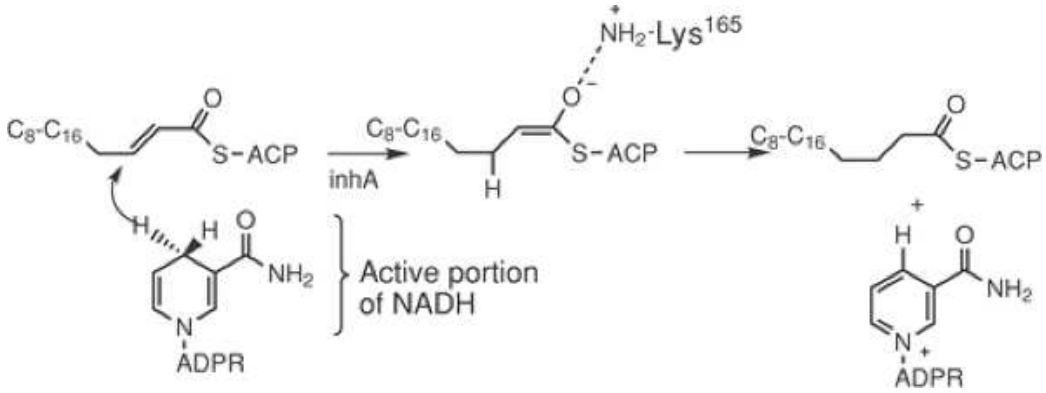


Fig. 41.4. Enoylthioester. ACP, acyl carrier (protein) reduction catalyzed by NADH and inhA.

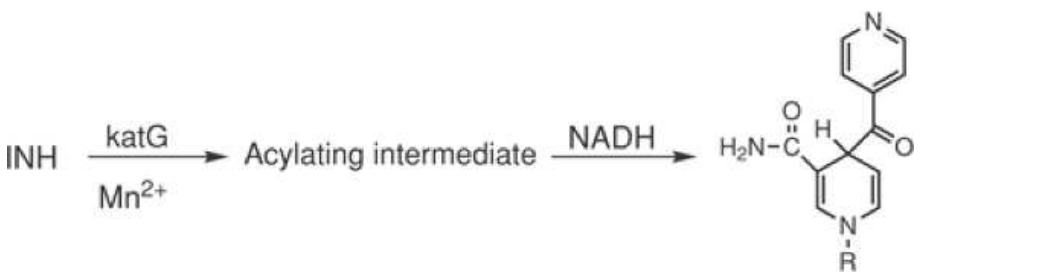

Fig. 41.5. Acylation of NADH and NADH-dependent enoylacyl protein (inhA).

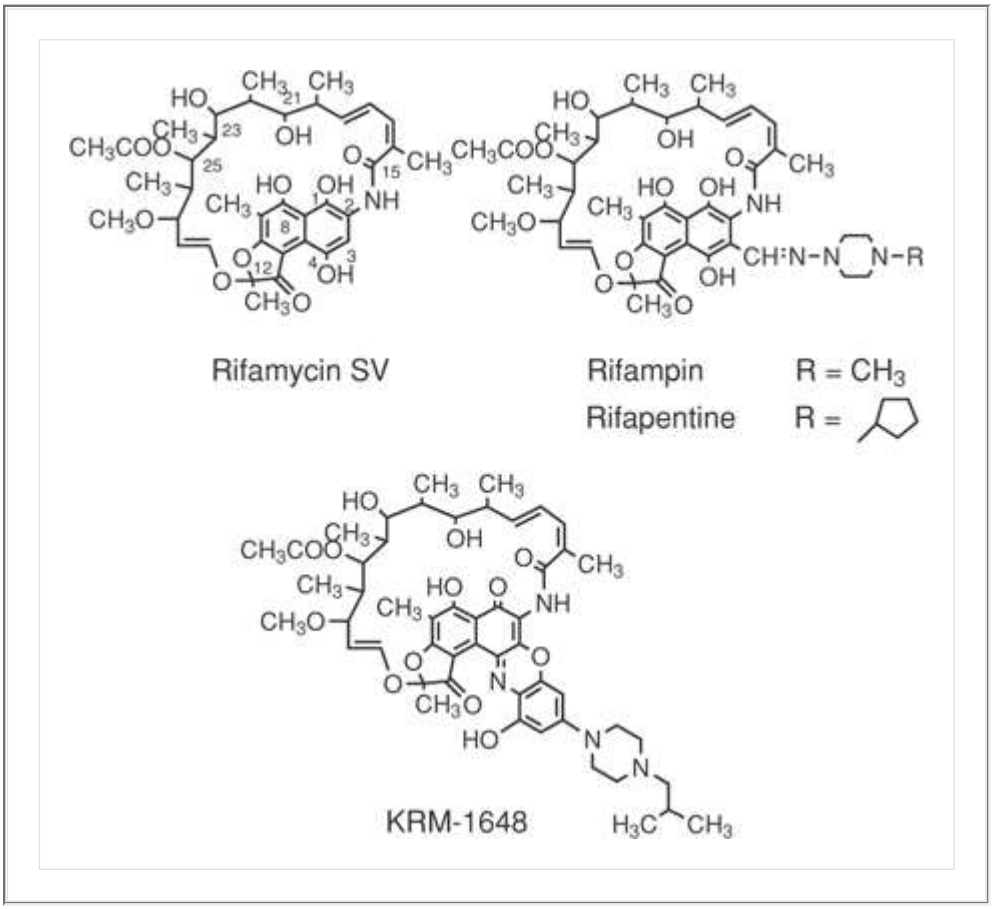

Mechanism of action

The rifamycins inhibit bacterial DNA-dependent RNA polymerase (DDRP) by binding to the β-subunit of the enzyme and are highly active against rapidly dividing intracellular and extracellular bacilli. Rifampin is active against DDRP from both Gram-positive and Gram-negative bacteria, but because of poor penetration of the cell wall of Gram-negative organisms by RIF, the drug has less value in infections caused by such organisms. Inhibition of DDRP leads to blocking the initiation of chain formation in RNA synthesis. It has been suggested that the naphthalene ring of the rifamycins π-π bonds to an aromatic amino acid ring in the DDRP protein (28). The DDRP is a metalloenzyme that contains two zinc atoms. It is further postulated that the oxygens at C-1 and C-8 of a rifamycin can chelate to a zinc atom, which increases the binding to DDRP, and finally, the oxygens at C-21 and C-23 form strong hydrogen bonds to the DDRP. The binding of the rifamycins to DDRP results in the inhibition of the RNA synthesis. Specifically, RIF has been shown to inhibit the elongation of full-length transcripts, but it has no effect on transcription initiation (8). Resistance develops when a mutation occurs in the gene responsible for the β-subunit of the RNA polymerase (*rpoB* gene), resulting in an inability of the antibiotic to readily bind to the RNA polymerase (29).

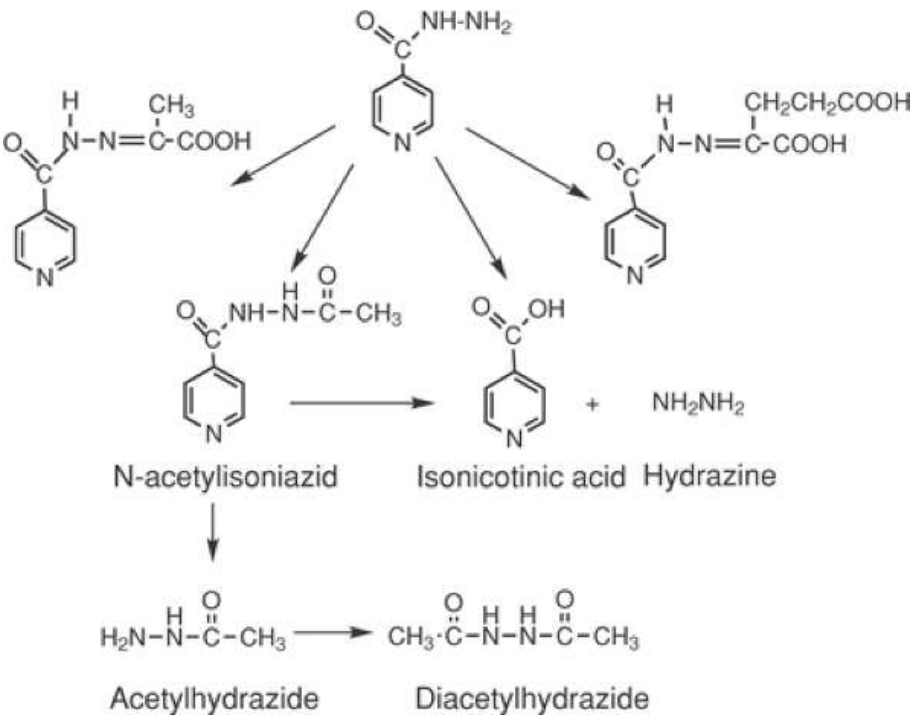

Fig. 41.6. Metabolism of isoniazid.

Structure–activity relationship

A large number of derivatives of the naturally occurring rifamycins have been prepared (30). From these compounds, the following generalizations can be made concerning the structure–activity relationship (SAR): 1) Free -OH groups are required at C-1, C-8, C-21, and C-23; 2) these groups appear to lie in a plane and to be important binding groups for attachment to DDRP, as previously indicated; 3) acetylation of C-21 and/or C-23 produces inactive compounds; 4) reduction of the double bonds in the macro ring results in a progressive decrease in activity; and 5) opening of the macro ring also gives inactive compounds. These latter two changes greatly affect the conformational structure of the rifamycins, which in turn

decreases binding to DDRP. Substitution at C-3 or C-4 results in compounds with varying degrees of antibacterial activity. The substitution at these positions appears to affect transport across the bacterial cell wall. A compound incorporating such substitution is the benzoxazinorifamycin KRM-1648, which is proceeding through clinical investigation. In vitro studies have shown rapid tissue sterilization and encouraging results concerning combination therapy for TB and, possibly, MAC.

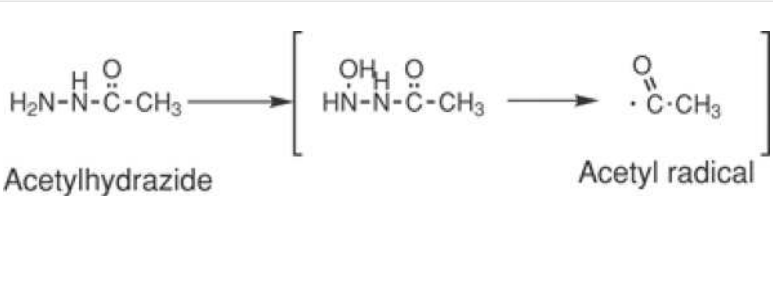

Fig. 41.7. Acylating metabolite of isoniazid.

Metabolism

Rifampin and rifapentine are readily absorbed from the intestine, although food in the tract may affect absorption. Rifampin's absorption may be reduced by food in the intestine; therefore, the drug should be taken on an empty stomach (24). Intestinal absorption of rifapentine has been reported to be enhanced when taken after a meal (31). Neither drug appears to interfere with the absorption of other antituberculin agents, but there are conflicting reports on whether INH affects absorption of RIF. The major metabolism of RIF and rifapentine is deacetylation, which occurs at the C-25 acetate (Fig. 41.8). The resulting product, desacetylrifampin and desacetylrifapentine, are still active antibacterial agents. The majority of both desacetyl products are found in the feces, but desacetylrifampin glucuronide may be found in the urine as well. 3-Formylrifamycin SV has been reported as a second metabolite following both RIF and rifapentine administration. This product is thought to arise in the gut from an acid-catalyzed hydrolysis reaction. Formylrifamycin is reported to possess a broad spectrum of antibacterial activity (32).

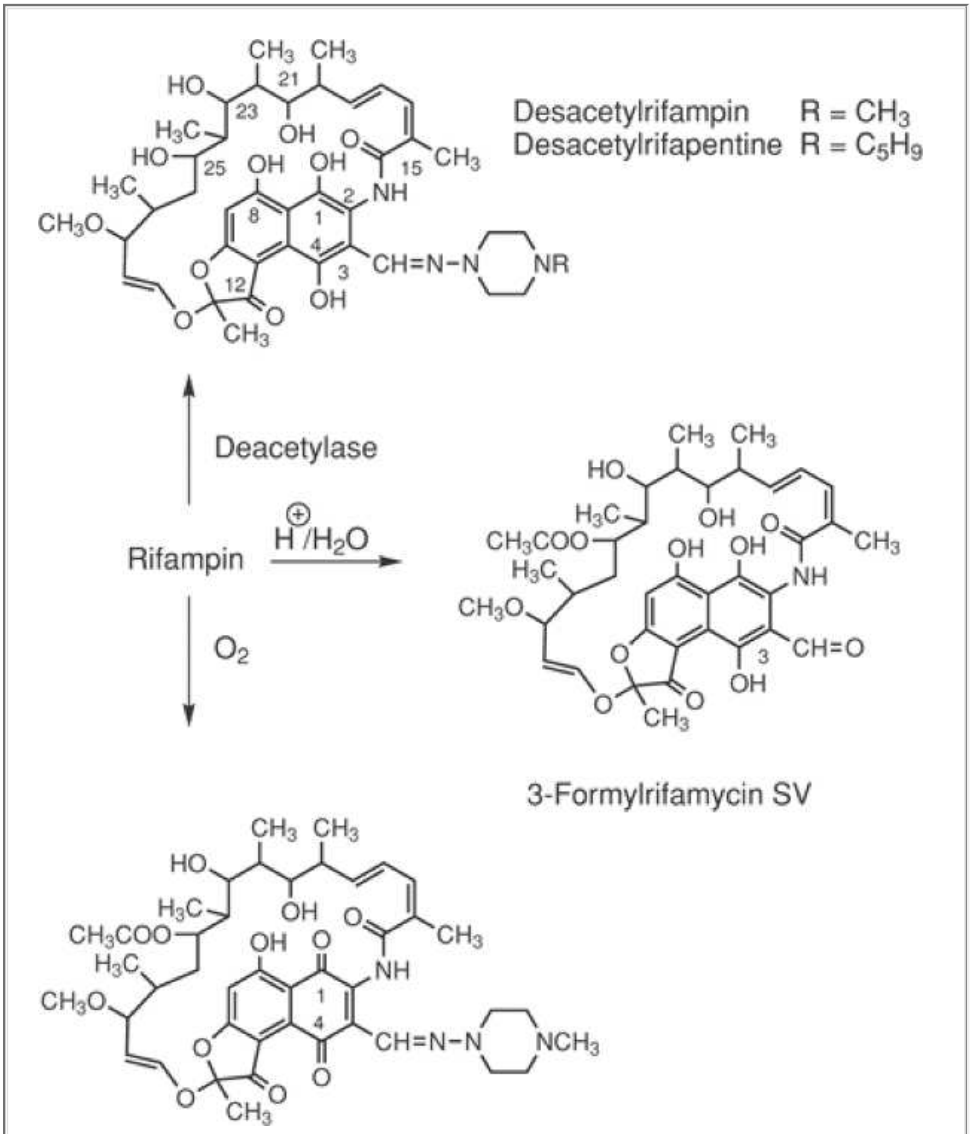

Fig. 41.8. Metabolism and in vitro reactions of rifampin.

Physicochemical properties

Rifampin and rifapentine are red-orange, crystalline compounds with zwitterionic properties. The presence of the phenolic groups results in acidic properties (pK_a ~ 1.7), whereas the piperazine moiety gives basic properties (pK_a ~ 7.9). These compounds are prone to acid hydrolysis, giving rise to 3-formylrifamycin SV, as indicated above. Rifampin and presumable rifapentine are prone to air oxidation of the *p*-phenolic groups in the naphthalene ring to give the *p*-quinone (C-1,4 quinone) (Fig. 41.8). Rifampin, rifapentine, and their metabolites are excreted in the urine, feces (biliary excretion), saliva, sweat, and tears. Because these agents have dye characteristics, one may note discoloration of the body fluids containing the drug. Notably, the tears may be discolored, and permanent staining of contact lenses may occur.

Therapeutic application

Rifampin (Rifadin, Rimactane)

With the introduction of RIF in 1967, the duration of combination therapy for the treatment of TB was significantly reduced (from 18 to 9 months). Rifampin is nearly always used in combination with one or more other antituberculin agents. The drug is potentially hepatotoxic and may produce GI disturbances, rash, and thrombocytopenic purpura. Rifampin is known to induce hepatic microsomal enzymes (cytochrome P450) and may decrease the effectiveness of oral contraceptives, corticosteroids, warfarin, quinidine, methadone, zidovudine, clarithromycin, and the azole antifungal agents (see Chapter 10) (33).

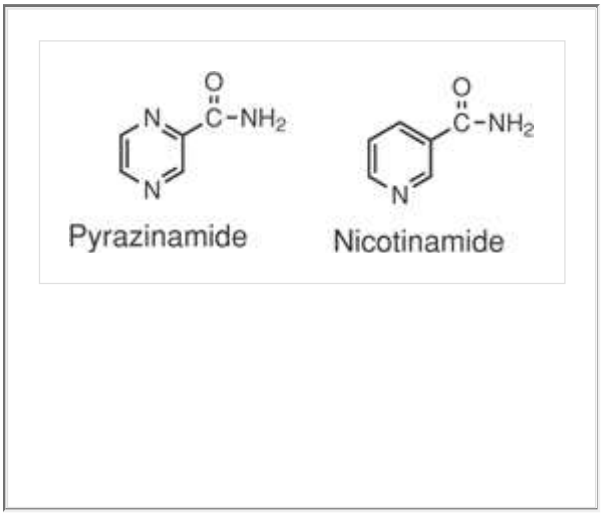
Because of the decreased effectiveness of protease inhibitors and nonnucleoside reverse transcriptase inhibitors used in the treatment of HIV, the CDC has recommended avoidance of RIF in treatment of HIV-infected patients presently on these HIV therapies.

Rifapentine (Priftin)

Rifapentine is the first new agent introduced for the treatment of pulmonary TB in the last 25 years. The drug's major advantage over RIF is the fact that when used in combination therapy, rifapentine can be administered twice weekly during the “intense” phase of therapy, followed by once-a-week administration during the “continuous” phase. In contrast, RIF normally is administered daily during the “intense” phase, followed by twice-a-week dosing during the “continuous” phase. Because relapse and the emergence of resistant strains of bacteria are associated with poor patient compliance, reduced dosing is expected to increase compliance. Initial clinical studies actually showed that the relapse rates in patients treated with rifapentine (10%) were higher than those in the patients treated with RIF (5%). It was found that poor compliance with the nonrifamycin antituberculin agents was responsible for the increased relapse (31).

Rifapentine is readily absorbed following oral administration and is highly bound to plasma protein (97.7% vs. 80% for RIF). Related to the higher plasma binding, refapentine has a longer mean elimination half-life (13.2 hours in healthy male volunteers) in comparison with the half-life reported for RIF (~2–5 hours). Greater than 70% of either drug is excreted in the feces. Rifapentine generally is considered to be more active than rifampin and can be used in patients with varying degrees of hepatic dysfunction without the need for dose adjustment (34). This drug, similar to what is seen with RIF, induces hepatic microsomal enzymes (cytochrome P450 3A4 and 2C8/9). Rifapentine has been reported to be teratogenic in rats and rabbits (31).

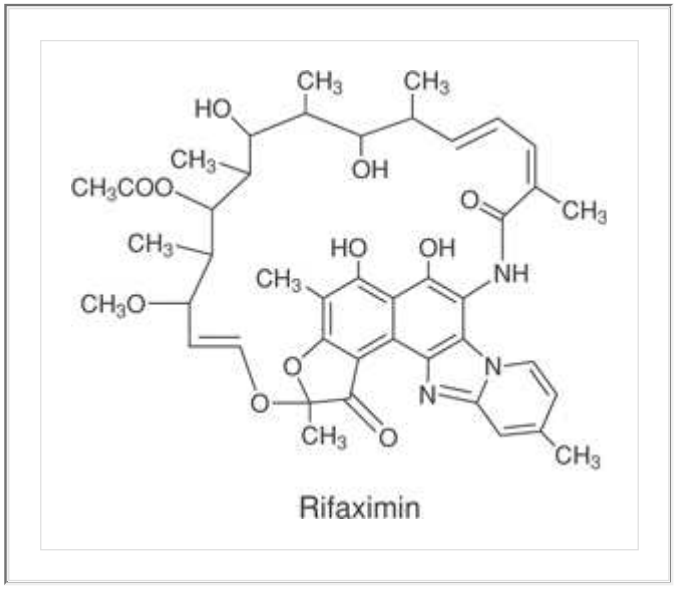
Pyrazinamide



Pyrazinamide (pyrazinecarboxamide) was discovered while investigating analogues of

nicotinamide. Pyrazinamide is a bio-isoster of nicotinamide and possesses bactericidal action against *Mycobacterium tuberculosis*. Pyrazinamide has become one of the more popular antituberculin agents despite the fact that resistance develops quickly. Combination therapy, however, has proven to be an effective means of reducing the rate of resistant strain development. The activity of pyrazinamide is pH dependent with good in vivo activity at pH 5.5, but the compound is nearly inactive at neutral pH.

Rifaximin (Xifaxan)



Recently, the U.S. Food and Drug Administration (U.S. FDA) has approved the release of rifaximin, a rifamycin antibiotic, for the treatment of travelers' diarrhea (TD) caused by enterotoxigenic *Escherichia coli*. Although the drug is not intended for the treatment of TD, there are indications that the drug may be effective as a prophylactic agent. Rifaximin is administered orally, with less than 0.4% absorption; therefore, its actions are limited to the GI tract. Its mechanism of action is essentially the same as that of other reifamcyin antibiotics (35).

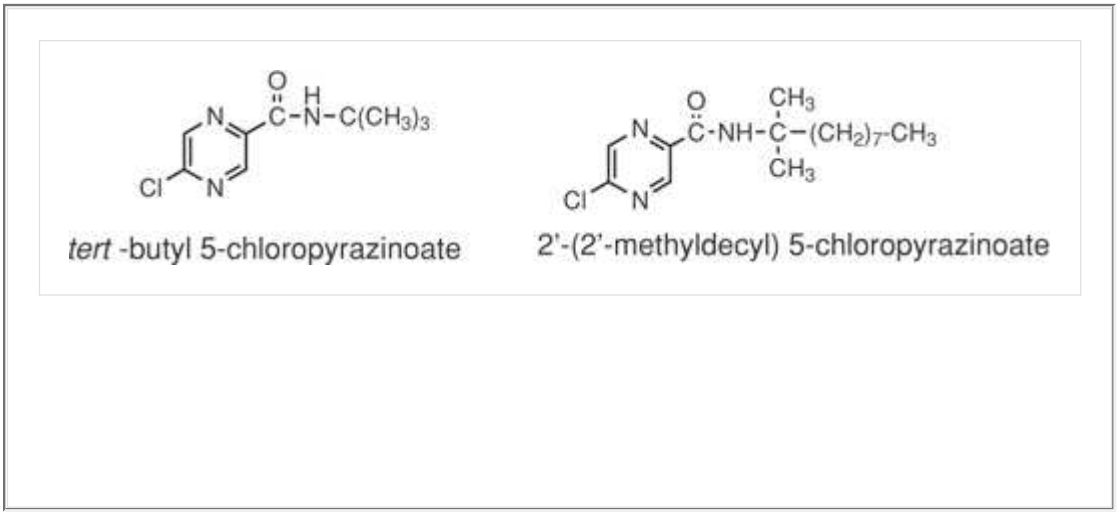
Mechanism of action

The mechanism of action of pyrazinamide is unknown, but recent findings suggest that pyrazinamide may be active either totally or in part as a pro-drug. Susceptible organisms produce pyrazinamidase, which is responsible for conversion of pyrazinamide to pyrazinoic acid intracellularly (8). Mutation in the pyrazinamidase gene (*pncA*) results in resistant strains of *M. tuberculosis* (36). Pyrazinoic acid has been shown to possess biological activity at a pH 5.4 or lower, in contract in vitro tests that show pyrazinoic acid is 8- to 16-fold less active than pyrazinamide (37). Pyrazinoic acid may lower the pH in the immediate surroundings of the *M. tuberculosis* to such an extent that the organism is unable to grow, but this physicochemical property appears to account for only some of the activity. The protonated pyrazinoic acid also can permeate the mycobacterial membrane to lower the pH of the cytoplasm. Recent evidence suggests that pyrazinoic acid decreases membrane potential in older, nonreplicating bacilli, thus decreasing membrane transport, and interferes with the energetics of the membrane (38).

Structure–activity relationship

Previous structural modification of pyrazinamide has proven to be ineffective in developing

analogues with increased biological activity. Substitution on the pyrazine ring or use of alternate heterocyclic aromatic rings have given compounds with reduced activity (39). More recently, using quantitative SAR, a series of analogues have been prepared with improved biological activity. The requirements for successful analogues include 1) provision for hydrophilicity to allow sufficient plasma concentrations such that the drug can be delivered to the site of infection, 2) lipophilicity to allow penetration into the mycobacterial cell, and 3) susceptibility to hydrolysis such that the pro-drug is unaffected by the "extracellular" enzymes but is readily hydrolyzed at the site of action. Two compounds have been found that meet these criteria: tert-butyl 5-chloropyrazinamide, and 2′-(2′-methyldecyl) 5-chloropyrazinamide (40).



Metabolism

Pyrazinamide is readily absorbed after oral administration, but little of the intact molecule is excreted unchanged (Fig. 41.9). The major metabolic route consists of hydrolysis by hepatic microsomal pyrazinamidase to pyrazinoic acid, which may then be oxidized by xanthine oxidase to 5-hydroxypyrazinoic acid. The latter compound may appear in the urine either free or as a conjugate with glycine (23).

P.1135

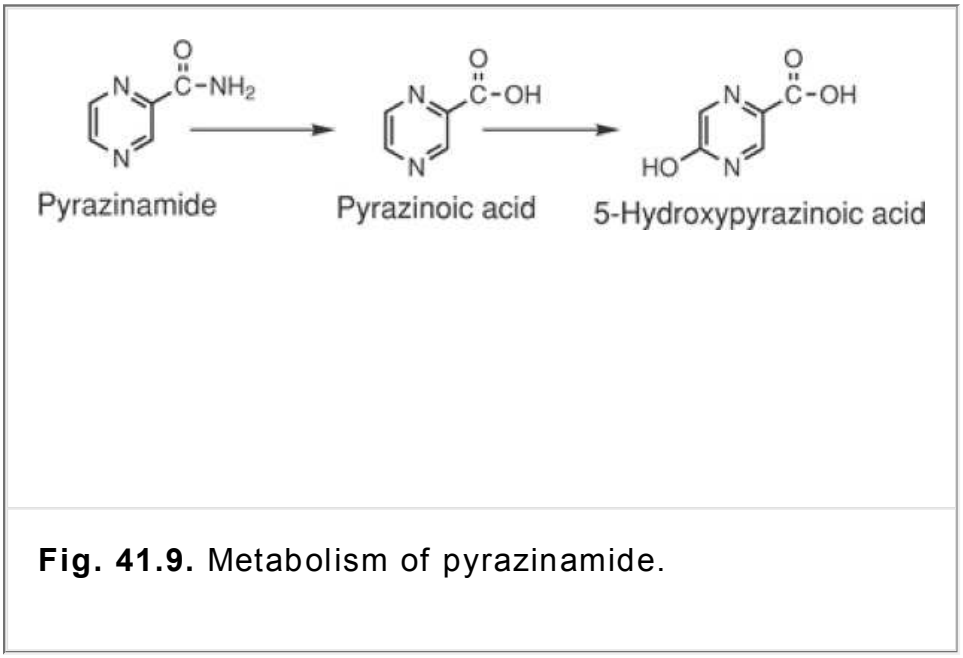


Fig. 41.9. Metabolism of pyrazinamide.

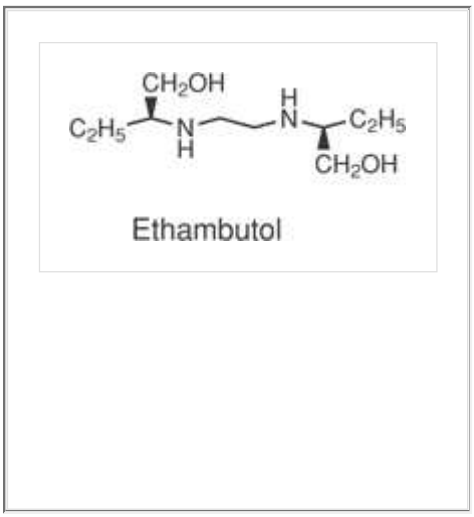
Therapeutic application

Pyrazinamide has gained acceptance as an essential component in combination therapy for the treatment of TB (component of Rifater with INH and RIF). The drug is especially beneficial in that it is active against semidormant intracellular tubercle bacilli that are not affected by other drugs (7,34). Evidence suggests that pyrazinamide is active against nonreplicating persister bacilli. The introduction of pyrazinamide combinations has reduced treatment regimens to 6 months from the previous 9-month therapy. The major serious side effect of pyrazinamide is the potential for hepatotoxicity. This effect is associated with dose and length of treatment. Pyrazinamide is not affected by the presence of food in the GI tract or by the use of aluminum-magnesium antacids (41).

Ethambutol (Myambutol)



Ethambutol (EMB), an ethylenediiminobutanol, is administered as its (+)-enantiomer, which is 200- to 500-fold more active than its (–)-enantiomer. The difference in activity between the two isomers suggests a specific receptor for its site of action. Ethambutol is a water-soluble, bacteriostatic agent that is readily absorbed (75–80%) following oral administration.

Mechanism of action

The mechanism of action of EMB remains unknown, although mounting evidence suggests a specific site of action for EMB. It has been known for some time that EMB affects mycobacterial cell wall synthesis; however, the complicated nature of the mycobacterial cell wall has made pinpointing the site of action difficult. In addition to the peptidoglycan portion of the cell wall, the mycobacterium have a unique outer envelop consisting of arabinofuranose and galactose (AG), which is covalently attached to the peptidoglycan and an intercalated framework of lipoarabinomannan (LAM) (Fig. 41.1). The AG portion of the cell wall is highly branched and contains distinct segments of galactan and distinct segments of arabinan. At various locations within the arabinan segments (terminal and penultimate), the mycolic acids are attached to the C-5′ position of arabinan (42,43). Initially, Takayama et al. (44) reported that EMB inhibited the synthesis of the AG portion of the cell wall. More recently, it has been reported that EMB inhibits the enzymes arabinosyl transferase. One action of arabinosyl transferase is to catalyze the polymerization of D-arabinofuranose, leading to AG (45,46). Ethambutol mimics arabinan, resulting in a buildup of the arabinan precursor β-D-arabinofuranosyl-1-monophosphoryldecaprenol and, as a result, a block of the synthesis of both AG and LAM (Fig. 41.10) (47). The mechanism of resistance to EMB involves a gene overexpression of arabinosyl transferase, which is controlled by the *embAB* gene (48).

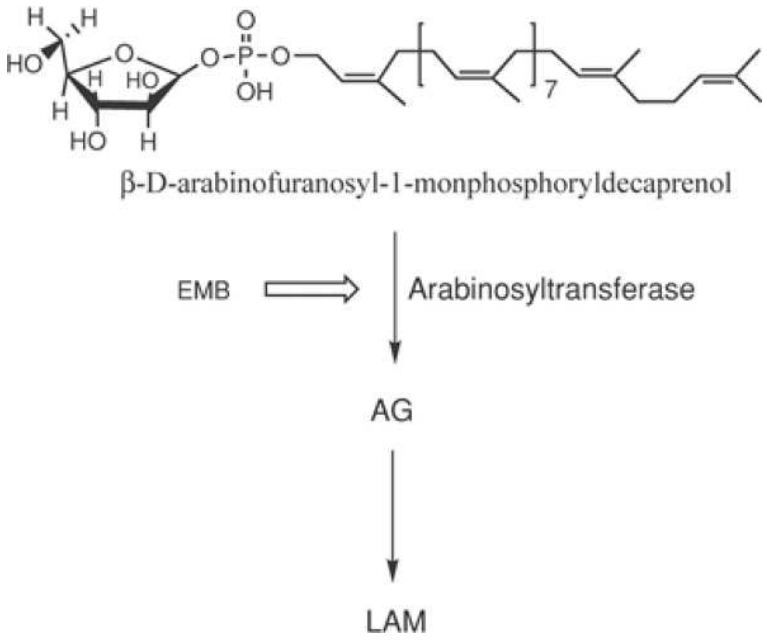


Fig. 41.10. Site of action of ethambutol (EMB) in cell wall synthesis.

This mechanism of action also accounts for the synergism seen between EMB and intracellular drugs, such as RIF. Damage to the cell wall created by EMB improves the cell penetration of the intracellular drugs, resulting in increased biological activity.

Structure–activity relationship

An extensive number of analogues of EMB have been prepared, but none has proven to be superior to EMB itself. Extension of the ethylene diamine chain, replacement of either nitrogen, increasing the size of the nitrogen substituents, and moving the location of the alcohol groups are all changes that drastically reduce or destroy biological activity.

Metabolism

The majority of the administered EMB is excreted unchanged (73%), with no more than 15% appearing in the urine as either Metabolite A or Metabolite B (Fig. 41.11). Both metabolites are devoid of biological activity.

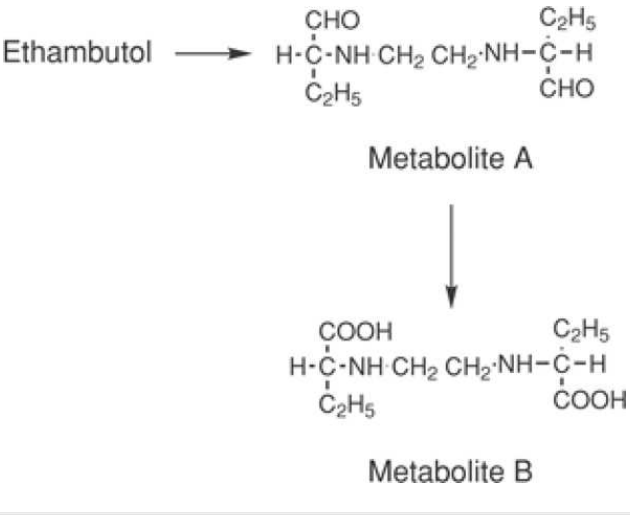

Fig. 41.11. Metabolism of ethambutol.

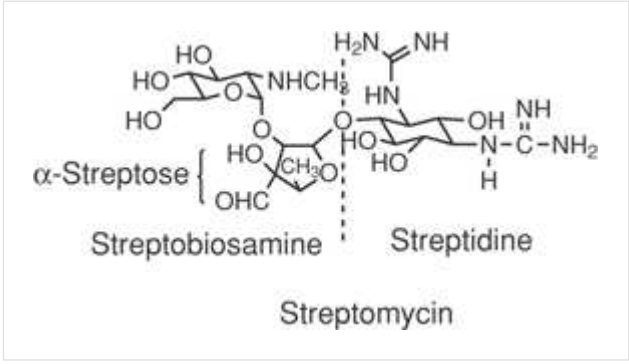
P.1136

Streptomycin



Streptomycin (STM) was first isolated by Waksman and coworkers in 1944 and represented the first biologically active aminoglycoside. The material was isolated from a manure-containing soil sample and, ultimately, was shown to be produced by *Streptomyces griseus*. The structure was proposed and later confirmed by Kuehl et al. (49) in 1948. Streptomycin is water soluble, with basic properties. The compound usually is available as the trihydrochloride or sesquisulfate salt, both of which are quite soluble in water. The hydrophilic nature of STM results in very poor absorption from the GI tract. Orally administered STM is recovered intact from the feces, indicating that the lack of biological activity results from poor absorption and not chemical degradation.

Mechanism of action

The mechanism of action of STM and the aminoglycosides in general has not been fully elucidated. It is known that the STM inhibits protein synthesis, but additional effects on

misreading of an mRNA template and membrane damage may contribute to the bactericidal action of STM. Streptomycin is able to diffuse across the outer membrane of *Mycobacterium tuberculosis* and, ultimately, to penetrate the cytoplasmic membrane through an electron-dependent process. Through studies regarding the mechanism of drug resistance, it has been proposed that STM induces a misreading of the genetic code and, thus, inhibits translational initiation. In STM-resistant organisms, two changes have been discovered: First, S12 protein undergoes a change in which the lysine present at amino acids 43 and 88 in ribosomal protein S12 is replaced with arginine or threonine, and second, the pseudoknot conformation of 16S rRNA, which results from intramolecular base pairing between GCC bases in regions 524 to 526 of the rRNA to CGG bases in regions 505 to 507, is perturbed (50). It is thought that S12 protein stabilizes the pseudoknot, which is essential for 16S rRNA function. By some yet-to-be-defined mechanism, STM interferes with one or both of the normal actions of the 16S protein and 16S rRNA.

Structure–activity relationship

All the aminoglycosides have very similar pharmacologic, pharmacodynamic, and toxic properties, but only STM and, to a lesser extent, kanamycin are used to treat TB. This is an indication for the narrow band of structurally allowed modifications giving rise to active analogues. Modification of the α-streptose portion of STM has been extensively studied. Reduction of the aldehyde to the alcohol results in a compound, dihydrostreptomycin, that has activity similar to STM but with a greater potential for producing delayed, severe deafness. Oxidation of the aldehyde to a carboxyl group or conversion to Schiff base derivatives (oxime, semicarbazone, or phenylhydrazone) results in inactive analogues. Oxidation of the methyl group in α-streptose to a methylene hydroxy gives an active analogue that has no advantage over STM. Modification of the aminomethyl group in the glucosamine portion of the molecule by demethylation or by replacement with larger alkyl groups reduces activity; removal or modification of either guanidine in the streptidine nucleus also decreases activity.

Metabolism

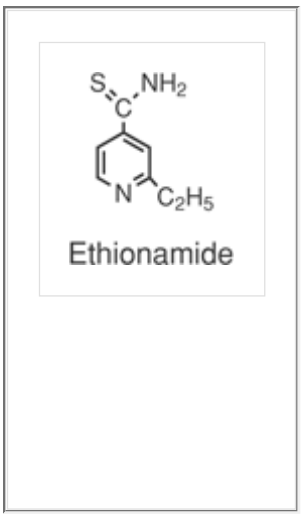
No human metabolites of STM have been isolated in the urine of patients who have been administered the drug, with approximately 50 to 60% of the dose being recovered unchanged in the urine (24). Metabolism appears to be insignificant on a large scale, but it is implicated as a major mechanism of resistance. One problem with STM that was recognized early was the development of resistant strains of *Mycobacterium tuberculosis*. Combination drug therapy was partially successful in reducing this problem, but over time, resistance has greatly reduced the value of STM as a chemotherapeutic agent for treatment of TB. Various mechanisms may lead to the resistance seen in *M. tuberculosis.* Permeability barriers may result in STM not being transported through the cytoplasmic membrane, but the evidence appears to suggest that enzymatic inactivation of STM represents the major problem. The enzymes responsible for inactivation are adenyltransferase, which catalyzes adenylation of the C-3 hydroxyl group in the N-methylglucosamine moiety to give the O-3-adenylated metabolite, and phosphotransferase, which phosphorylates the same C-3 hydroxyl to give O-3-phosphorylate metabolite (Fig. 41.12). This latter reaction appears to be the most significant clinically. The result of these chemical modifications is that the metabolites produced will not bind to ribosomes.

Second-Line Agents

A number of drugs, including ethionamide, *p*-aminosalicylic acid, cycloserine, capreomycin, and kanamycin, are considered to be second-line agents (it should be noted that some authorities classify STM as a second-line agent). These agents are active antibacterial agents, but they usually are less well tolerated or have a higher incidence of adverse effects. These agents are

utilized in cases of resistance, retreatment, or intolerance to the first-line drugs.

Ethionamide (Trecator-SC)



P.1137

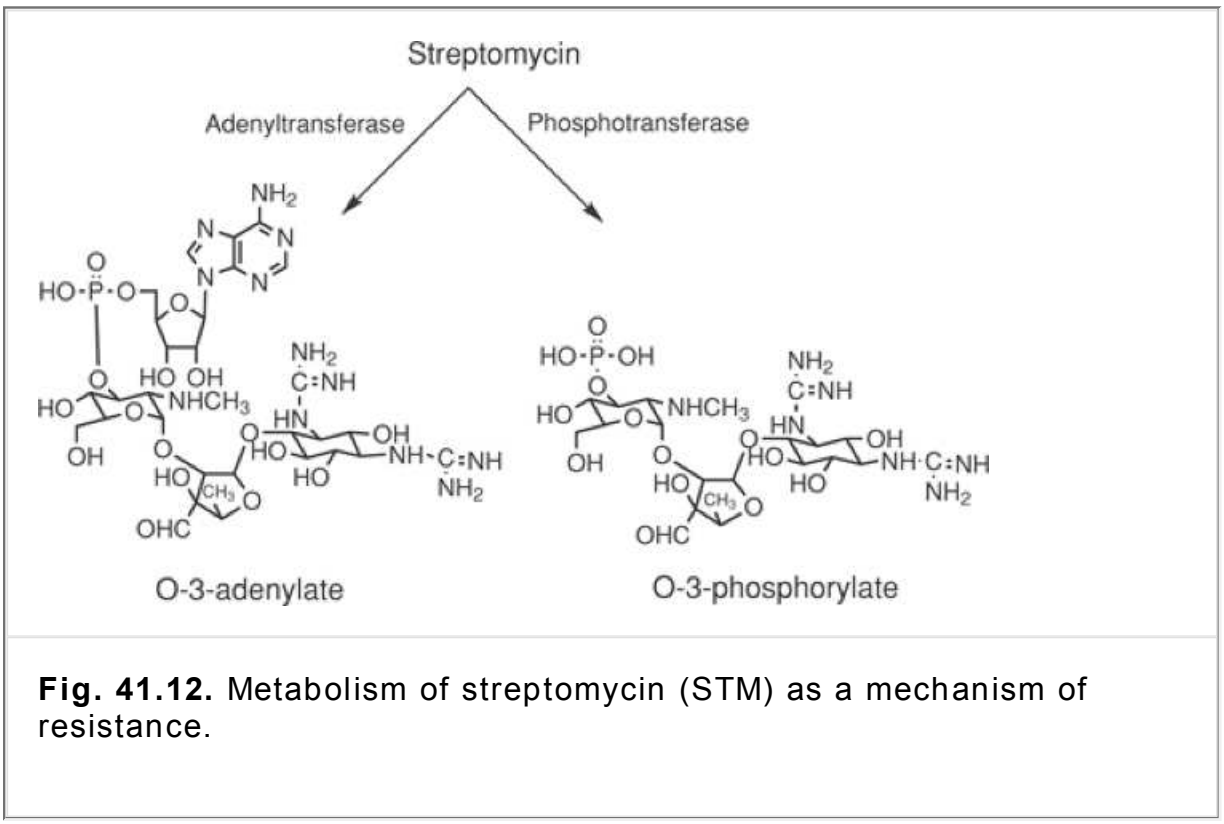


Fig. 41.12. Metabolism of streptomycin (STM) as a mechanism of resistance.

The synthesis of analogues of isonicotinamide resulted in the discovery of ethionamide and a homologue in which the ethyl group is replaced with a propyl (prothionamide). Both compounds have proven to be bactericidal against *Mycobacterium tuberculosis* and *Mycobacterium leprae*.

Mechanism of action

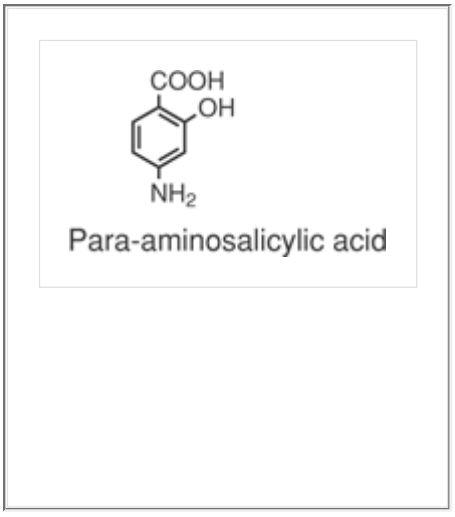
Evidence has been presented suggesting that the mechanism of action of ethionamide is similar to that of INH (see Mechanism of action under *Isoniazid*) (11,15). Similar to INH, ethionamide is considered to be a pro-drug, which is converted via oxidation by catalase-peroxidase to an active

acylating agent, ethionamide sulfoxide, which in turn inactivates the inhA enoyl reductase enzyme (Fig. 41.13). In the case of ethionamide, it has been proposed that the ethionamide sulfoxide acylates Cys-243 in inhA protein.

Metabolism

Ethionamide is orally active but is not well tolerated in a single large dose (>500 mg). The GI irritation can be reduced by administration with meals. Additional side effects may include central nervous system (CNS) effects, hepatitis, and hypersensitivities. Less than 1% of the drug is excreted in the free form, with the remainder of the drug appearing as one of six metabolites. Among the metabolites are ethionamide sulfoxide, 2-ethylisonicotinamide, and the N-methylated-6-oxodihydropyridines (Compounds A, B, and C in Fig. 41.14) (51).

p-aminosalicylic Acid



Once a very popular component in TB therapy, *p*-aminosalicylic acid (PAS) is utilized as a second-line agent today. A combination of bacterial resistance and severe side effects has greatly reduced is value. As a bacteriostatic agent, PAS is used at a dose of up to 12 g/day, which causes considerable GI irritation. In addition, hypersensitivity reactions occur in 5 to 10% of the patients, with some of these reactions being life-threatening.

Mechanism of action

p-aminosalicylic acid is thought to act as an antimetabolite interfering with the incorporation of p-aminobenzoic acid into folic acid. When coadministered with INH, PAS is found to reduce the acetylation of INH, itself being the substrate for acetylation, thus increasing the plasma levels of INH. This action may be especially valuable in patients who are rapid acetylators.

Metabolism

p-aminosalicylic acid is extensively metabolized by acetylation of the amino group and by conjugation

with glucuronic acid and glycine at the carboxyl group. It is used primarily in cases of resistance, retreatment, and intolerance of other agents and is available from the CDC.

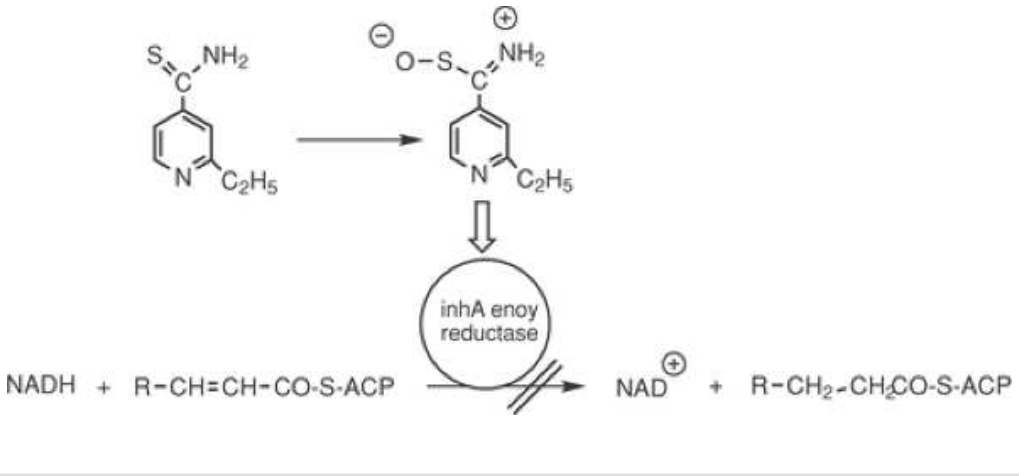


Fig. 41.13. Mechanism of action of ethionamide.

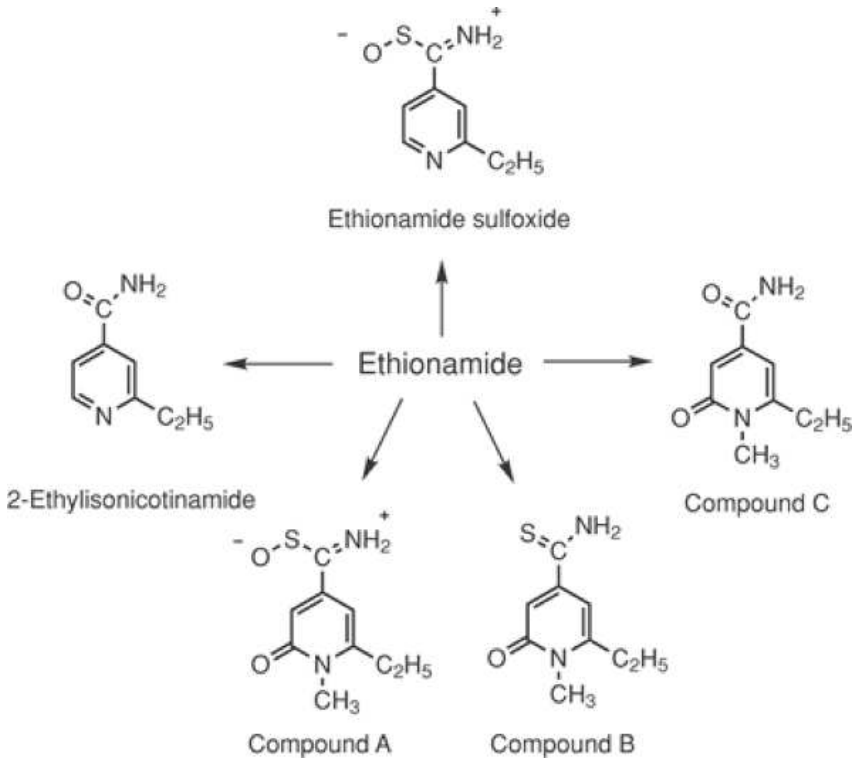

Fig. 41.14. Metabolism of ethionamide.

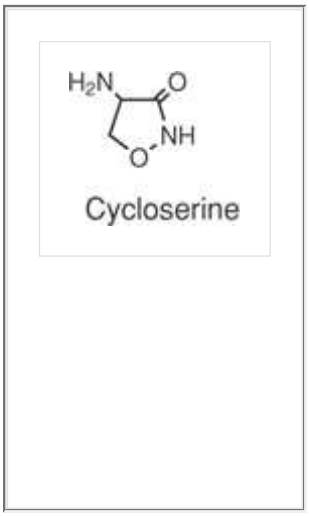
Cycloserine (Seromycin)



Cycloserine is a natural product isolated from *Streptomyces orchidaceus* as the D-(+)-enantiomer.

Mechanism of action

D-Cycloserine is considered to be the active form of the drug, having its action associated with the ability to inhibit two key enzymes, D-alanine racemase and D-alanine ligase. D-Alanine is an important component of the peptidoglycan portion of the mycobacterial cell wall. Mycobacterium are capable of utilizing natural occurring L-alanine and converting the L-alanine to D-alanine via the enzyme D-alanine racemase. The resulting D-alanine is coupled with itself to form a D-alanine–D-alanine complex under the influence of D-alanine ligase, and this complex is incorporated into the peptidoglycan of the mycobacterial cell wall (Fig. 41.15). D-Cycloserine is a rigid analogue of D-alanine; therefore, it competitively inhibits the binding of D-alanine to both of these enzymes and its incorporation into the peptidoglycan (Fig. 41.15) (52). Resistance is associated with an over expression of D-alanine racemase.

Side effects

Cycloserine is readily absorbed after oral administration and is widely distributed, including the CNS. Unfortunately, D-cycloserine binds to neuronal N-methylasparate receptors and, in addition, affects synthesis and metabolism of γ-aminobutyric acid, leading to complex series of CNS effects. As a second-line agent, cycloserine should only be used when retreatment is necessary or when the organism is resistant to other drugs. Cycloserine should not be used as a single drug; it must be used in combination.

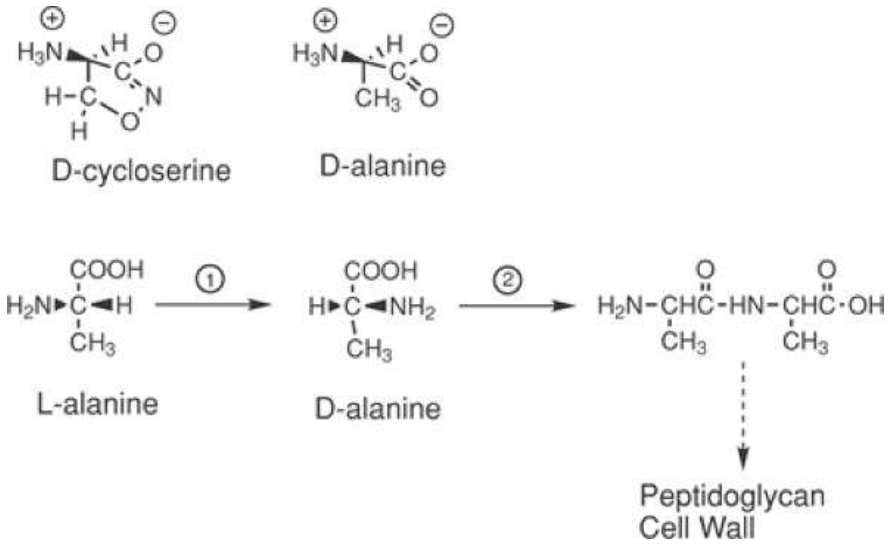


Fig. 41.15. Sites of action of D-cycloserine: 1, D-alanine racemase; 2, D-alanine ligase.

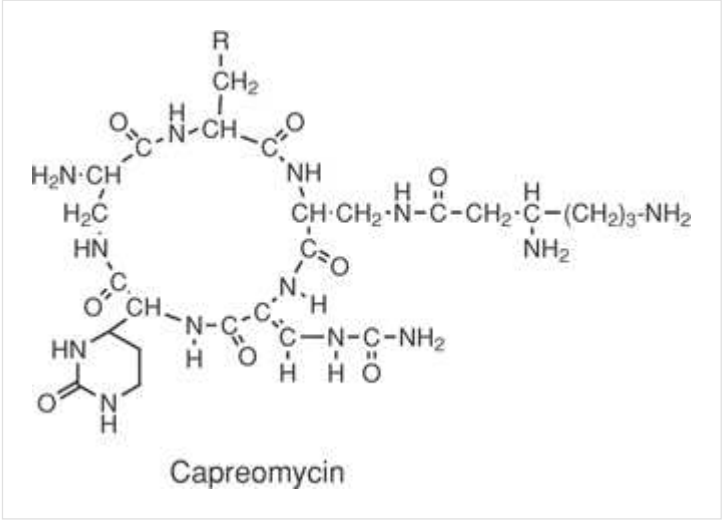
Capreomycin (Capastat)



Capreomycin is a mixture of four cyclic polypeptides, of which capreomycin Ia (R = OH) and Ib (R = H) make up 90% of the mixture. Capreomycin is produced by *Streptomyces capreolus* and is quite similar to the antibiotic viomycin. Little, if anything, is known about its mechanism of action, but if the chemical and pharmacological similarity to viomycin carries over to the mechanism of action, then one might expect something similar. Viomycin is a potent inhibitor of protein synthesis, particularly that which depends on mRNA at the 70S ribosome (53). Viomycin blocks chain elongation by binding to either or both the 50S or 30S ribosomal subunits. A

Chapter 42

Cancer and Chemotherapy

Victoria F. Roche

Drugs covered in this chapter:

DNA alkylating agents

- Chlorambucil
- Cyclophosphamide
- Estramustine
- Ifosfamide
- Mechlorethamine
- Melphalan
- Thiotepa

Nitrosoureas

- Carmustine
- Lomustine
- Streptozocin

Procarbazine and triazenes

- Dacarbazine
- Procarbazine
- Temozolomide

Miscellaneous alkylating agents

- Altretamine
- Busulfan

Organoplatinum complexes

- Carboplatin
- Cisplatin
- Oxaliplatin
- Satraplatin

Antibiotics

- Bleomycin
- Dactinomycin
- Daunorubicin
- Doxorubicin
- Epirubicin
- Idarubicin
- Mitoxantrone

- Mitomycin
- Valrubicin

Antimetabolites

- DNA polymerase inhibitors
    - Cladribine
    - Clofarabine
    - Cytarabine
    - Fludarabine
    - Gemcitabine
- Pyrimidine antagonists
    - Capecitabine
    - Floxuridine
    - Fluorouracil
    - Methotrexate
    - Pemetrexed
- Purine antagonists
    - Mercaptopurine
    - Thioguanine
- Miscellaneous antimetabolites
    - Hydroxyurea
    - Pentostatin

Mitosis Inhibitors

- Docetaxel
- Etoposide
- Irinotecan
- Paclitaxel
- Teniposide
- Topotecan
- Vinblastine
- Vincristine
- Vinorelbine

Miscellaneous anticancer agent

- Azacitidine

Introduction

Overview

Healthy cells are under strict biochemical control for growth and differentiation. Cells divide and proliferate under the influence of various growth stimulators and are subject to arrested growth (senescence) and programmed cell death (apoptosis). In cancer, these regulatory processes have gone awry, and cells grow and divide uncontrollably, consuming energy and losing both structure and function because of an inability to adequately differentiate. To add insult to injury, rampant cell division is accompanied by disabled cell-death

processes, leading first to cellular immortality and, eventually, to genetic instability. The causes of cancer are many and varied (e.g., chemical, environmental, viral, and mutagenic), but all ultimately lead to an aberration in the expression of proto-oncogenes, the products of which control normal cell life. When these genes mutate to become oncogenes in a sequential, multistep process, cancer results. Oncogenes (e.g., *myc* and *ras*) can either overexpress or underexpress regulatory biochemicals, resulting in preferential and accelerated cellular growth. Concomitantly, tumor suppressor genes (e.g., anti-oncogenes like *p53*, *p21,* p^{INK4A}, and *retinoblastoma*) can be inhibited (1).

Initially, tumors grow exponentially, taking a consistent amount of time for every doubling of the tumor cell population size. In fact, the majority of a cancer cell's lifetime is spent before the tumor presents clinically. Initially, growth is very rapid (doubling time measured in days), but doubling time can slow to weeks or months as the tumor ages (2) because of increasingly poor vascularization and the resulting decrease in access to blood and essential nutrients.

Selected Definitions

Oncogenes and Tumor Suppressor Genes

Oncogenes are regulators of cellular communication with the outside environment. They are derived through the mutation of proto-oncogenes, which are normal and ubiquitous genes involved in the regulation of homeostatic cellular functions. Mutations in proto-oncogenes can occur as spontaneous point mutations, inherited germline mutations, chromosomal rearrangements or through augmentation of gene expression. Regardless of the mutational mechanism, when the mutated oncogenes are

stimulated by exposure to chemical, environmental, or viral carcinogens, they produce proteins that are either wrongly expressed within their normal cell or expressed in inappropriate tissues. In either case, cellular proliferation leading to cancer results (1,3).

Clinical Significance

Chemotherapy has significantly changed the treatment of cancer since the first agents were studied in the 1940s. Understanding the chemical mechanism of action for traditional chemotherapeutic agents, including whether the agent is cell-cycle specific or cell-cycle nonspecific, is important so that administration can be planned accordingly and coadministration of agents with similar toxicities can be avoided.

The disadvantage of traditional chemotherapeutic agents is the inability of the agent to recognize the difference between normal cells and cancer cells. So, although the agents may shrink or eliminate the tumor, the treatment is accompanied by many unwanted side effects. There are numerous examples in which a chemical understanding of the chemotherapeutic agent is needed. For example, hydration with chloride-containing fluid is necessary with cisplatin to keep cisplatin in its inactive form in the kidneys and to avoid renal toxicity. Another example can be found when using cyclophosphamide or ifosfamide. The dissociation of aldophosphamide produces the active compound phophoramide mustard, but it also produces acrolein, which can cause significant damage to the bladder. This bladder damage, or hemorrhagic cystitis, can be prevented with the use of mesna, which inactivates the effects of acrolein in the bladder. Understanding the chemical basis for the toxicities seen with chemotherapy is imperative in managing or preventing them in clinical practice.

Kelly Nystrom, Pharm.D., BCOP
Assistant Professor, Pharmacy Practice Department, School of Pharmacy and Health Professions, Creighton University

Tumor suppressor genes are intended to keep oncogenes in check by halting uncontrolled cellular growth. In direct opposition to oncogenes, which induce cancer when stimulated or amplified, tumor suppressor genes promote cancer when inactivated or attenuated. Two of the most prevalent tumor suppressor genes involved in the generation of cancer are *p53* and *retinoblastoma*, or *Rb*. When either of these two suppressor genes

loses function, the negative control on cellular proliferation is lifted and cells gain immortality (an essential quality of a cancer cell). The loss or disruption of function of the *p53* tumor suppressor gene is found in approximately half of human cancers and is a harbinger of a poor prognosis.

Oncogenes and tumor suppressor genes that have been linked to specific types of cancer are identified in Table 42.1. Table 42.2 relates oncogenic markers of selected cancers to disease prognosis and treatment strategy.

Cell Cycle

When cells reproduce, they do so via a very specific game plan known as the cell cycle. Cell division (mitosis) kicks off the cycle, and after a period of 30 to 60 minutes, the cells go into either a resting phase (called G_0) or a presynthetic (gap) phase (called G_1), in which enzyme production occurs in preparation for de novo nucleic acid synthesis. Production of DNA then occurs in an S phase that can last up to 20 hours. The S phase is followed by a gap phase (G_2), in which RNA, critical proteins, and the mitotic spindle apparatus are generated for the next mitotic (M) phase (3,4).

This is important to our discussion, because some anticancer agents are specific for a certain phase of the cell cycle. For example, antimetabolite antineoplastics damage cells in the S phase, whereas mitosis inhibitors pack their greatest cell-killing punch in the M phase. The administration of cell-cycle phase–specific antineoplastics is carefully planned so that the drug encounters cancer cells at their most vulnerable moments. Other antineoplastic agents are toxic to cells regardless of cycle phase (e.g., DNA alkylating agents and most antineoplastic antibiotics). These cell-cycle phase–nonspecific agents can be administered at any time that is feasible for the provider and convenient for the patient.

In general, cancer cells undergoing rapid division are most vulnerable to the cytotoxic action of antineoplastic agents, and antineoplastic therapy holds its greatest

promise for positive outcomes if initiated when the tumor is small but growing aggressively. Conversely, slow-growing tumors with a high percentage of cells remaining in the G_0 phase (e.g., nonsmall cell lung cancer) often are nonresponsive to standard chemotherapy (4). If the tumor is not detected until it is quite large, therapy also can be compromised by inefficient or substandard drug delivery because of poor tumor vascularization.

Table 42.1. Oncogenic Origin of Selected Cancers (1,3)

Cancer Type	Common Oncogenic or Tumor Suppressor Gene Origin
Chronic myelogenous leukemia	*bcr-abl* proto-oncogene translocation
Follicular lymphoma	*bcl-2* amplification, *myc* mutation
Sporadic thyroid cancer	*ret* mutation
Colorectal and gastric cancer	*APC* gene mutation
Familial breast and ovarian cancer	*BRCA1, BRCA2* mutation
Invasive ductal breast cancer	*HER-2* amplification

Familial melanoma	*p16*^{INK4A} mutation
Childhood neuroblastoma and small cell lung cancer	N-*myc* amplification
Leukemia, breast, colon, gastric, and lung cancer	*c-MYC* amplification
Renal cell cancer	Von Hippel-Lindaugene (VHL) dysfunction

Table 42.2. Oncogenic Markers and Therapeutic Strategies in Selected Cancers (1)

Cancer Type	Oncogenic Marker	Prognosis/Responsiveness to Chemotherapy	Approach
Breast cancer	HER-2 amplification	Poor	Aggressive chemotherapy, targeted therapy
Acute myelogenous leukemia	t(8;21) or inv(16) translocation	Good	Standard chemotherapy
Acute lymphocytic leukemia	*bcr-abl* rearrangement	Poor	Bone marrow transplantation

Metastasis

Metastasis refers to the process by which malignant cells leave the parent tumor, migrate to distant sites, and invade new tissue. The primary metastatic “highways” utilized by meandering cancer cells are the blood and lymph fluids. Sloughed cells must find a biological environment with all of their essential growth factors in place before they can put down roots and evolve into a full-fledged metastatic tumor. Because many distinct and interdependent steps must be accomplished to establish metastatic disease, the process has been termed the “metastatic cascade” (5). Fortunately, there are many opportunities within the cascade for the body to mount a successful defense and destroy the potential invaders.

Cancer Staging

Clinicians need to have a common language through which to communicate about disease severity to make the best team-based decisions about the relative risks and benefits of treatment options. In the TNM cancer staging classification, the severity of solid tumor neoplastic growth is characterized by the size of the tumor mass (T_1–T_4), the extent of lymph node involvement (N_1–N_3), and whether distant metastasis has occurred (M_0 or M_1). The higher the subscripted number in each of these parameters, the more advanced and/or disseminated the disease. Taken together, the TNM characteristics of a tumor can be translated into a comprehensive staging scale ranging from I (localized) to IV (metastatic). The intermediate disease severity

stages indicate local (Stage II) or regional (Stage III) tissue invasion (3). Staging is an essential prerequisite for the prediction of prognosis and the identification of the most appropriate treatment plan and optimal dosing regimen (2).

Response Criteria

In this era of patient-centered, team-based care, it is equally beneficial to quantify a patient's clinical response to therapy in a manner that is consistent and universally understood by all health care providers. Five discrete anticancer therapy response categories have been defined, with criteria established for each (3). Whereas "cure" is obviously the most noble goal, it is very difficult to achieve in most types of cancer. "Cure" for all cancers except breast and melanoma equates to no evidence of disease for a minimum of 5 years. More commonly, the response category viewed as the pinnacle is "complete response," in which the patient has no evidence of cancer for at least 1 month following the cessation of therapy but where relapses are still possible. A "partial response" is claimed when tumor size or disease severity has been cut at least in half and there is no evidence of new lesions at the primary site or elsewhere. If this level of clinical improvement is not reached, yet the patient has experienced significant attenuation of symptoms and/or enhancement of quality of life, the response is termed "clinical benefit." A less optimistic response category is "stable disease," in which tumor size or disease severity has changed by 25% or less in either direction. Most dire is "progression," a category that is characterized by tumor growth or worsening disease severity at the 25% or higher level.

Historical Background (6)

> "Those who have not been trained in chemistry or medicine, which after all is only applied chemistry, may not realize how difficult the problem of [cancer] treatment really is. It is almost, not quite, but almost as hard as finding some agent that will dissolve away the left ear, say, yet leave the right ear unharmed: so slight is the difference between the cancer cell and its normal ancestor."

Thus wrote noted cancer researcher and physician Dr. William H. Woglom in a monograph published by the American Association for the Advancement of Science in 1947 (7). Although somewhat predictive of what we now know to be true regarding the relationship between resident genes and oncogenes, Dr. Woglom's rather gloomy prognosis of our ability to meet cancer on its own ground and beat it was underpinned by centuries of unsuccessful attempts to treat neoplastic disease with toxic metals, including lead, arsenic, silver, zinc, antimony, mercury, and bismuth. The era of more promising chemotherapy was just on the horizon, however, even as Woglom penned his words of therapeutic woe.

Among the first nonmetallic therapeutic agents to show benefit in the treatment of cancer was cortisone and, later, prednisone. In the 1940s, these glucocorticoids were shown to induce tumor regression in a laboratory cancer model (murine lymphosarcoma) and in acute leukemia. In the same decade, the retrospective recognition that World War I soldiers exposed to sulfur mustard gas, used as an agent of war, suffered from damaged lymphoid tissue and bone marrow led to the development of the cytotoxic nitrogen mustards for the treatment of lymphoma. Chemists then used their scientific understanding of mustard reactivity to design agents that were either "superpotent" and nonselective (e.g., highly toxic) or of lower reactivity so as to provide oral activity and less systemic toxicity.

The discovery in 1940 that *p*-aminobenzenesulfonamide was effective against streptococcal infections ushered in the era of antimetabolite chemotherapy. The development of antifolate antineoplastics, which were shown to be effective in combating childhood leukemias, got its start in the late 1940s. In the mid- to late-1950s, on the heels of the success of antifolates, came the development of antimetabolites based on the structures of endogenous purine and pyrimidine bases. Perhaps the most exciting discovery in this regard was the recognition that a very simple analogue of the endogenous pyrimidine uracil (5-fluorouracil) was a potent inhibitor of deoxythymidine monophosphate biosynthesis and that inhibiting the production of this essential nucleotide produced positive results in patients suffering from colon, stomach, pancreatic, and breast cancers. Antimetabolites that target DNA polymerase (e.g., cytarabine) were conceptualized and synthesized in the late 1950s and subsequently shown to be effective in acute myeloblastic leukemia.

The antibiotic antineoplastics came into clinical utility when the highly toxic actinomycin (discovered in the

1940s) was found to be effective in the treatment of human testicular cancer and uterine choriocarcinoma. Other natural anticancer antibiotics, such as bleomycin, subsequently were found to be active against various hematological cancers and solid tumors (1960s), which led to the development of semisynthetic analogues with both high potency and wider margins of safety in more recent times. The antimitotic vinca alkaloids vincristine and vinblastine were shown to have activity against Hodgkin's disease and acute lymphoblastic leukemia around the same time that the antibiotic antineoplastics were being developed.

Cancer chemotherapy appears to have come full circle since the "metal-intense Renaissance," because some of the newest anticancer drugs to join the U.S. market are organometallic platinum complexes. The activity of cisplatin (the first such complex to be commercially available) against lymphosarcoma and solid tumors of the head, neck, and reproductive organs was first noted in the early 1970s. The fortuitous discovery of organoplatinum complexes in the treatment of cancer is attributed to Dr. Barnett Rosenberg, who was studying the impact of electromagnetic radiation on bacterial cell growth using platinum electrodes. He followed up on the astute observation that the bacteria exposed to the electrodes experienced profound changes in cellular structure, which ultimately were attributed to the in situ generation of cisplatin. Both Pt(II) and Pt(IV) analogues of cisplatin, which offer high potency coupled with lower resistance potential and fewer use-limiting side effects (e.g., oto-, nephro-, and hematotoxicity), are currently on the market and in clinical trials. In addition to organometallics, the efficacy of sex hormones and hormone antagonists in fighting hormone-dependent cancers (e.g., estrogen receptor–positive breast cancer or prostate cancer) and the advent of therapeutic biological response modifiers with direct antiproliferative effects (e.g., interferons) has added significantly to the therapeutic options available to providers and the cancer patients for whom they care.

Despite the wide range of antineoplastic agents currently available, it has been estimated that more than half of all patients with cancer ultimately succumb to their disease (8). Novel therapies based on an in-depth understanding of the molecular mechanisms involved in the complex cascade of events we call cancer are urgently needed. Fortunately, molecular targets for focused chemotherapeutic interventions are being discovered with increasing regularity, opening the door for the scientifically grounded development of new drugs. The critical role of computer-based technology in facilitating the ability of chemists to conceptualize and visualize molecular interactions between potential drugs and putative receptor targets that lead to rational drug design and development, as well as in analyzing and managing the overwhelming amounts of data that are generated from these studies, cannot be underestimated. Likewise, the availability of viable tumor cell lines has facilitated a disease-specific orientation to the hunt for more effective therapies. Currently, there are tumor cell lines for lung, colon, breast, and kidney cancers, as well as for melanoma and leukemia (8).

Several monoclonal antibodies targeted to tumor cell antigens or proteins critical to cellular proliferation (e.g., human epidermal growth factor, vascular endothelial growth factor, tyrosine kinase, and proteasomes) have found their way to the U.S. market. In addition, several new targets for anticancer drug development currently are being actively explored by biomedical scientists (1,3). For example, cancer cells overexpress the enzyme telomerase, which inhibits the natural destruction of chromosomal telomeres (DNA caps), leading to unwanted cellular immortality. Telomerase inhibitors would be expected to reestablish cellular senescence and to halt uncontrolled cell division by maintaining the integrity of the telomeres and are being pursued as a new biochemical approach to disease attenuation or control. Other potential antineoplastic drug targets being seriously investigated are aberrant genes or enzymes unique to specific tumors and P-glycoprotein, which is overexpressed in

many cancers as a result of an amplified *mdr-1* gene and responsible for the rapid ejection of antineoplastic agents from target cells. Other multidrug resistance–associated proteins (the MRP family) involved in this devastating rebound of the cancer cell also are being investigated as potential sites of therapeutic intervention. The intense focus on resistance molecules such P-glycoprotein is warranted, because patients whose tumors express this efflux-promoting protein respond poorly to chemotherapy and have a poor prognosis (2).

Table 42.3. Estimated 2005 Incidence and Mortality of Common Cancers (3)

	Prostate/Breast		Lung		Colorectal	
	Men	Women	Men	Women	Men	Women

Incidence	232,090	211,240	93,010	79,560	71,820	73,470
	(33%)	(32%)	(13%)	(12%)	(10%)	(11%)
Mortality	30,350	40,410	90,490	73,020	28,540	27,750
	(10%)	(15%)	(31%)	(27%)	(10%)	(10%)

In the future, it is hoped that clinicians will be able to generate a genetic expression profile for each patient with cancer to help them predict response to all possible therapies and to guide pharmacotherapy selection.

Disease State

Cancers generally can be classified as lymphatic, epithelial, nerve, or connective tissue related, and tumor nomenclature is based on tissue of origin as follows: carcinoma (epithelial origin), sarcoma (muscle or connective tissue origin), leukemia and lymphoma (lymphatic or hematologic origin), and glioma (neural origin). The risk of developing epithelial-derived cancers increases with age.

Incidence

Approximately 1.3 million cases of cancer are diagnosed each year in the United States, resulting in an estimated 570,280 annual deaths (3). The most commonly acquired cancers include those of the prostate, breast, lung, colon, and rectum. Lung cancer is the most fatal and is responsible for approximately 160,000 deaths each year. These prominent cancers (prostate/breast, lung, and colorectal) occur with very similar frequency in men and women, and little gender-related differences in mortality are noted (Table 42.3). Some geographical differences in incidence have been noted, with lung cancer being more prevalent in rural southern U.S. states, and breast and colon cancer more commonly diagnosed in the “northeast corridor” of the United States (9).

Table 42.4. The American Cancer Society's Major Warning Signs of Cancer (10,11)

Cancer Warning Signs in Adults	Cancer Warning Signs in Children
Change in bowel or bladder habits	Continued, unexplained weight loss
A sore that does not heal	Frequent headaches, with vomiting
Unusual bleeding or discharge	Localized pain or persistent limping
Thickening or lump in breast or elsewhere	Any unusual mass or swelling
Indigestion or difficulty in swallowing	Sudden eye or vision changes

Obvious change in a wart or mole	Recurrent or unexplained fever
Nagging cough or hoarseness	Excessive bruising or bleeding Noticeable paleness or loss of energy

Signs and Symptoms

The clinical manifestations of cancer can vary widely depending on type and stage of neoplastic disease. The American Cancer Society has been promulgating its list of the major warning signs of cancer for decades (Table 42.4) (10,11). Patients are well-served by being familiar with these early warning signs, because cancer is most effectively treated when diagnosed before more life-threatening symptoms appear. One readily recognized symptom of cancer is persistent weight loss (especially in children), and severe, unrelenting pain is a hallmark symptom of cancer in the later stages. Solid tumors can become palpable or observable masses when the cancer is advanced.

Biochemical Bases and Causes of Cancer

Currently, it is understood that cancer is caused by mutations in "resident" or normal genes rather than by the introduction of foreign genes into otherwise healthy systems (1,3). The single-gene theory of cancer (where a single mutation could result in neoplastic disease) has been abandoned in favor of the multiple mutation prerequisite, and complex gene pathways, interactions, and communications are now the focus of study in the understanding of

malignant processes and their treatments. Once determined, the "mutational profile" of malignant cells may very well predict such parameters as disease severity, most promising therapeutic interventions, and clinical outcome.

Table 42.5. RNA and DNA Viruses Associated with Cancer Development (12,13)

RNA Virus	Cancer
Human T-lymphotrophic virus	Adult T-cell leukemia (ATL)
Hepatitis C	Hepatocellular carcinoma (HCC)
DNA Virus	Cancer
Hepadnavirus	Hepatocellular carcinoma (HCC)
Papillomavirus	Skin cancer, cervical cancer
Epstein-Barr virus	Burkett's lymphoma, Hodgkin's disease, anaplastic nasopharyngeal carcinoma, gastric cancer

Herpesvirus	Karposi's sarcoma

The development of cancer occurs in four discrete steps or phases. In the **initiation** phase, exposure to a precipitating carcinogen prompts irreversible mutation in a number of different genes. The **promotion** phase is a time during which mutated cells arising from altered genes grow preferentially compared to normal cells. This preferential growth can result from continued exposure to the original carcinogen or from promotion by environmental "accelerants." This stage is reversible, so cancer sometimes can be avoided with appropriate changes in diet and lifestyle. The **transformation** phase is the 5- to 20-year progression of a mutated cell to a cancer cell. Cellular proliferation, clonal colony development, tissue invasion and destruction, and metastasis defines the final **progression** phase of cancer development (3).

As previously mentioned, the genetic mutations leading to the diseases that we call cancer can be stimulated by a variety of chemical, environmental, and viral triggers. Both RNA retroviruses and DNA viruses have been implicated in human cancer causation (Table 42.5), although many more DNA than RNA viruses have oncogenic potential (12,13).

Individuals in certain occupations may be at enhanced risk for the development of some cancers because of unavoidable exposure to carcinogenic chemicals (9). Perhaps the best-known example of occupationally induced cancer involves exposure to asbestos, which has been conclusively linked with the development of lung, pleural, and peritoneal malignancies. Miners exposed to radon also are at a significantly enhanced risk for the development of lung cancer, as are individuals exposed through their work to soot, tars, hexavalent chromium, and nickel-containing compounds. The aromatic amines β-naphthylamine and 4-aminobiphenyl are known to induce bladder cancer, and exposure to the common organic solvent benzene has been linked to the development of leukemia.

Table 42.6. Some Environmental Precipitants of Cancer (9)

Environmental Cancer Precipitant	Cancer Type
Tobacco	Lung, oral, bladder, pancreatic, stomach, and renal cancer
Alcohol	Liver, rectal. and breast cancer
Tobacco plus alcohol	Oral cancers
Radon	Lung cancer
Halogenated compounds	Bladder cancer
Immunosuppressive agents	Lymphoma
Herbicides	Lymphoma
Ionizing or ultraviolet radiation	Leukemia, breast, thyroid, lung, and skin cancer

Environmental carcinogens are all around us (Table 42.6). Fortunately, however, individuals can do many

things to protect themselves from exposure or from negative consequences of limited exposure. The chemicals deposited in the lungs from inhaling cigarette smoke are the primary cause of lung cancer in the United States, but smokers who quit decrease their risk for this often-fatal cancer by 67% or more after 10 smoke-free years (9). Nonsmokers can protect themselves from the cancer-promoting effects of secondhand smoke by removing themselves from smoke-filled environments, although this is not always as simple as it sounds. Smoking combined with alcohol has a synergistic effect in promoting the development of oral cancer. In addition to quitting smoking, abstaining from alcohol or drinking in moderation is a choice that individuals can make in an effort to decrease their overall risk of developing cancer.

Other measures that patients can take to minimize the risk of cancer from environmental causes include protection from damaging ultraviolet rays through the use of high-SPF sunscreens and the consumption of foods that are low in fat but rich in carotenoids, vitamins A and C, folate, selenium, and/or fiber (9).

General Therapeutic Approaches

Overview

Cancer treatment can be comprised of surgery, radiation, antineoplastic chemotherapy, and/or therapy with biological response modifiers, which stimulate the patient's own immunological defense mechanisms. Surgery and radiation (ionizing, thermal, or photodynamic) are favored for isolated or localized cancers; chemotherapy and biological response modifiers (with or without surgery and/or radiation) are reserved for disseminated or systemic cancers. Chemotherapy also can be used after surgery and/or radiation as an “insurance policy” against microscopic metastatic disease (adjuvant therapy) or before surgery to decrease the size of the mass to be removed (neoadjuvant therapy).

Unfortunately, cancer cells do not simply “lie down” in the face of chemotherapeutic intervention. Rather, these aggressive cells fight back in an attempt to retain their

immortality. Some cancer cells acquire resistance to anticancer drugs by down-regulating enzymes essential for drug transport or for the activation of antineoplastic pro-drugs or by up-regulating enzymes involved in inactivating biotransformation. As noted previously, other mechanisms of biochemical retaliation include down-regulation of target enzymes, altered drug uptake and efflux mechanisms (e.g., amplification of the gene that encodes for P-glycoprotein or the multidrug resistance–associated protein), inhibition of cellular repair proteins, and apoptosis inhibition (2,3,4).

Cancer Chemotherapy

The word “antineoplastic” means “against new growth.” In general, the mechanism of cytotoxic action for all antineoplastic agents is interference with cellular synthesis or the function of RNA, DNA, and the proteins that sustain life. All antineoplastic agents are poisons, because they are designed to kill cells. An ideal antineoplastic, however, would be both tissue specific (i.e., would only target the diseased organ or physiological system) and cell specific (i.e., would only destroy malignant cells), leaving healthy cells and organ systems alone. Unfortunately, the ideal is not yet the reality, because currently available anticancer drugs are highly and, often, generally toxic, especially for cells with short half-lives. For example, nonspecific destruction of the rapidly dividing cells of the gastrointestinal (GI) tract leads to the severe nausea and vomiting associated with cancer chemotherapy, whereas alopecia and fatigue (as well as susceptibility to infection) are the result of the destruction of rapidly dividing cells in hair follicles and bone marrow, respectively. Factors such as the extent and severity of the disease, individual sensitivity to the antineoplastic mechanism employed by the drugs selected for use, and the kinetics controlling drug transport and cell-cycle specificity all impact the chance for chemotherapeutic success (2).

Because cancer chemotherapy often is given in several courses or “rounds,” with an interval of several days or weeks in between to permit attenuation of side effects, three distinct aspects of drug dosing must be considered when determining the impact of antineoplastic therapy on overall patient welfare. First, the dose that ideally should be given per course has been identified for each commonly employed antineoplastic agent but can be altered significantly by individual patient health status (e.g., hepatic, renal, cardiovascular, hematopoietic, pulmonary, and/or other comorbidities), activity/performance status, genetic makeup, and the nature and anticipated severity of side effects. Each round of antineoplastic therapy kills a given percentage of cancer cells with each administration (“cell kill hypothesis”), and the percentage killed rises proportionally

with the dose of drug. If chemotherapy can shrink the tumor to 10^4 or fewer cells, normal host defense systems usually are capable of eradicating them (2,3). Therefore, the dose of drug that comes as close as possible to the recommended dose is the goal. Expect significant interpatient variation in response to the same chemotherapeutic regimen secondary to individual genetics, level of debilitation, extent of tissue invasion, critical organ system function (including bone marrow), and past exposure to chemotherapeutic agents.

An ever-growing understanding of genetic polymorphism and its impact on the biosynthesis of target proteins and metabolizing enzymes is helping health care providers make wiser decisions about antineoplastic therapy and drug regimens. The length of the "drug-free" interval is the second important drug-dosing consideration, because a shorter interval (or higher dose intensity—the "one-two punch") is associated with a more aggressive inhibition of tumor growth. Often, however, patients cannot tolerate the debilitating side effects (e.g., myelosuppression) without a prolonged interval between rounds. The advent of genetically engineered biological response modifiers, such as granulocyte colony-stimulating factor, which boosts the ability of bone marrow to produce neutrophils, has had a positive impact on optimizing dosing intensity/density.

Finally, many chemotherapeutic agents produce serious chronic or delayed toxicities that may be irreversible, particularly in heart, lung, and kidneys, which demands that the total cumulative dose be taken into account when designing the regimen. The ultimate balancing act is to give the patient as much antineoplastic drug as normally is recommended in the time frame most likely to kill the greatest percentage of cancer cells without inducing intolerable or life-threatening toxicity in healthy organs and tissues. Armed with the knowledge of the biochemical and/or molecular basis of toxicity, the pharmacist is in an excellent position to employ appropriate pharmacotherapeutic agents to attenuate unavoidable side effects.

One approach for minimizing unwanted toxicity is to employ a chemotherapeutic regimen of several drugs that act by distinct mechanisms and/or precipitate different side effects. Attacking the tumor with different therapeutic "guns" should permit a lower dose of each to be used compared to single-agent therapy, and it should target a larger variety of the mutant cells that comprise the tumor. Minimizing side effect overlap provides a greater chance that the patient will be able to tolerate therapy and accommodate a shorter interval between courses (2,3).

As previously noted, it is essential that the oncology pharmacist be well versed in the pharmacotherapy-based management of severe pain, infection, and the nausea, vomiting, and fatigue associated with chemotherapy. The provision of contemporary and valid drug information to patients and families is essential, as is assistance in helping with the interpretation of information that patients and loved ones secure either through their health care providers or independently (e.g., from the Internet).

Therapeutic Classes of Anticancer Drugs

DNA Cross-Linking Agents (Alkylators and Organic Metallics)

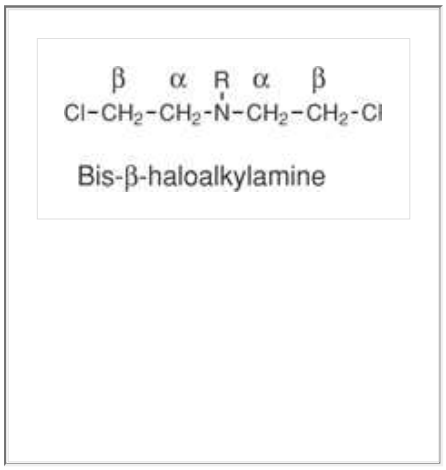
The primary target of DNA cross-linking agents is the actively dividing DNA molecule. The DNA cross-linkers are all extremely reactive electrophilic (δ^+) structures. When encountered, the nucleophilic groups on various DNA bases (particularly, but not exclusively, the N^7 of guanine) readily attack the electrophilic drug, resulting in irreversible alkylation or complexation of the DNA base.

Some DNA alkylating agents, such as the nitrogen mustards and nitrosoureas, are bifunctional, meaning that one molecule of the drug can bind two distinct DNA bases. Most commonly, the alkylated bases are on different DNA molecules, and interstrand DNA cross-linking through two guanine N^7 atoms results. The DNA alkylating antineoplastics are not cell-cycle specific, but they are more toxic to cells in the late G_1 or S phases of the cycle. This is the time when DNA is unwinding and exposing its nucleotides, enhancing the chance that vulnerable DNA functional groups will encounter the electrophilic antineoplastic drug and launch the nucleophilic attack that leads to its own destruction. The DNA alkylators have a great capacity for inducing both mutagenesis and carcinogenesis; in other words, they can promote cancer in addition to treating it.

Organometallic antineoplastics (platinum coordination complexes) also cross-link DNA, and many do so by binding to adjacent guanine nucleotides, called diguanosine dinucleotides, on a single strand of DNA. This leads to intrastrand DNA cross-linking. The anionic phosphate group on a second strand of DNA stabilizes

the drug-DNA complex and makes the damage to DNA replication irreversible. Some organometallic agents also damage DNA through interstrand cross-linking.

Nitrogen Mustards and Aziridine-Mediated Alkylators



Nitrogen mustards are bis(β-haloalkyl)amines. The term “bis” means two, and the “halo” (short for “halogen”) in the nomenclature is invariably chlorine. The two chlorine atoms dramatically decrease the basic strength of the amino nitrogen through a strong negative inductive effect. As a result, the un-ionized conjugate of these drugs predominates at physiological pH. This is intentional, because it is the unionized amine (with its lone pair of electrons) that allows the formation of the highly electrophilic aziridinium ion, which is the reactive DNA-destroying intermediate generated by all true mustards.

Mechanism of action

The mechanism of action of the nitrogen mustards (14) is depicted in Figure 42.1. In step 1, the lone pair of electrons on the un-ionized amino group conducts an intramolecular nucleophilic attack at the β-carbon of the mustard, displacing chloride ion and forming the highly electrophilic aziridinium ion intermediate, a quaternary amine salt. The carbon atoms of this strained cyclic structure are highly electrophilic

because of the strong negative inductive effect of the positively charged nitrogen atom.

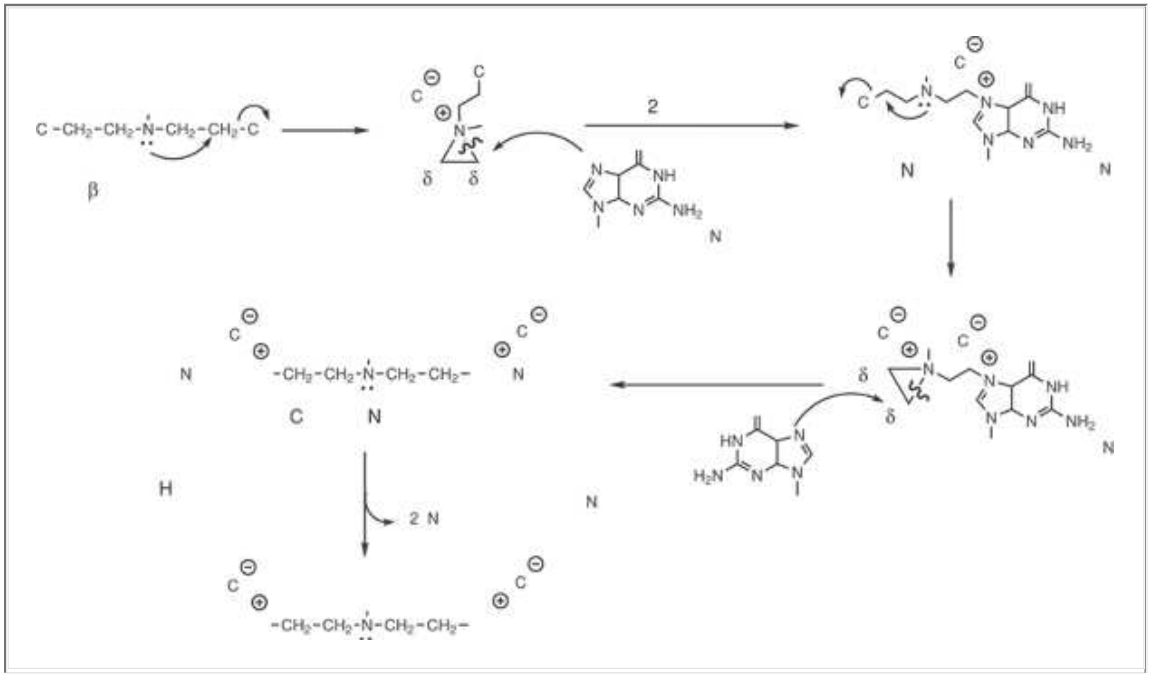


Fig. 42.1. DNA destruction through nitrogen mustard-mediated alkylation.

In step 2, a DNA nucleophile conducts an intermolecular nucleophilic attack, which breaks the aziridine ring and alkylates DNA. Although guanine is the preferred nucleic acid base involved in the alkylation reaction, adenine also is known to react. Of critical importance is the fact that the lone pair of electrons on the mustard nitrogen is regenerated when the aziridine ring cleaves.

Steps 3 and 4 are simply repetitions of steps 1 and 2, respectively, involving the second arm of the mustard and a second molecule of DNA. Ultimately, two molecules of DNA will be cross-linked through the carbon atoms of what was once the nitrogen mustard. Finally, hydrolytic depurination (step 5) cleaves the bound guanine residues from the DNA strand. This is an attempt to liberate the DNA from the mustard's covalent "stranglehold," but the DNA released from this mustard trap is damaged and unable to replicate. Cell death is the inevitable result. If this is happening in a tumor cell, the therapeutic goal has been accomplished. If it is happening in a healthy cell, particularly one with a short half-life, then the patient may experience side effects that can be use-limiting.

Structure–activity relationships

The structure of nitrogen mustards differs only in the nature of the third group (R) attached to the amino nitrogen. This group, which can be either aliphatic or aromatic, is the prime determinant of chemical reactivity, oral bioavailability, and the nature and extent of side effects.

An aliphatic nitrogen substituent (e.g., CH_3) will push electrons to the amine through σ bonds. This electronic enrichment enhances the nucleophilic character of the lone pair of electrons and increases the speed at which the δ^+ β-carbon of the mustard will be attacked. Whether in a tumor cell or a healthy cell, the aziridinium ion, as soon as it forms, will react with unpaired DNA and/or other cell nucleophiles, such as electron-rich SH, OH, and NH groups of amino acids on enzymes or membrane-bound receptors. The body's water also can react with (and inactivate) the aziridinium ion. The intra- and intermolecular reactions designated as steps 1 through 4 in Figure 42.1 happen so rapidly that almost no chance exists for tissue or cell specificity, which means a greatly increased risk of serious side effects and use-limiting toxicity.

Conversely, an aromatic nitrogen substituent (e.g., phenyl) conjugated with the mustard nitrogen will stabilize the lone pair of electrons through resonance. Resonance delocalization significantly slows the rate of intramolecular nucleophilic attack, aziridinium ion formation, and DNA alkylation. Aromatic mustards have a reactivity sufficiently controlled to permit oral administration and attenuate the severity of side effects. The higher stability also provides the chance for enhanced tissue selectivity by giving the intact mustard time to reach malignant cells before generating the electrophilic aziridinium ion.

Nitrogen mustards can decompose in aqueous media through formation of the inactive dehalogenated diol shown in Figure 42.2. Both the mustard nitrogen (pathway a) and the oxygen of water (pathway b) can act as nucleophiles to advance this degradative process. The decomposition reactions can be inhibited if the nucleophilic character of these atoms is eliminated through protonation, so buffering solutions to a slightly acidic pH helps to enhance stability in aqueous solution.

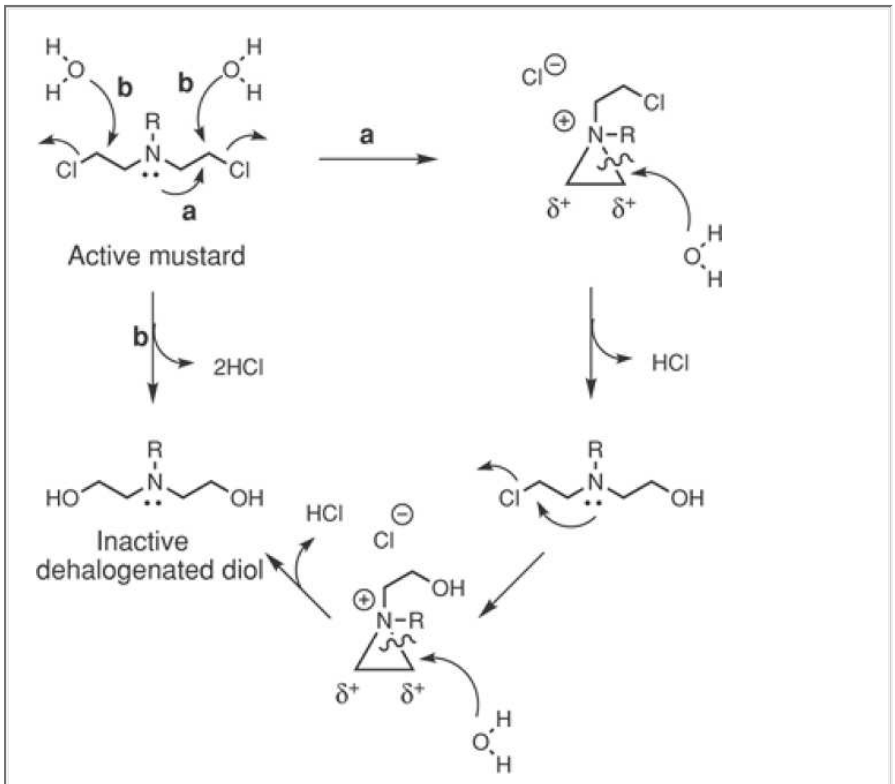

Fig. 42.2. Aqueous decomposition of nitrogen mustards.

Specific drugs

Mechlorethamine Hydrochloride

Mechlorethamine is the only aliphatic nitrogen mustard currently on the U.S. market (Fig. 42.3). Its use is limited by extremely high reactivity, which leads to rapid and nonspecific alkylation of cellular nucleophiles and excessive toxicity. It is a severe vesicant, and if accidental skin contact occurs, the drug must be inactivated with 2% sodium thiosulfate ($Na_2S_2O_3$) solution. This reagent reacts with the mustard to create an inactive, highly ionized, and water-soluble thiosulfate ester that can be washed away (Fig. 42.4). The affected tissue also should be treated with an ice compress for 6 to 12 hours.

Mechlorethamine is marketed in hydrochloride salt form to provide water solubility for intravenous (IV) or intracavitary administration. The strong electron-withdrawing effect of the two chlorine atoms reduces the pK_a of mechlorethamine to 6.1, which gives a ratio of un-ionized to ionized drug forms of approximately 20:1 at pH 7.4. This agent is too reactive for oral administration and too toxic to use alone. In addition to severe nausea and vomiting, myelosuppression (lymphocytopenia and granulocytopenia), and alopecia, it can cause myelogenous leukemia with extended use because of its mutagenic/carcinogenic effects on bone marrow stem cells. Mechlorethamine is still used in regimens for cancers of the blood (e.g., Hodgkin's disease, chronic myelocytic, or chronic lymphocytic leukemia); fortunately, however, safer and still highly potent antineoplastic agents are now available.

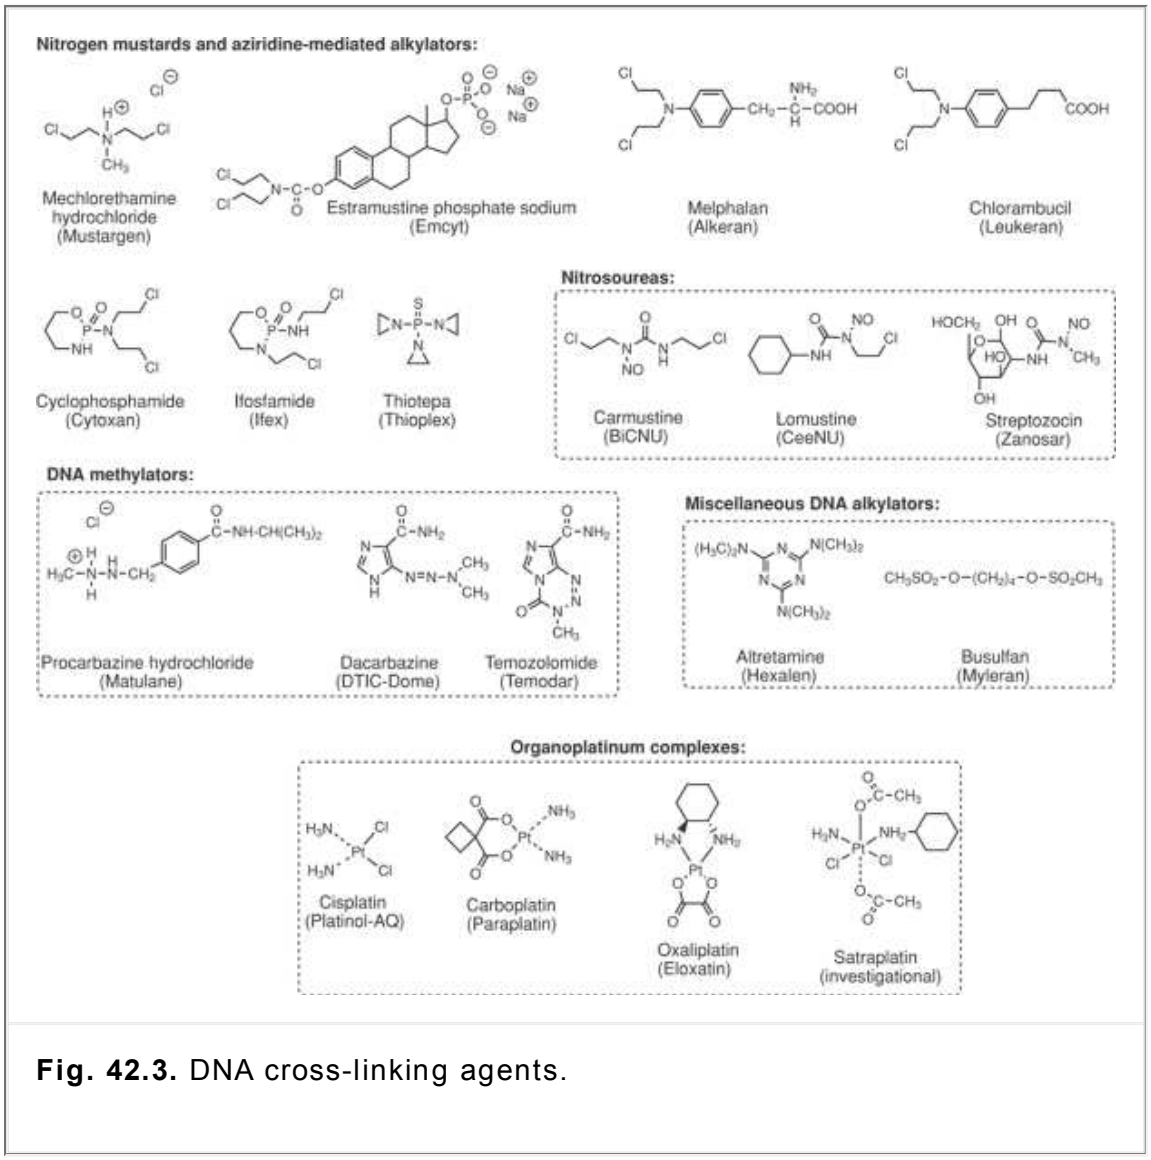

Fig. 42.3. DNA cross-linking agents.

Melphalan

This aromatic mustard, used primarily in the treatment of multiple myeloma, is able to stabilize the lone pair of electrons on the mustard nitrogen through resonance with the conjugated phenyl ring, slowing the formation of the reactive aziridinium ion. The L-isomer of the amino acid Phe was purposefully incorporated into this antineoplastic agent (Fig. 42.3), because naturally occurring L–amino acids are preferentially transported into cells by the action of specific amino acid carrier proteins. It was assumed that the L-Phe would act as a homing device and actively transport the toxic mustard inside the tumor cells, but some studies indicate that melphalan enters cells through facilitated diffusion rather than by active transport (15).

Because the lone pair of electrons of melphalan (and other aromatic mustards) is less reactive, there is a greater opportunity for distribution to cancer cells and a decreased incidence of severe side effects. There is a lower incidence of nausea and vomiting compared to mechlorethamine, but patients still experience myelosuppression, which can

be severe. This drug also is mutagenic and can induce leukemia.

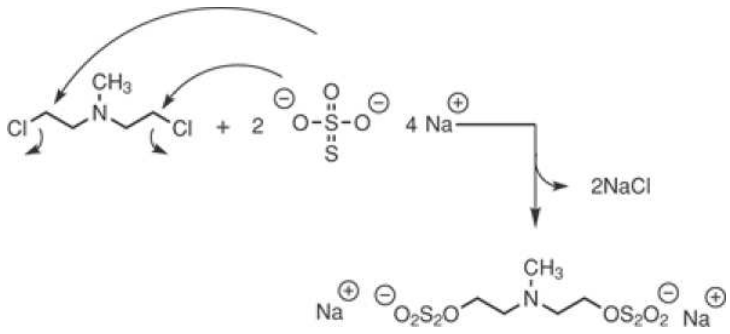

Fig. 42.4. Mechlorethamine inactivation by sodium thiosulfate.

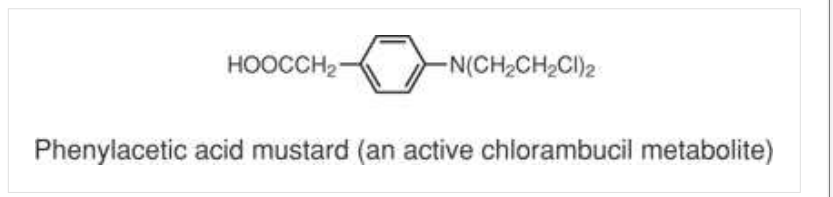
Melphalan is orally active, but absorption can be erratic. Absorption is decreased with food, but dosing regimens do not demand an empty stomach. The drug can be formulated for IV administration, but the risk of serious side effects is higher. Melphalan distributes into body water, so toxicity can be pronounced in dehydrated patients or in those with renal dysfunction. Dehydration can be corrected, but dosage adjustments should be considered in patients with renal disease.

Chlorambucil

Like melphalan, chlorambucil (Fig. 42.3) has good oral bioavailability, which is decreased in the presence of food, and the potential to induce nonlymphocytic leukemia. This drug is active intact and also undergoes β-oxidation to provide an active phenylacetic acid mustard metabolite, which is responsible for some of the observed antineoplastic activity. It is used in the palliative treatment of chronic lymphocytic leukemia, malignant lymphoma, and Hodgkin's disease.



Phenylacetic acid mustard (an active chlorambucil metabolite)

Estramustine Phosphate Sodium

This resonance-stabilized, mustard-like antineoplastic agent utilizes an estradiol carrier (Fig. 42.3) to selectively deliver drug to steroid-dependent prostate tissue, and its use is limited to the palliative treatment of progressive prostate cancer. The essential 17β-OH group has been esterified with phosphoric acid, and the C_3-phenol has been carbamylated. The body still, however, transports the basic steroidal pharmacophore into cells. The ionized sodium phosphate ester of the active 17β-OH group makes the compound water soluble and able to distribute in the blood. The ester is readily cleaved during absorption to provide the active 17β-OH.

The nitrogen mustard moiety of estramustine is incorporated into a carbamate group made from the

C_3-phenolic OH group of the estradiol structure. The resonance and negative induction capabilities of the carbamate extensively delocalize the lone pair of electrons on the mustard nitrogen. This stabilizes the lone pair in the same qualitative way that conjugation with the phenyl ring of melphalan and chlorambucil does, and it is very slow to attack the electrophilic β-carbon. Because the formation of the aziridinium ion is significantly delayed, DNA alkylation is controlled, and the drug can be given orally. Estramustine is considered to be a weak alkylating agent, and its primary mechanism of antineoplastic action actually is inhibition of cellular mitosis.

The carbamate group containing the mustard moiety can be cleaved in vivo to generate estradiol (Fig. 42.5). This is obviously not desired, because the chemically reactive mustard is being detached from the carrier molecule designed to take it to the prostatic tumor cell. The normal metabolites of estradiol (conjugates of estradiol and estriol) are found in the feces. The formation of active estrogens is why this drug is not used to treat estrogen-dependent tumors (e.g., estrogen-dependent breast cancer). The liberated estradiol also can increase blood pressure and induce blood clots, leading to myocardial infarction. Fortunately, the myocardial infarctions usually are nonfatal, but the drug should be used with extreme caution in men who are predisposed to clotting disorders or who have a history of cerebral vascular disease or coronary artery disease. Hepatotoxicity also is associated with estramustine use.

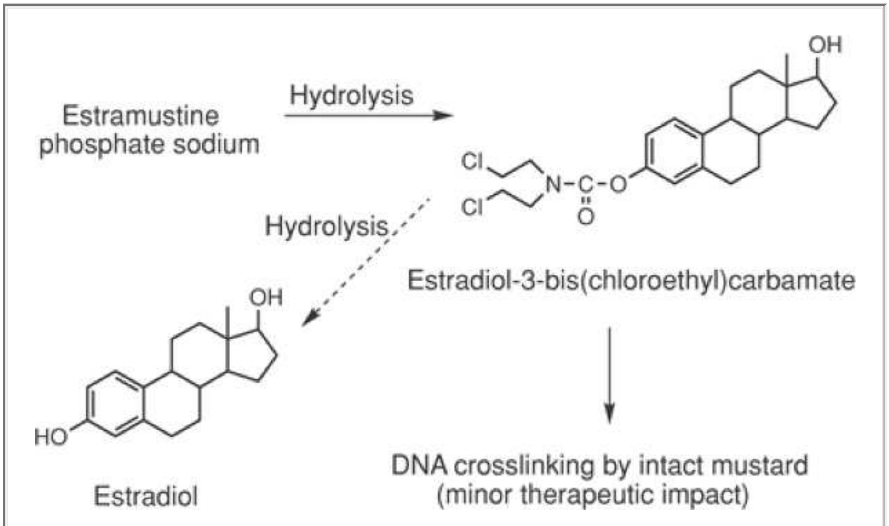


Fig. 42.5. Estramustine metabolism.

Cyclophosphamide

Cyclophosphamide (Fig. 42.3) is a prodrug, antineoplastic agent requiring activation by metabolic and nonmetabolic processes (Fig. 42.6). The initial metabolic step is mediated primarily by CYP2B6 (and, to a much lower extent, by CYP3A4) and involves hydroxylation of the oxazaphosphorine ring to generate a carbinolamine (16). This hydroxylation reaction must occur before the molecule will be transported into cells. CYP3A4 (but not CYP2B6) also catalyzes an inactivating N-dechloroethylation reaction, which yields highly nephrotoxic and neurotoxic chloroacetaldehyde (16). Chloroacetaldehyde toxicity is accompanied by glutathione depletion, indicating that, as expected, this electrophilic by-product alkylates Cys residues of critical cell proteins (17). Alkylation of Lys, adenosine, and cytidine residues also is possible.

The CYP-generated carbinolamine undergoes nonenzymatic hydrolysis to provide the aldophosphamide either in the bloodstream or inside the cell. If this hydrolysis occurs extracellularly, the aldophosphamide is still able to penetrate cell membranes to reach the intracellular space. Once inside the cell, acrolein (a highly reactive α,β-unsaturated aldehyde) splits off, generating phosphoramide mustard. With a pK_a of 4.75, the mustard will be persistently anionic at intracellular pH and trapped inside the cell.

The fate of phosphoramide mustard is varied. Most of it cyclizes to form the quaternary aziridinium ion, which alkylates DNA in the manner of all mustards. Some of it will decompose, losing phosphoric acid (H_3PO_4)

and ammonia (NH_3) and leaving the naked bis(β-chloroethyl)amine mustard. This secondary amine cyclizes in a manner similar to the tertiary phosphoramide mustard, forming a tertiary aziridine (rather than a quaternary aziridinium) species. The free tertiary aziridine can protonate at intracellular pH to provide the cationic aziridine species, which is in equilibrium with the free-base form. Some electrophilic character is lost, but the carbon atoms in both forms are still δ^+ enough to attract DNA nucleophiles, albeit less vigorously. The net result of this attack is DNA alkylation and cell death.

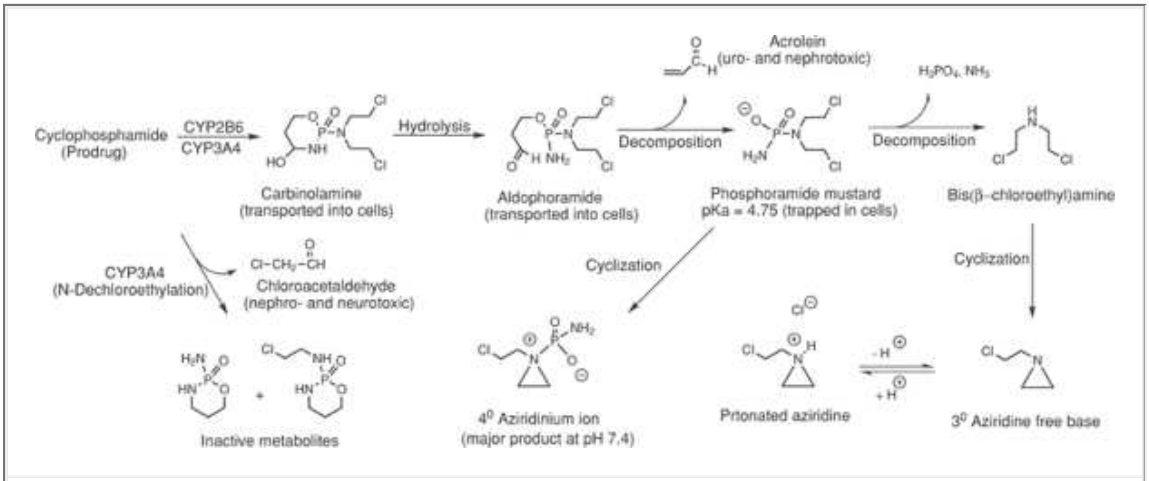

Fig. 42.6. Cyclophosphamide metabolism.

The need for metabolic activation in the liver means lowered GI toxicity and less nonspecific toxicity for cyclophosphamide compared with other DNA alkylating agents, but cyclophosphamide is not without its toxic effects. Acrolein, generated during the formation of phosphoramide mustard, is a very electrophilic and highly reactive species and causes extensive damage to cells of the kidney and bladder. Potentially fatal acute hemorrhagic cystitis is a significant risk of cyclophosphamide therapy.

Bladder damage from acrolein results from attack by Cys sulfhydryl groups at the δ^+ terminal carbon of the acrolein structure, resulting in renal cell alkylation and cell death. Physiological results can include severe hemorrhage, sclerosis, and on occasion, induction of bladder cancer. Acrolein also damages the nephron, particularly when used in high doses, in children, in patients with only one kidney, or when coadministered with other nephrotoxic agents (e.g., cisplatin). To minimize the risk of bladder toxicity from acrolein, fluids should be forced and the bladder irrigated. Mesna (Mesnex) also is available as adjuvant therapy in case of overt toxicity or as a prophylactic protectant. A sulfhydryl reagent, mesna competes with Cys residues for the alkylating arolein, as shown in Figure 42.7. Mesna concentrates in the bladder and will prevent damage to those cells. It does not concentrate to any appreciable extent in the nephron and, therefore, is not good protection against cyclophosphamide-induced nephrotoxicity.

As effective as mesna is for preventing acrolein-induced urotoxicity, it does little to spare the kidney and nerve cells from chloroacetaldehyde, the other toxic by-product of cyclophosphamide metabolism (18). Luckily, only approximately 10% of a standard dose of cyclophosphamide undergoes the dechloroethylation reaction, although this percentage can rise if higher doses are used (16).

Cyclophosphamide most commonly is used in combination with other antineoplastic agents to treat a wide range of neoplasms, including leukemias and malignant lymphomas, multiple myeloma, ovarian adenocarinoma, and breast cancer. The drug is metabolized in the liver

and is eliminated via the kidney, with approximately 15% of a given dose being excreted unchanged. Doses should be reduced in patients with levels of creatinine clearance less than 30 mL/min. Interestingly, hepatic dysfunction does not seem to alter metabolism of this drug, but caution should be exercised in patients with inhibited cytochrome P450 (CYP450) enzymes or with a combination of factors that could negatively impact drug activation/inactivation pathways.

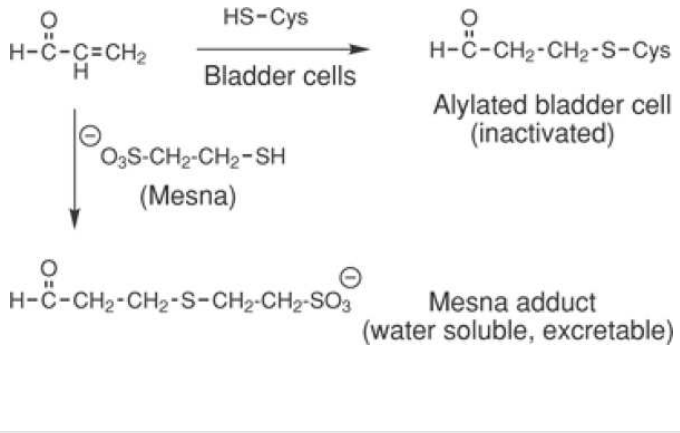

Fig. 42.7. Sulfhydryl alkylation by acrolein.

Ifosfamide

This cyclophosphamide analogue has the two arms of the mustard on different nitrogen atoms (Fig. 42.3). Ifosfamide also requires metabolic activation (Fig. 42.8), but this time it is the CYP3A4 isoform that converts the majority of the dose to the carbinolamine, with CYP2B6 taking on a minor, supporting role (19). Because ifosfamide has a lower affinity for the hydroxylating CYP3A4 and CYP2B6 enzymes, presumably as a result of steric hindrance, bioactivation proceeds at a slower rate (20). Doses three- to fourfold higher than cyclophosphamide are required to achieve the same antineoplastic result.

Unlike cyclophosphamide, dechloroethylation is a significant metabolic pathway for ifosfamide, and approximately 45% of a standard dose will undergo this inactivating and toxicity-inducing biotransformation. CYP3A4 catalyzes approximately 70% of ifosfamide dechloroethylation, with CYP2B6 taking care of the remainder (16). The fact that this reaction can occur in the renal tubule, generating chloroacetaldehyde right in the nephron, contributes to its significantly higher nephrotoxicity (20). Ultimately, both chloroalkyl groups are lost before the compound is excreted.

It bears repeating that there is a significantly higher risk of bladder toxicity and nephrotoxicity with ifosfamide than with cyclophosphamide. This is because:

- Significantly more chloroacetaldehyde is generated through CYP3A4- and CYP2B6-mediated dechloroethylation. This biotransformation can take place in the nephron, which places the toxic by-product right where it will do the most damage.
- Ifosfamide is more water soluble than cyclophosphamide and will concentrate in the renal system. Between 20 and 50% of a dose is excreted unchanged in the urine.
- Acrolein also is formed when this alkylator generates the cytotoxic aziridiniun ion.
- Higher doses must be administered to achieve the same degree of antineoplastic action, so more molecules of acrolein and chloroacetaldehyde will be produced.

Because acrolein is formed, the same precautions against hemorrhagic cystitis that were previously outlined for cyclophosphamide must be taken: hydrate well, irrigate thoroughly, and administer with mesna. As previously stated, mesna will not prevent chloroacetaldehyde-induced toxicity.

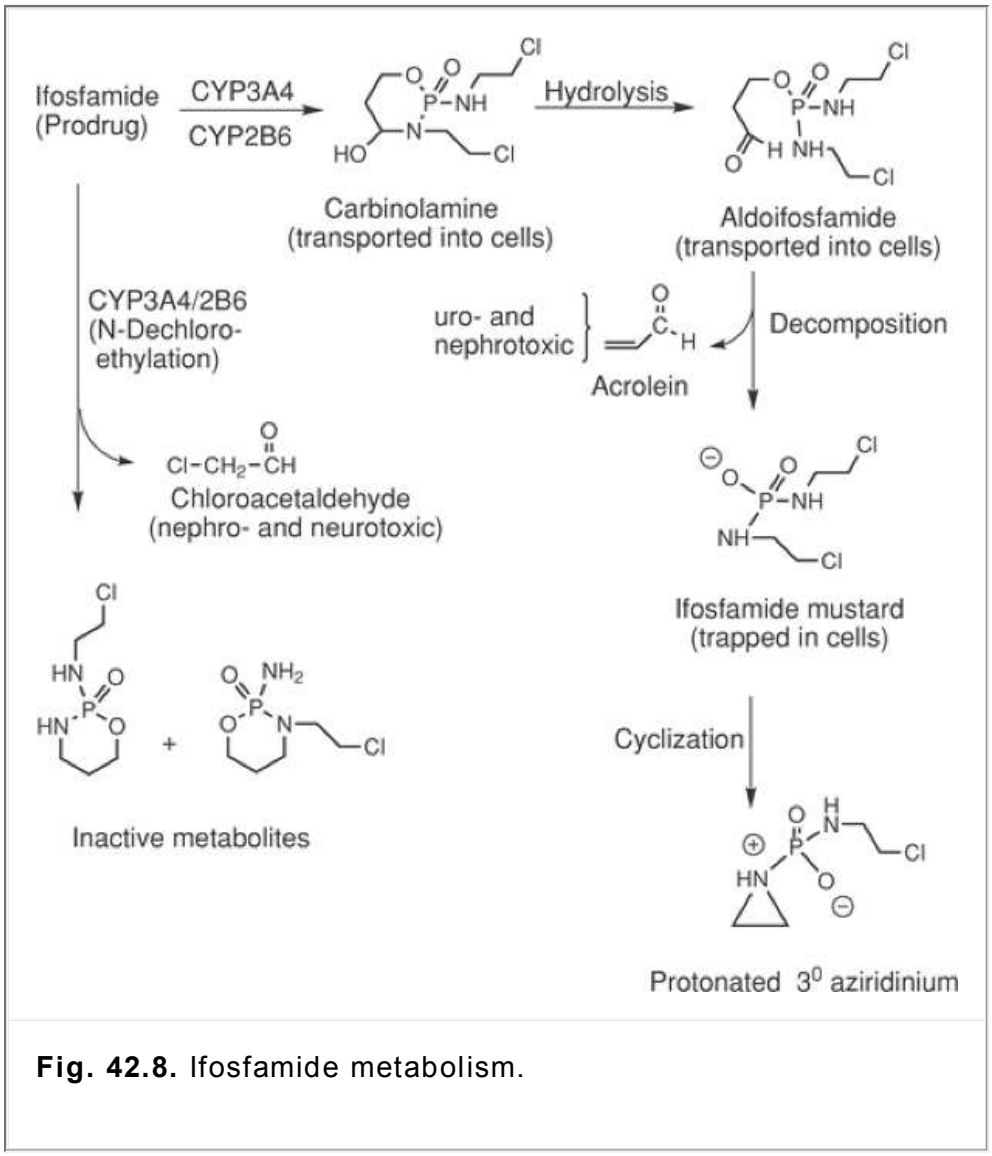

Fig. 42.8. Ifosfamide metabolism.

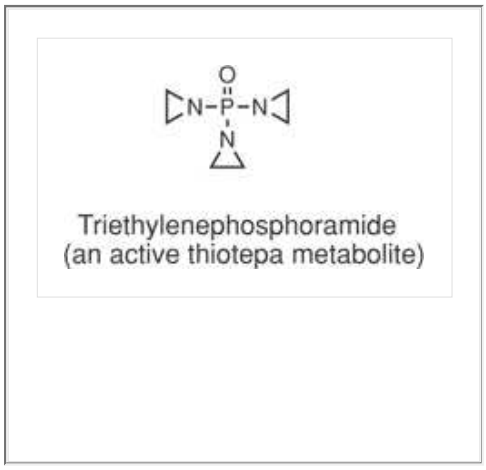
Ifosamide currently is used as “third-line” therapy against testicular cancer, although it also has shown activity in a number of solid tumors and hematologic cancers. Patients on ifosfamide (but not cyclophosphamide) commonly exhibit central nervous system (CNS) toxicity. In severe forms, CNS depression can progress to coma and death.

Thiotepa

Thiotepa (Fig. 42.3), a tertiary aziridine, is less reactive than quaternary aziridinium compounds and is classified as a weak alkylator. It is possible for the nitrogen atoms to be protonate before reacting with DNA (a positively charged aziridine is more reactive than the un-ionized aziridine), but the electron-withdrawing effect of the sulfur atom decreases the pK_a to approximately six, which keeps the percentage ionized at pH 7.4 relatively low. Thiotepa undergoes oxidative desulfuration, forming an active cytotoxic metabolite known as TEPA (triethylenephosphoramide). This antineoplastic agent is most commonly employed in the treatment of ovarian and breast cancers, as well as papillary carcinoma of the bladder.



Triethylenephosphoramide
(an active thiotepa metabolite)

Thiotepa and the TEPA metabolite readily enter the CNS after systemic administration, leading to dizziness, blurred vision, and headaches. More critically, these agents also are severe myelosuppressants and can induce leukopenia, thrombocytopenia, and anemia. Patients treated with thiotepa are at high risk for infection and hemorrhage. Oral absorption is unreliable, so thiotepa is given IV or can be instilled intravesically in the treatment of bladder cancer. Even when administered locally in bladder cancer, high levels of this lipophilic drug reach the systemic circulation, resulting in bone marrow depression. Patients have died from myelosuppression after intravesically administered thiotepa. The drug also causes damage to the hepatic and renal systems. Dose and/or administration frequency should be increased slowly, even if the initial response to the drug is sluggish, or unacceptable toxicity may result.

Nitrosoureas

Mechanism of action

The nitrosoureas are unstable structures that decompose readily in the aqueous environment of the cell. Nonenzymatic fragmentation is stimulated by the loss of proton from the urea moiety. Cyclization of the resultant anion to an unstable oxazolidine (pathway A) is followed by decomposition to vinyl diazotic acid and a substituted isocyanate, both of which release a gaseous fragment (nitrogen and carbon dioxide, respectively) to generate cytotoxic electrophiles (Fig. 42.9). Vinyl carbocation, acetaldehyde, and 2-chloroethylamine generated from the 2-chloroethylisocyanate moiety of carmustine are all capable of alkylating DNA in the standard manner (21). A second decomposition mechanism (pathway B) ultimately produces an electrophilic 2-chloroethylcarbocation capable of DNA alkylation at guanine-N^7 and O^6 as well as an isocyanate that can carbamylate amino acid residues (e.g., Lys).

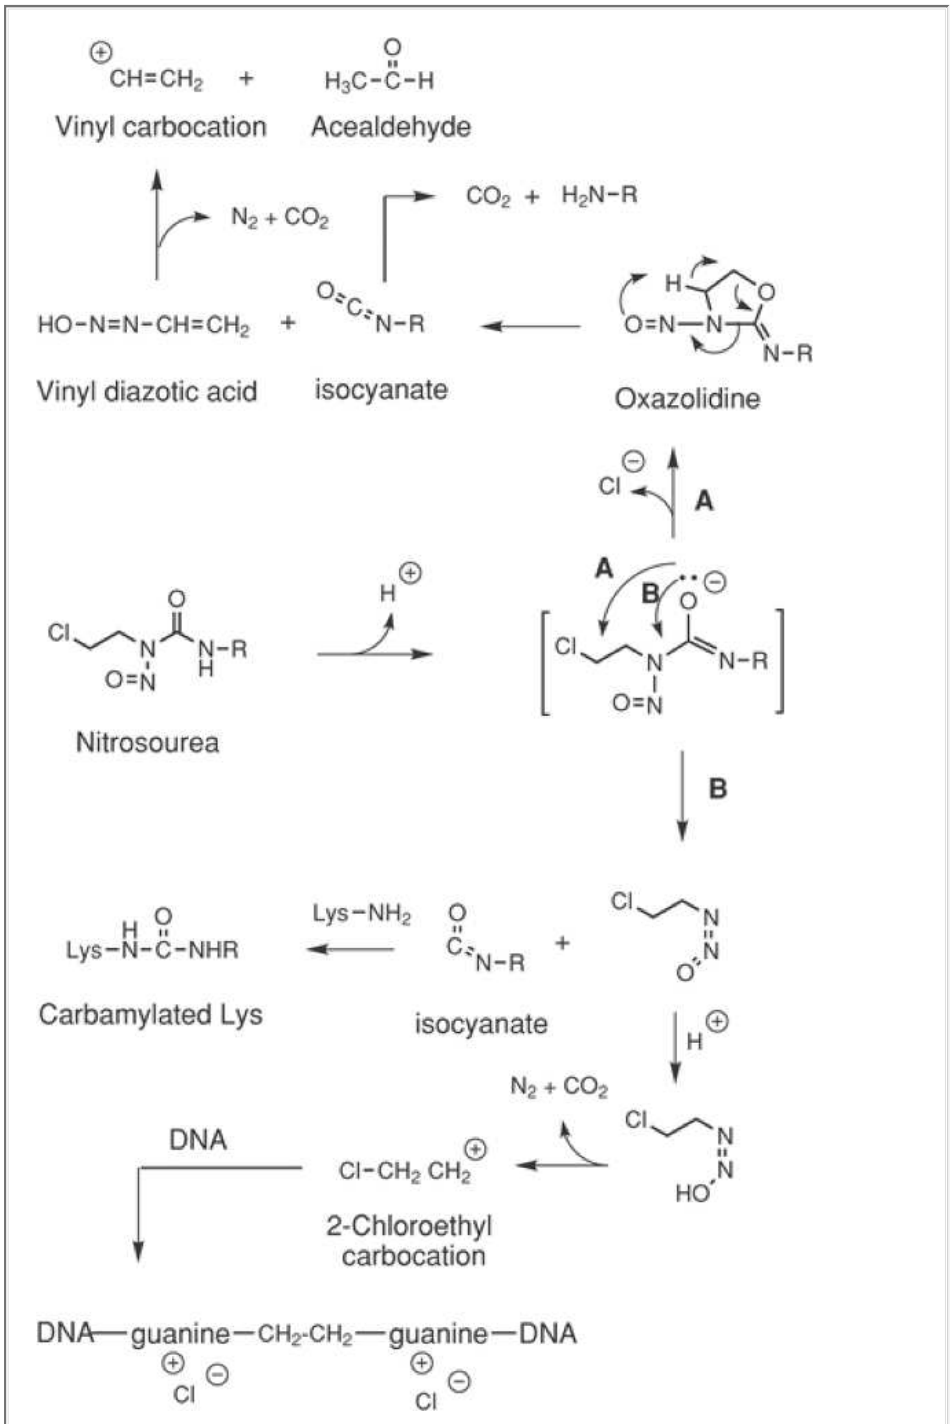


Fig. 42.9. Nitrosourea decomposition to active electrophiles.

Specific drugs

Carmustine and Lomustine

Carmustine and lomustine are both highly lipophilic chloroethylnitrosourea analogues marketed for use in brain tumors and Hodgkin's disease. Carmustine also has shown value in the treatment of non-Hodgkin's lymphoma and multiple myeloma, and it is given IV or incorporated into biodegradable wafers that are implanted directly into the CNS after tumor resection. The high lipophilicity of carmustine precludes a totally

aqueous IV formulation, and the drug is administered in 10% ethanol. Although carmustine degrades within 15 minutes of IV administration, lomustine is stable enough for oral use and is marketed in capsule form. Carmustine also can

decompose in vitro if exposed to temperatures around 90°F. Pure carmustine is a low-melting solid, but the decomposed product is an oil and, therefore, is readily detected. Vials of carmustine that appear oily should be discarded.

Both carmustine and lomustine can induce thrombocytopenia and leukopenia, leading to hemorrhage and massive infection. Acute (as well as potentially fatal delayed) pulmonary toxicity also is a risk. Pulmonary toxicity is dose-related, and individuals who received the drug in childhood or early adolescence are at higher risk for the delayed reaction. The grand mal seizures that are possible from the wafer formulation of carmustine appear to result from the wafer rather than from the nitrosourea.

Streptozocin

The glucopyranose moiety of streptozocin confers both islet cell specificity and high water solubility to this nitrosourea-based antineoplastic. As a result, it is used exclusively in metastatic islet cell carcinoma of the pancreas and is administered IV in D5W or normal saline. Lacking the 2-chloroethyl substituent of carmustine and lomustine, it is much less reactive as a DNA alkylating agent, and myelotoxicity is relatively rare but not unknown. Cumulative, dose-related renal toxicity can be severe or fatal, however, and 67% of patients receiving this drug will exhibit some kidney-related pathology. Good hydration is essential to successful therapy, and kidney function should be monitored weekly.

Procarbazine and Triazenes

Mechanism of action

Procarbazine and the triazenes dacarbazine and temozolomide act by different mechanisms, but they all exert an antineoplastic effect through the O^6-methylation of guanine nucleotides. O^6-methylguanine pairs preferentially with thymine, and these “mispairs” prompt point mutations during subsequent DNA replication cycles and trigger cell destruction through the activation of the normal postreplication mismatch repair (MMR) system. Patients who are able to repair this damage through the action of O^6-alkylguanine-DNA-alkyltransferase, which transfers the offending CH_3 group to a Cys residue on the alkyltransferase protein, will exhibit resistance to these agents, whereas those who underexpress this protein should respond well (22). Because the alkyltransferase is irreversibly inactivated in the DNA rescue process, enzyme depletion (and subsequent loss of DNA repair capability) is a significant risk.

Procarbazine metabolism involves CYP1A and CYP2B enzymes (23), and DNA alkylation operates through a free radical mechanism (Fig. 42.10). The major degradation pathway involves benzylic oxidation of azoprocarbazine, producing methylhydrazine that generates a methyl radical through an unstable diazene intermediate (24,25) In addition to O^6, the reactive methyl radical formed can alkylate the C^8 and N^7 positions of guanine. In contrast, the triazenes methylate DNA guanine via diazomethane and/or methyl carbocation generated in situ. Although temozolomide is converted to the diazomethane precursor 3-methyl-(triazen-l-yl) imidazole-4-carboxamide (MTIC) through nonenzymatic mechanisms, the conversion of dacarbazine to MTIC depends on the action of CYP1A1 and CYP1A2 enzymes, with a smaller contribution by CYP2E1 (Fig. 42.11) (23,26). The O^6 and N^7 positions of guanine are the most vulnerable to triazene methylation.

Specific drugs

Procarbazine

This methyl radical generator is utilized predominantly in the treatment of Hodgkin's disease. It is administered as part of a multidrug regimen that also includes a nitrogen mustard (mechlorethamine), a mitosis inhibitor (vincristine), and prednisone. It is administered as capsules and is well absorbed after oral administration. Procarbazine is extensively metabolized in the liver, and 70% of an administered dose is excreted in the urine as N-isopropylterephthalamic acid (Fig. 42.10). In addition to

methylating DNA guanine residues, it is proposed to inhibit the de novo synthesis of proteins and nucleic acids. Procarbazine inhibits monoamine oxidase, leading to several significant and potentially fatal drug–drug and drug–food interactions. Facial flushing and other disulfiram-like symptoms are noted when alcohol is concomitantly consumed, because the drug also inhibits enzymes involved in ethanol metabolism.

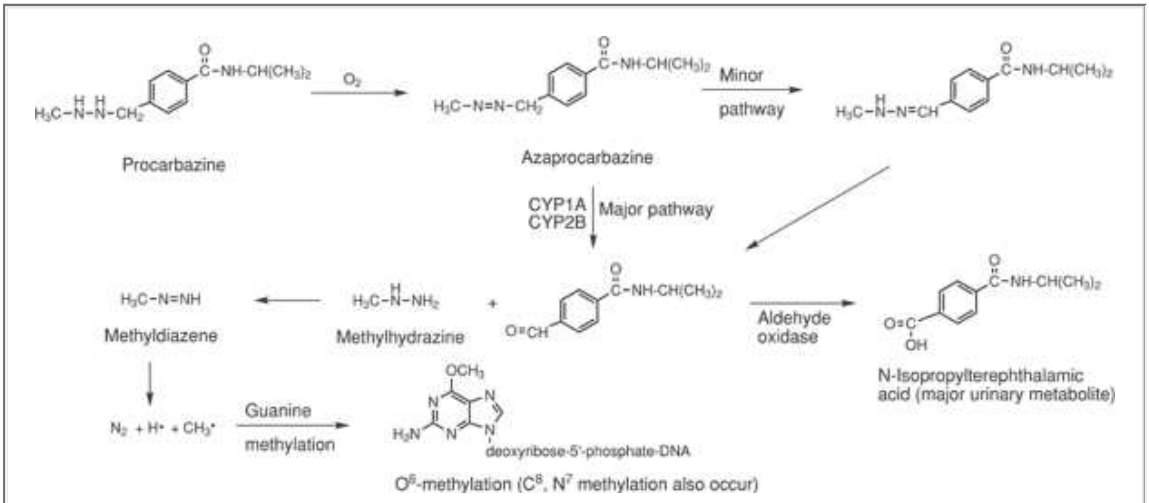

Fig. 42.10. Procarbazine metabolism and mechanism of action.

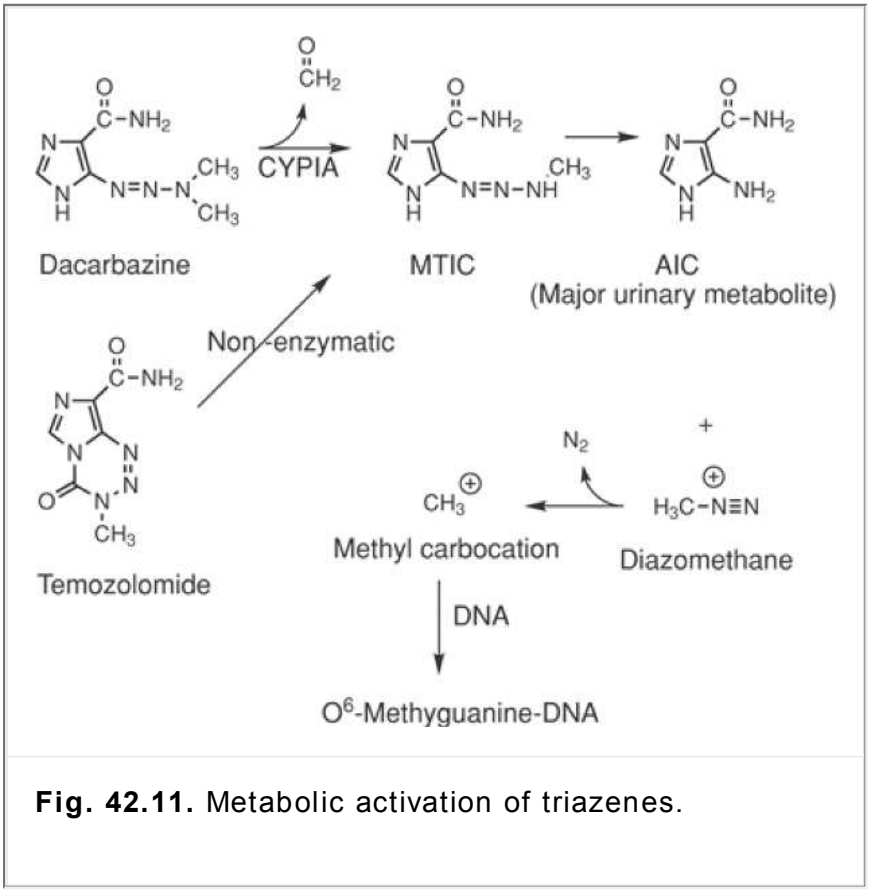

Fig. 42.11. Metabolic activation of triazenes.

Dacarbazine

This DNA methylating agent is administered IV as a single agent in the treatment of malignant melanoma and in combination with other agents in the treatment of metastatic melanoma. Approximately 40% of the drug is

excreted unchanged, but both the 5-aminoimidazole-4-carboxamide (AIC, formed through the action of CYP1A enzymes) and the carboxylic acid (AIC hydrolysis product) are major urinary metabolites (Fig. 42.11). Leukopenia and thrombocytopenia are the most common side effects and may be fatal. Patients also are at risk for hepatotoxicity, including hepatocellular necrosis.

Temozolomide

This imidazolotetrazine derivative is administered orally in capsule form for the treatment of glioblastoma multiforme or in patients with anaplastic astrocytoma who have not responded to procarbazine or the nitrosoureas. Oral absorption is rapid and complete. The CYP450 enzymes are not extensively involved in temozolomide metabolism, and less than 6% of the drug is excreted unchanged in the urine. Women clear the drug less effectively than men and have a higher incidence of severe neutropenia and thrombocytopenia in the initial therapy cycle. Food decreases temozolomide absorption, and myelosuppression is the most significant adverse effect.

Miscellaneous DNA Alkylating Agents

Altretamine

This unique structure (Fig. 42.3) is believed to damage tumor cells through the production of the weakly alkylating species formaldehyde, a product of CYP450-mediated N-demethylation. Administered orally, altretamine is extensively metabolized on first pass, producing primarily mono- and didemethylated metabolites. Additional demethylation reactions occur in tumor cells, releasing formaldehyde in situ before the drug is excreted in the urine. The carbinolamine (methylol) intermediates of CYP450-mediated metabolism also can generate electrophilic iminium species that are capable of reacting covalently with DNA guanine and cytosine residues as well as protein (Fig. 42.12). Iminium-mediated DNA cross-linking and DNA-protein interstrand cross-linking, mediated through both the iminium intermediate and formaldehyde, have been demonstrated (27,28), although the significance of DNA cross-linking on altretamine antitumor activity is uncertain. Resistance to altretamine has been shown to parallel resistance to formaldehyde-induced cytotoxicity (27). Its use currently is restricted to patients with ovarian cancer who have not responded to organoplatinum therapy. The toxicities induced by altretamine are GI, neurologic, and hematologic in nature.

Busulfan

Chemically, busulfan is classified as an alkyl sulfonate (Fig. 42.3). One or both of the methylsulfonate ester moieties can be displaced by the nucleophilic N^7 of guanine, leading to monoalkylated and cross-linked DNA, as shown in Figure 42.13. The extent of alkyl sulfonate–mediated DNA interstrand cross-linking has been shown to vary with the length of the alkyl chain between sulfonate esters, with the tetramethylene-containing busulfan showing less interstrand cross-linking capability than hexamethylene, methylene, or octamethylene analogues (29).

Intrastrand cross-linking also occurs, preferentially at 5′-GA-3′ but also at 5′-GG-3′ sequences (30). Alkylation of Cys sulfhydryl groups is yet another mechanism of cytotoxicity. Busulfan is used in the treatment of chronic myelogenous leukemia and can be administered either orally or by IV infusion. Serious bone marrow hypoplasia and myelosuppression are possible with this agent, and recovery from busulfan-induced pancytopenia can take up to 2 years.

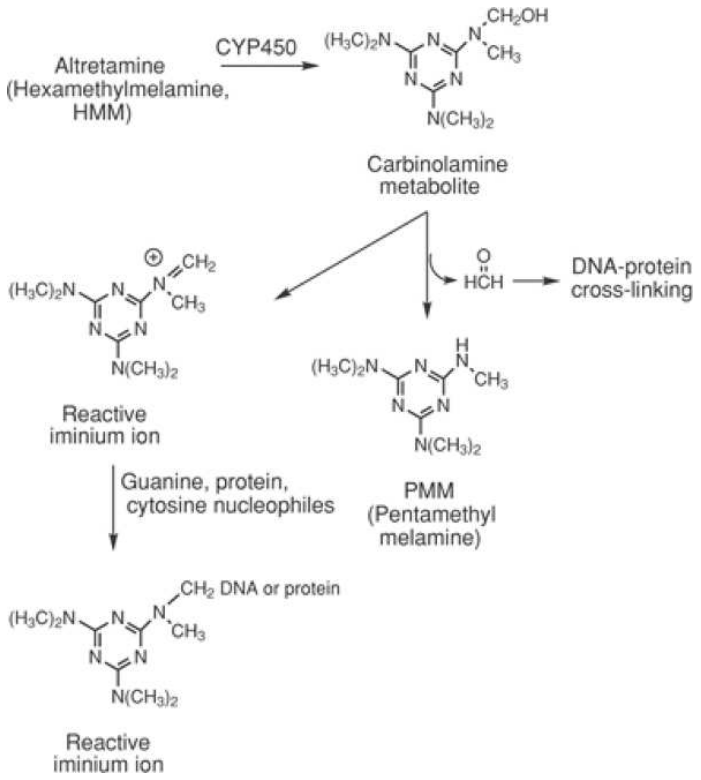

Fig. 42.12. Altretamine metabolism and mechanism of action.

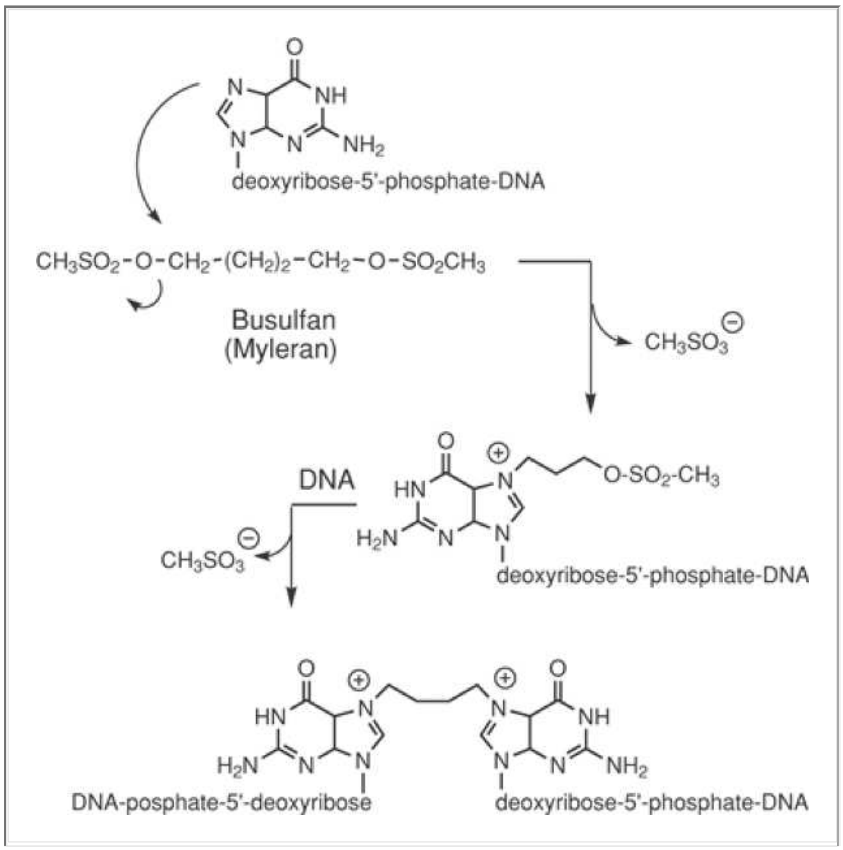

Fig. 42.13. Busulfan-mediated DNA alkylation.

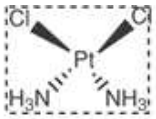
Organoplatinum Complexes

Mechanism of action

Organoplatinum antineoplastic agents contain an electron-deficient metal atom that acts as a magnet for electron-rich DNA nucleophiles. Like nitrogen mustards, organoplatinum complexes are bifunctional and can accept electrons from two DNA nucleophiles. Intrastrand cross-links most frequently occur between adjacent guanine residues referred to as diguanosine dinucleotides (60–65%) or adjacent guanine and adenine residues (25–30%). Interstrand cross-linking, which occurs much less frequently (1–3%), usually involves guanine and adenine bases (31). All the currently marketed organoplatinum anticancer agents are Pt(II) complexes with square-planar geometry, although an octahedral Pt(IV) complex currently is undergoing clinical trials.



Cisplatin (square planar geometry)

Platinum is inherently electron deficient, but the net charge on the organometallic complex is zero because of the contribution of electrons by two of the four ligands bound to the parent structure. Most commonly, the electron-donating ligand is chloride. Before reacting with DNA, the electron-donating ligands most commonly are displaced through nucleophilic attack by cellular water. When the displaced ligands are chloride anions (e.g., in cisplatin), the chloride-poor environment of the tumor cell facilitates the process, driving the generation of the active, cytotoxic hydrated forms (Fig. 42.14). Because the original ligands leave the metal with their electrons, the hydrated organoplatinum molecule has a net positive charge (32).

The hydrated platinum analogues are readily attacked by DNA nucleophiles (e.g., the N^7 of adjacent guanine residues) because of the net positive charge that has

been regained on the Pt atom (Fig. 42.14). The DNA bases become coordinated with the platinum, and in the *cis* configuration, DNA repair mechanisms are unable to correct the damage. The net result is a major change in DNA conformation such that base pairs that normally engage in hydrogen-bond formation are not permitted to interact. The two ammine ligands of the complex are bound irreversibly to the Pt atom through very strong coordinate covalent bonds. They cannot be displaced by DNA nucleophiles, but they do stabilize the cross-linked DNA-platinum complex by forming strong ion–dipole bonds with the anionic phosphate residues on DNA.

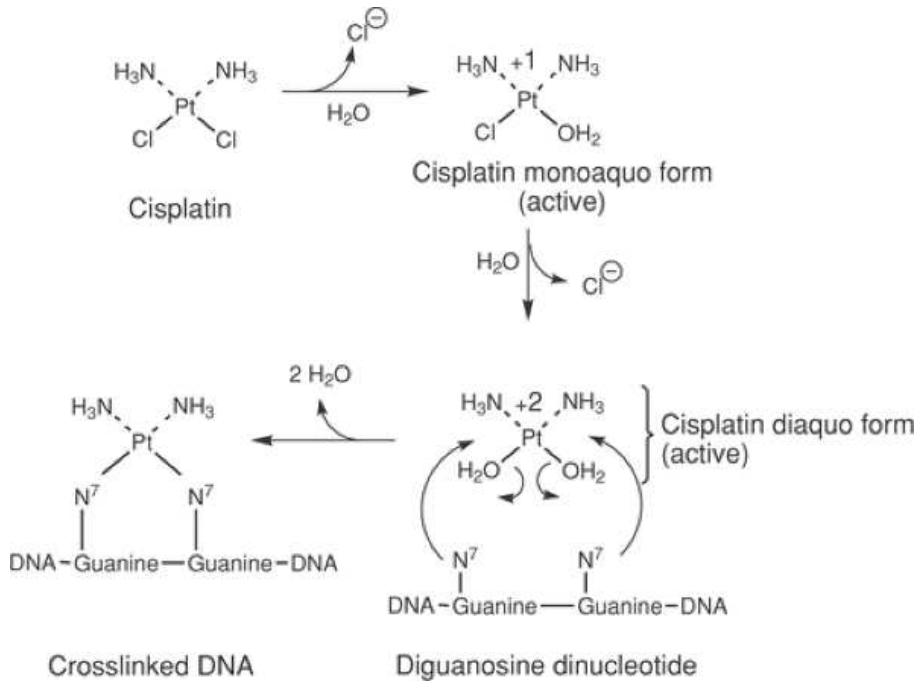


Fig. 42.14. Cisplatin activation and DNA cross-linking.

Specific drugs

Cisplatin

The simplest of the organometallic antineoplastic agents, cisplatin is utilized IV in the treatment of metastatic testicular and ovarian cancer and advanced bladder cancer. It is rapidly hydrated, resulting in a short plasma half-life of less than 30 minutes. It is eliminated predominantly via the kidney, but approximately 10% of a given dose undergoes biliary excretion. It is highly nephrotoxic and can cause significant damage to the renal tubules, especially in patients with preexisting kidney disease or one kidney or who are concurrently receiving other nephrotoxic drugs (e.g., cyclophosphamide or ifosfamide). Dosages should be reduced in any of the above situations. Clearance decreases with chronic therapy, and toxicities can manifest at a late date.

To proactively protect patients against kidney damage, patients should be hydrated with chloride-containing solutions. Saline or mannitol diuretics can be administered to promote continuous excretion of the drug and its hydrated analogues. Sodium thiosulfate, which accumulates in the renal tubules, also has been used to neutralize active drug in the kidneys in an effort to avoid nephrotoxicity (Fig. 42.15). The reaction of sodium thiosulfate with cisplatin in the serum is much slower, because the drug does not concentrate there and what is there is very strongly bound to serum proteins. The very strong protein binding explains why dialysis, even when prolonged, cannot rescue patients from cisplatin toxicity. Myelosuppression and ototoxicity, including irreversible hearing loss, also can occur with cisplatin use. Cisplatin is a very severe emetogen, and vomiting almost always will occur unless antiemetic therapy is coadministered.

Cisplatin and the other organoplatinum anticancer agents react with aluminum and cannot be administered through aluminum-containing needles. The drug is photosensitive, is packaged in amber bottles, and must be protected from light.

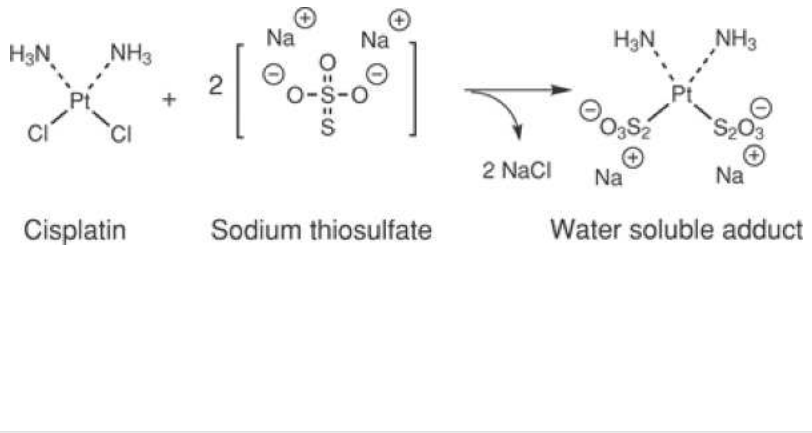

Fig. 42.15. Cisplatin inactivation by sodium thiosulfate.

Carboplatin

Carboplatin (Fig. 42.3), another square planar Pt(II) complex, forms the same cytotoxic hydrated intermediate as cisplatin but does so at a slower rate, making it a less potent chemotherapeutic agent. The ultimate damage done to cells as a result of carboplatin use, however, approaches that of cisplatin. The plasma half-life of carboplatin is 3 hours, and the drug is less extensively bound to serum proteins. Excretion is predominantly renal, and doses must be reduced in patients with kidney disease. Suppression of platelets and white blood cells is the most significant toxic reaction of carboplatin use. This drug induces fewer nonhematological toxicities (e.g., emesis, nephrotoxicity, and ototoxicity) compared to cisplatin, and it is approved for use only in the treatment of ovarian cancer. Unlabeled uses include combination therapy in lung, testicular, and head and neck cancers.

Oxaliplatin

This Pt(II) complex loses oxalic acid as oxalate anion ($^{-}$OOC-COO^{-}) in vivo to form the mono- and dihydrated diaminocyclohexane (DACH) platinum analogues shown in Figure 42.16. The *trans*-(*R,R*)-DACH structure serves as the carrier for the cytotoxic hydrated platinum and extends into the major groove of DNA when the DNA-Pt complex forms (33). Hydrophobic DNA intrusion is believed to contribute to the cytotoxicity of this organometallic agent. Oxaliplatin engages primarily in intrastrand cross-linking with diguanosine dinucleotides, adjacent A-G nucleotides, and guanines that are separated by one nucleotide (G-X-G). Interstrand cross-linking, although less common, also occurs.

The adduct formed between oxaliplatin and DNA diguanosine dinucleotides is conformationally distinct from the adduct formed with cisplatin. Specifically, whereas the cisplatin diguanosine dinucleotide adduct bends the DNA by 60 to 80° and presents a relatively wide minor groove, the oxaliplatin adduct produces a 31° bend with a comparatively narrow minor groove (34).

This distinct oxaliplatin conformation is believed to result from the steric impact of the (*R,R*)-DACH carrier, which orients the hydrogen atoms on the ammine ligands such that the *cis*-NH_3 can form a hydrogen bond with a guanine-O^6, a bond that the inactive (*S,S*)-isomer is unable to form (35). The conformation of the oxaliplatin-DNA adduct is much less likely to be recognized by MMR proteins, and the effectiveness of oxaliplatin in MMR-deficient cells is believed to be responsible for the lack of resistance that has plagued cisplatin and carboplatin (36,37). Oxaliplatin often retains activity in patients who are no longer responding to the “first-generation” organometallics and also is significantly less mutagenic, nephrotoxic, hematotoxic, and ototoxic than cisplatin. Excretion is via the kidney.

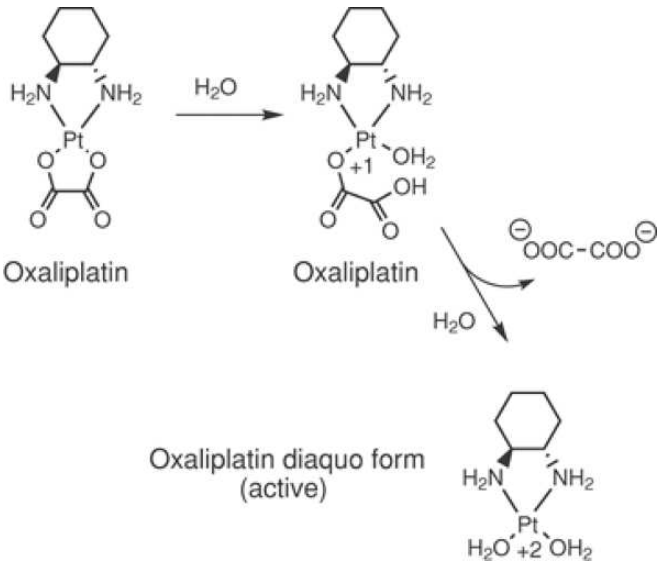

Fig. 42.16. Activation of oxaliplatin.

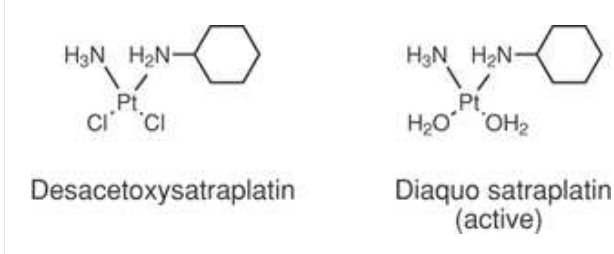
Oxaliplatin decomposes in alkaline media and should not be coadministered with drugs that will increase the pH of the IV solution. Oxaliplatin is used in the treatment of metastatic colon or rectal cancer, either alone or in combination with 5-fluorouracil. Pulmonary fibrosis and peripheral sensory neuropathies that can be life-threatening are known to occur. It has been proposed that the latter adverse effect is caused by oxalate-based chelation of intracellular Ca^{2+}, which inhibits voltage-gated sodium channels in sensory nerve cells (38). This hypothesis is supported by the observation that infusions of calcium or magnesium salts can significantly attenuate oxaliplatin-induced neuropathy without compromising therapeutic efficacy (39). In the future, exploitation of genetic differences in the expression of various repair proteins, growth factors, and metabolizing enzymes may allow the tailoring of oxaliplatin therapy based on an individual's pharmacogenetic profile (37).

Satraplatin

This newest organometallic agent (Fig. 42.3) currently is in clinical trials as a second-line agent for the treatment of hormone-refractory prostate cancer (36). There is hope that it also will find value in ovarian cancer and small cell lung cancer. Satraplatin is a Pt(IV) complex. As with the Pt(II) complexes, the platinum has no net charge in the parent drug, because its original +4 charge has been “neutralized” by the donation of four electrons from the chloride and acetate ligands. Unlike the square-planar Pt(II) complexes currently on the market, it is active by the oral route. It is metabolized quickly in whole blood, producing up to six metabolites. The major metabolite is the desacetoxy analogue. As with other organoplatinum complexes, the diaquo form is active. At this early stage, the toxicity profile appears to be mild, with dose-related myelosuppression, particularly neutropenia and thrombocytopenia, being the major use-limiting side effect.



Antibiotics

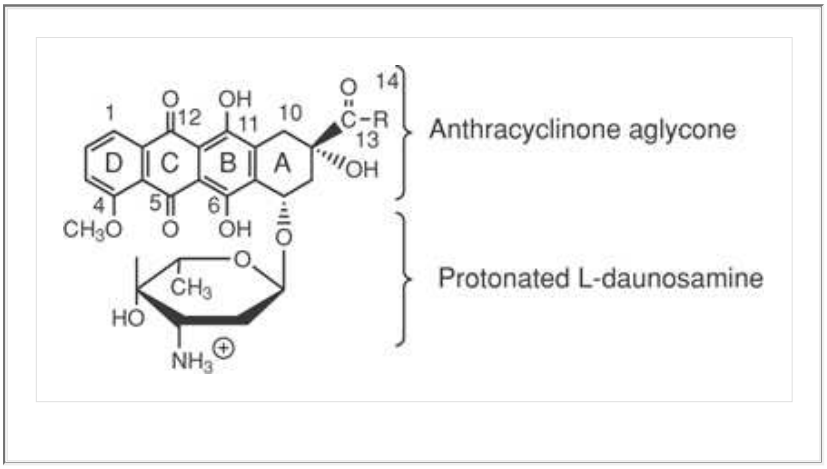
The antibiotic antineoplastics (Fig. 42.17) are a broad category of natural or semisynthetic compounds that block DNA transcription by nicking and/or inducing point mutations in the DNA strand and/or by inhibiting enzymes critical to the DNA replication process. Antibiotic antineoplastics that interact directly with DNA first intercalate the double-stranded helix by inserting between the base pairs and forming strong noncovalent interactions with DNA bases. The highly stabilized complex deforms and uncoils the DNA, prohibiting proper replication. To bulldoze its way between the bonded DNA strands, a segment of the antibiotic must have the trigonal coplanar geometry guaranteed by aromaticity.

Many of the antineoplastic antibiotic compounds inhibit topoisomerase II, an enzyme responsible for maintaining proper DNA structure during replication and transcription to RNA. Topoisomerase II normally cleaves DNA during the replication phase but repairs its own damage after replication is complete. Topoisomerase II inhibitors act to stimulate the cleavage reaction but inhibit the DNA resealing activity of the enzyme, leaving the DNA irreversibly damaged and unable to replicate.

Yet another proposed mechanism of cytotoxic action is the generation of cytotoxic free radicals that cause single-strand breaks in DNA. One antibiotic (mitomycin) is capable of alkylating DNA, a mechanism more commonly associated with the nitrogen mustard antineoplastics but which is entirely predictable from the nucleophilic aziridine ring found within the structure of this anticancer agent.

Anthracyclines and Anthracenediones

Anthracycline antineoplastic antibiotics are very closely related to the tetracycline antibacterials. Structurally, they are glycosides and contain a sugar portion (L-daunosamine) and a nonsugar organic portion. The nonsugar portion of glycosides is generically referred to as an aglycone. In anthracyclines, the aglycone moiety is specifically called anthracyclinone or anthroquinone.



Mechanism of action

As previously mentioned, DNA intercalation initiates the antineoplastic action of the anthracyclines. The anthracyclinone portion of the structure, particularly rings B, C, and D, is large and predominantly aromatic. This flat ring system slides between the two DNA strands, orienting itself in a perpendicular fashion relative to the long axis of DNA. Once intercalated, the anthracycline-DNA complex is stabilized through van

der Waals, hydrophobic, and hydrogen bonds. Binding is best in DNA regions that are rich in guanine and cytosine bases.

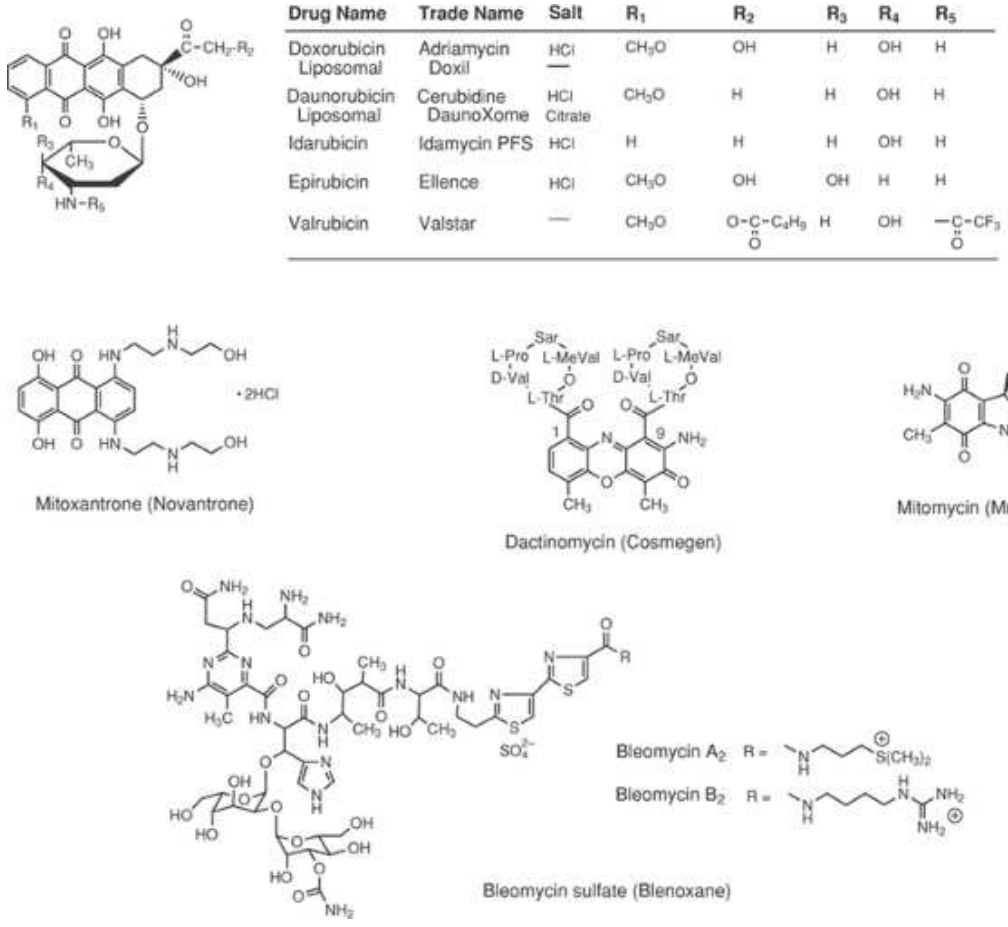


Fig. 42.17. Anticancer antibiotics.

The protonated 3′-amino group on the daunosamine sugar has long been thought to stabilize the intercalated complex through interaction with an anionic DNA phosphate, but investigators recently have proposed that this substituent may link covalently to the C_2-NH_2 of guanine via a methylene bridging unit provided by formaldehyde (40). Regardless of the interaction, the daunosamine amino group is believed to play a crucial role in orchestrating the DNA sequence specificity of the intercalation process (41). The loss or epimerization of the 3′-amino moiety decreases, but does not destroy, DNA binding. In fact, the antitumor activity of these drugs is related more to the proper positioning and stabilization of the drug at its binding site than to the actual affinity of the drug for the DNA (41,42).

Even though DNA intercalation is required before the antineoplastic action of the anthracyclines can be realized, it alone does not kill the cell. Rather, the predominant cytotoxic effect is topoisomerase II inhibition. Anthracyclines bind to the DNA-enzyme complex in the area close to the DNA cleavage site. They stabilize a ternary cleavable complex that allows the DNA to be cut and covalently linked to topoisomerase Tyr residues but that does not permit the cleaved DNA to reseal. The aromatic portion of the anthracyclinone ring system and the daunosamine sugar bind to DNA, whereas the anthracyclinone A ring is believed to bind with the topoisomerase II enzyme (41). Removal of the 4-OCH_3 group found on all natural anthracycline anticancer products increases antitumor activity by facilitating the intercalation process and directing the binding of the dauosamine sugar in a way that stabilizes the ternary complex and promotes the cleavage (but not the resealing) of DNA (42). The daunosamine sugar is known to bind in the minor groove of DNA at the DNA-topoisomerase interface, but specific binding interactions between drug functional groups and topoisomerase residues have yet to be fully elucidated. Because a small

number of anthracycline-induced DNA breaks can result in a high level of cell death, it has been

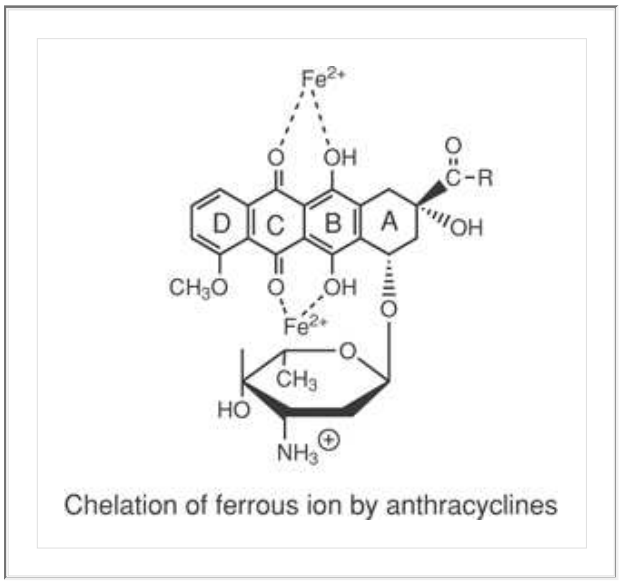
hypothesized that the site of DNA cleavage, which contains an essential T-A dinucleotide, is particularly lethal to the cell (43).

Mechanism of cardiotoxicity

A very important mechanism of use-limiting anthracycline cardiotoxicity involves the formation of cytotoxic free radicals. A free radical is a highly reactive species with an unpaired electron. Of particular importance to the antineoplastic action of these drugs is the formation of the superoxide radical anion ($\cdot O_2^-$) and the hydroxyl radical (·OH), both of which are formed via reduction of the anthracyclinone quinone (ring C) to hydroquinone by NADPH/CYP450 reductase. The mechanism by which cytotoxic free radicals are generated is shown in Figure 42.18.

When NADPH/CYP450 reductase reduces the quinone ring to a hydroquinone, superoxide radical anions ($\cdot O_2^-$) are generated. Superoxide radical anions react to generate hydrogen peroxide (H_2O_2), a reaction that requires protons and is catalyzed by the enzyme superoxide dismutase in a Cu^{2+} mediated process. The fate of this hydrogen peroxide dictates the degree of cytotoxicity observed from the anthracycline.

In the presence of the enzyme catalase, hydrogen peroxide is rapidly converted to water and oxygen, which obviously are harmless chemicals as far as the body is concerned. In the presence of ferrous ion (Fe^{2+}), however, hydrogen peroxide is converted into the highly toxic hydroxyl radical through a process called the Fenton reaction. Hydroxyl radicals promote single-strand breaks in DNA, which is therapeutically desirable to treat the uncontrolled growth of cancer cells. Anthracycline anticancer agents also are known to interfere with normal ferritin-iron mobilization, resulting in iron accumulation (44). The anthracyclines chelate strongly with di- and trivalent cations, including intracellular Fe^{2+}, so the generation of cytotoxic hydroxyl radicals after the initial NADPH/CYP450 reductase reduction is essentially guaranteed. Hydroxide anion and ferric ion also are formed during the production of hydroxyl radicals.



The generation of hydroxyl radicals inside the tumor cell might augment the antineoplastic effect of the anthracyclines, but such generation is uncommon at standard antineoplastic doses (43). These cytotoxic radicals are generated within the heart, however, leading to acute and often severe cardiotoxicity. Cardiac tissue is particularly vulnerable to free radical damage by the anthracyclines because it does not contain the catalase enzyme (45). When hydrogen peroxide forms in the myocardium, it has no choice but to go down the Fenton pathway. Cardiac toxicity is the major use-limiting side effect of anthracycline use, but coadministration of dexrazoxane (an antioxidant and iron chelator) has been shown to lower its incidence (46). A role for nitric oxide metabolism, particularly nitric oxide synthase, in anthracycline-mediated cardiotoxicity recently has been proposed (47). In the future, nitric oxide metabolic enzymes may be key targets for drugs that, when coadministered with anthracyclines, could lower the risk of cardiotoxicity.

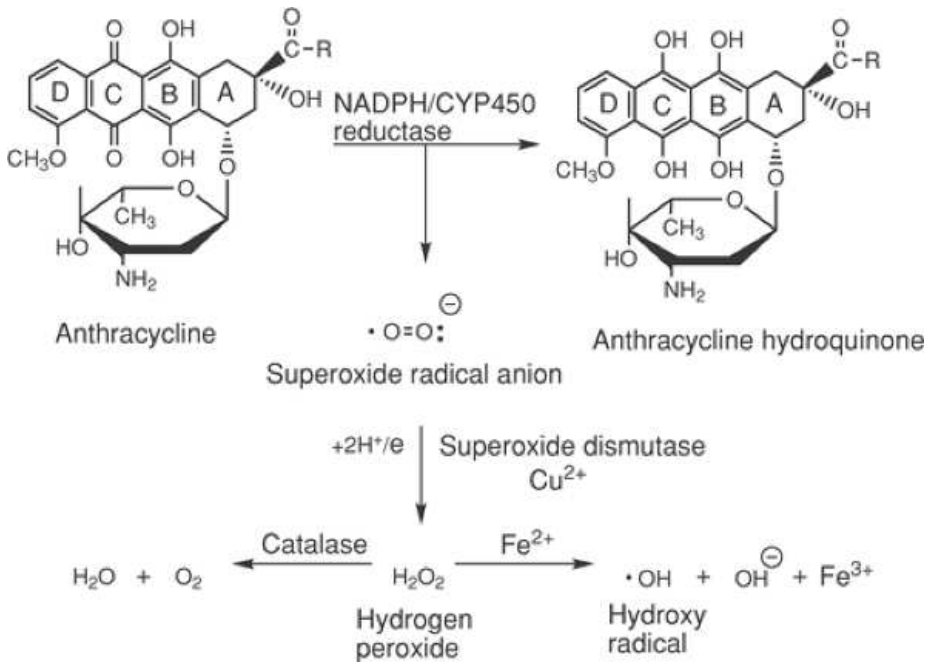


Fig. 42.18. Anthracycline-medicated free radical formation.

P.1168

Although the rate of quinone metabolism influences the risk of acute anthracycline-induced cardiotoxicity, metabolism at C_{13} is believed to be responsible for the severe and chronic cardiotoxicity that some patients experience. The C_{13}-carbonyl is reduced to the active secondary alcohol via cytosolic aldoketoreductase enzymes (Fig. 42.19), and the larger the R group, the slower this reaction and the longer the duration of antineoplastic action. The C_{13}-substituents found on most marketed anthracyclines include CH_3 (daunorubicin and idarubicin) and CH_2OH (doxorubicin and epirubicin). Before excretion, anthracyclines are further metabolized to their aglycones, followed by O-dealkylation of the C_4 methoxy ether (if present) and conjugation with either glucuronic acid or sulfate.

The active secondary alcohol metabolites formed by aldoketoreductase induce a prolonged inhibition of calcium loading, opens a selective ion channel leading to increased cytosolic levels of Ca^{2+} in the sarcoplasmic reticulum, and inhibits Na^+,K^+–adenosine triphosphatase action in the sarcolemma. Collectively, these cellular events can induce a chronic cardiomyopathy that presents as severe congestive heart failure involving systolic and diastolic dysfunction (44). Chronic anthracycline-induced congestive heart failure can manifest without warning years after therapy, and it often is unresponsive to therapeutic intervention. Those at highest risk include the very young or very old, those with underlying cardiovascular disease, those receiving high cumulative doses, and those being treated with cyclophosphamide. Because toxicity is dose-dependent, patients with liver dysfunction who cannot adequately metabolize and clear the anthracycline also are at risk. Dosage adjustments in patients with liver disease must be made to avoid life-threatening toxicity.

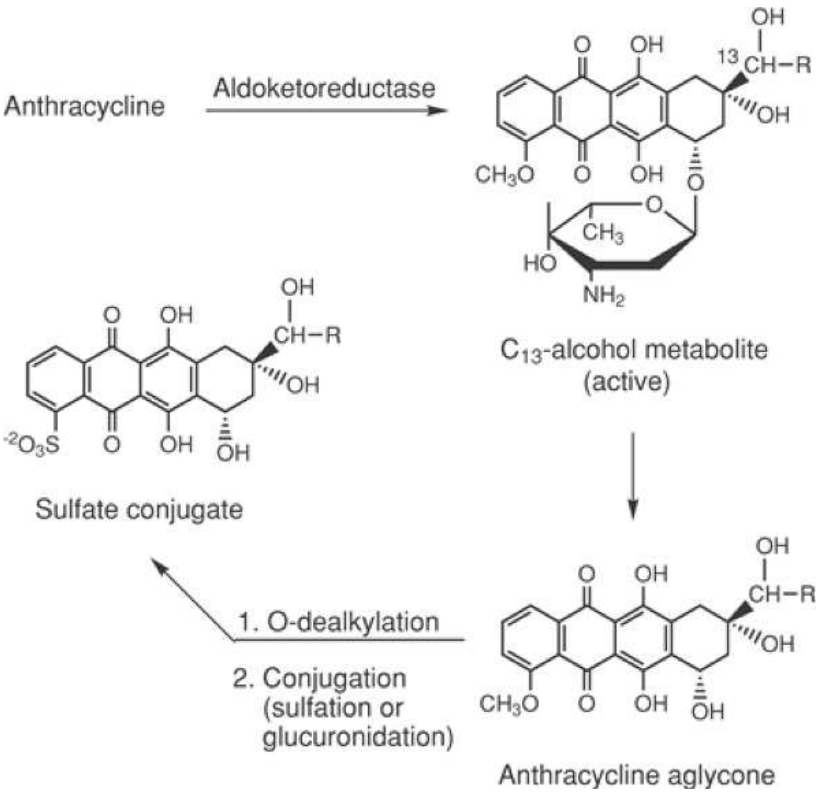

Fig. 42.19. Anthracycline metabolism.

Additional side effects

In addition to cardiac toxicity, all anthracycline antineoplastics can cause severe myelosuppression (especially leukocytopenia) as well as moderate to severe nausea and vomiting, mucositis leading to hemorrhage and potentially fatal infection, and alopecia. Side effects are dose-dependent. Most of the anthracyclines are orally inactive and must be given by IV injection. They are highly necrotic to skin and, if extravasation occurs, can cause such severe blistering and ulceration that skin excision, followed by plastic surgery, may be indicated. The anthracyclines contain photosensitive phenolic groups that must be protected from light and air. The highly conjugated structure imparts a reddish-orange color to these compounds (implied in the name “rubicin”), which is maintained when these compounds are excreted in the urine. Patients should be warned that the reddish urine they will experience is not hemorrhagic but, rather, simply the result of the conjugated chemistry of this class of drugs.

Specific drugs

Doxorubicin Hydrochloride

The C_{13} substituent of doxorubicin is hydroxymethyl (Fig. 42.17), which retards the action of cytosolic aldoketoreductase and slows the conversion to the equally active, but chronically cardiotoxic, doxorubicinol. This contributes to the longer duration of action compared to analogues that have CH_3 at this position (e.g., daunorubicin). Doxorubicin is highly lipophilic and concentrates in the liver, lymph nodes, muscle, bone marrow, fat, and skin. Elimination is triphasic, and the drug has a terminal half-life of 30 to 40 hours. The majority of an administered dose is excreted in the feces. Doxorubicin is utilized either alone or in combination therapy to treat a wide range of neoplastic disorders, including hematologic cancers and solid tumors in breast, ovary, stomach, bladder, and thyroid gland.

A liposomal formulation of doxorubicin (Fig. 42.17) is used in the treatment of AIDS-related Kaposi's sarcoma

and organoplatinum-resistant ovarian cancer. Liposomes are taken up selectively into tumor cells, presumably because of their persistence in the bloodstream and enhanced permeability of tumor vascular membranes. In liposomal form, the drug is protected against enzymes that generate cardiotoxic free radicals, although this form of the drug can still induce potentially fatal congestive heart failure. Clinical experience with the liposomal formulation is limited, and few studies comparing the long-term toxicity with that of conventional doxorubicin therapy have been conducted. Therefore, all precautions outlined for the use of doxorubin also are employed when the liposomal formulation is used. The half-life of Doxil is extended to approximately 55 hours, and it is administered in doses ranging from 20 to 50 mg/m^2 every 3 to 4 weeks. The area under the curve of the liposomal formulation is approximately threefold that of the

free drug formulation. It is cleared more slowly than conventional doxorubicin and generates very little of the doxorubicinol metabolite. Significant side effects have occurred when the liposomal formulation is erroneously dispensed, so pharmacists must be vigilant when interpreting therapeutic orders.

Epirubicin Hydrochloride

This stereoisomer of doxorubicin has the 4′-hydroxy group of the daunosamine sugar oriented in the β-position (Fig. 42.17). Epirubicin will be slowly reduced to the active C_{13} alcohol (epirubicinol), giving it a 30- to 38-hour half life, which is similar to that of doxorubicin. Unlike doxorubicinol, however, which was equally active with doxorubicin, epirubicinol has only one-tenth the activity of its parent drug and is not believed to contribute significantly to the therapeutic action of this agent. Cleavage of the epimerized sugar will occur before excretion, generating an aglycone that is indistinguishable from that generated by doxorubicin. Although excretion is primarily biliary, dosage reduction in severe renal impairment, as well as in hepatic dysfunction, is warranted.

Epirubicin is indicated for use in breast cancer, and the starting dose is 100 to 120 mg/m^2 (compared to a starting dose of 60–75 mg/m^2 for doxorubicin). The side effects and precautions are as outlined previously for doxorubicin, although there is a lower risk of serious myocardial toxicity or myelotoxicity.

Valrubicin

Chemically, valrubicin differs from its doxorubicin parent by the addition of a C_{14}-valerate ester and a 3′-trifluoroacetamide (Fig. 42.17). The carbon-rich valerate obviously is lipophilic, and acylation of the daunosamine amino group makes the 3′-substituent un-ionizable. Both of these structural changes promote a more rapid and extensive penetration into tumor cells.

Valrubicin currently has orphan drug status in the treatment of bacille Calmette-Guérin (BCG)–refractory bladder cancer (the total patient population is ~1,000 individuals) and is used with patients for whom surgical intervention would result in high morbidity or death. It is administered directly into the bladder through a catheter (intravesically). The lipophilic drug is water insoluble, but it dissolves in an aqueous vehicle that includes polyoxyethylene glycol and ethanol. The patient retains the drug in the bladder for 2 hours, then voids the solution in the normal fashion.

Valrubicin is active as administered, and despite the fact that hydrolysis of the ester and trifluoroacetamide can be envisioned, it is excreted essentially unchanged. Less than 1% of an administered dose is absorbed systemically, so there is essentially no exposure to metabolizing enzymes. The reduced C_{13}-alcoholic metabolite does not form to any appreciable extent during the 2-hour treatment period. Therapy is considered to be almost exclusively local, and there is little risk for cardiac toxicity, bone marrow suppression, drug–drug interactions, or other side effects. The most commonly reported adverse reactions are abdominal pain, urinary tract infection, hematuria, and dysuria. Systemic exposure to the drug and its metabolites would, of course, be greater in patients whose bladder wall integrity has been compromised by disease, and these patients should not receive valrubicin.

Daunorubicin Hydrochloride

The absence of the OH group at C_{14} in daunorubicin (Fig. 42.17) results in a faster conversion to the equally active and chronically cardiotoxic C_{13}-ol metabolite (daunorubicinol) compared to hydroxymethyl-substituted anthracyclines like doxorubicin. The 18.5-hour terminal half-life of daunorubicin is approximately half that of doxorubicin, and the terminal half-life of the active daunorubicinol metabolite is 26.7 hours. Excretion is approximately 40% biliary and 25% urinary. Daunorubicin is administered IV at a dose of 45 mg/m^2 for the

treatment of lymphocytic and nonlymphocytic leukemia. The toxicity and side-effect profile of this anthracycline is similar to that of doxorubicin, and all previously identified precautions apply.

The citrate salt of daunorubicin is marketed as a liposomal formulation (Fig. 42.17), which promotes the use of this agent in solid tumors. Like Doxil (the liposomal formulation of doxorubicin), DaunoXome is indicated for use in AIDS-related Kaposi's sarcoma and is administered IV at a dose of 40 mg/m^2 every 2 weeks. The pharmacokinetic profiles of Doxil and DaunoXome are similar.

Idarubicin Hydrochloride

Idarubicin (Fig. 42.17) is the 4-desmethoxy analogue of daunorubicin. The loss of the C_4-ether flattens the D ring, facilitating intercalation between DNA base pairs. In turn, this orients the daunosamine sugar in the minor groove in a way that better stabilizes the ternary complex between drug, DNA, and topoisomerase (42).

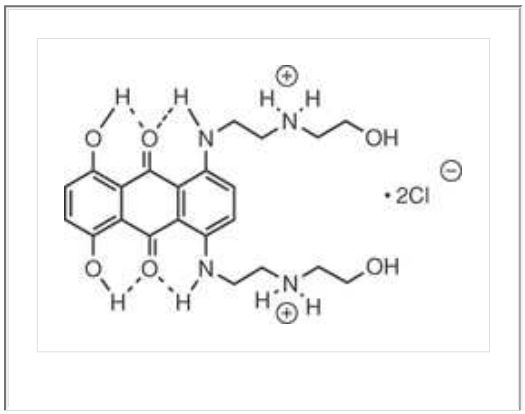
The loss of the 4-methoxy moiety also makes this compound more lipophilic than either doxorubicin or daunorubicin. This results in a better penetration into tumor cells and an enhanced antineoplastic potency. Increased rates of remission have been noted with the use of idarubicin compared to other anthracyclines antineoplastic agents. Unlike its congeners, idarubicin shows significant oral bioavailability and is lipophilic enough to penetrate the blood-brain barrier. Currently, however, it is given only by the IV route and is not used in the treatment of brain cancer. Its primary indication is in acute myeloid leukemia, and it is administered in combination with other antileukemic drugs.

Idarubicin is reduced by aldoketoreductases to idarubicinol, which is as active as the parent drug. Because there is no aromatic methoxy group, there is no O-dealkylation to the C_4-phenol. The major metabolite is free, unconjugated idarubicinol. The half-lives of both idarubicin and idarubicinol are 22 and 45 hours, respectively. Idarubicin is administered IV at a dose of 10 to 12 mg/m^2/day for 3 to 4 days, and the idarubicinol metabolite can still be found in therapeutic concentrations in

the blood 8 days after administration. Like other anthracyclines, excretion primarily is fecal, with a lesser dependence on renal elimination. Some authors have shown that idarubin is transported into cardiac tissue via a saturable transporter and that the coadministration of methylxanthines (e.g., caffeine) can increase both myocardial drug concentrations and the risk of idarubicin-induced cardiotoxicity (48).

Mitoxantrone Hydrochloride

Chemically, mitoxantrone is classified as an anthracenedione (Fig. 42.17). The sugar moiety is missing, but the cationic side-chain amino nitrogens could bind to the anionic phosphate residue of the DNA backbone in the same fashion that the cationic L-daunosamine amino group of the true anthracyclines has been presumed to do. This molecule has the structural features needed to intercalate DNA and inhibit topoisomerase II, but the enhanced stability of the quinone ring (possibly through an increased potential for intramolecular hydrogen bonding) makes the ring highly resistant to NADPH/CYP450 reductase. This limits the formation of the superoxide radicals that are required for the generation of the highly toxic hydroxyl radical. In addition, there is no active cardiotoxic metabolite to induce chronic toxicity by disrupting the flow of myocardial cations. The chance of cardiovascular toxicity from mitoxantrone is significantly decreased, although patients who have been previously treated with anthracycline antineoplastics may still be at risk. It is thought that any observed myocardial toxicity may be operating through mechanisms other than the generation of cytotoxic radicals.



In addition, the risk of ulceration and necrosis on extravasation, as well as of nonmarrow-related toxicities such as nausea, vomiting, mucositis, and alopecia, is significantly less than observed with true anthracyclines. There is a significant risk of bone marrow suppression, however. The risk of myelosuppression increases with dose, but it can be observed even when low doses are used.

Mitoxantrone excretion primarily is biliary. Both the unchanged drug and inactive metabolites resulting from N-dealkylation, deamination, and oxidation of the resultant aldehyde to the carboxylic acid are observed. Both arms of the structure can be metabolized, leading to mono- or dicarboxylic acid metabolites (Fig. 42.20), which are excreted as the glucuronide conjugate. The conjugated metabolites are an intense, dark blue in color and will result in blue-green urine. The whites of the eyes and, in some cases, the skin also may take on a bluish cast.

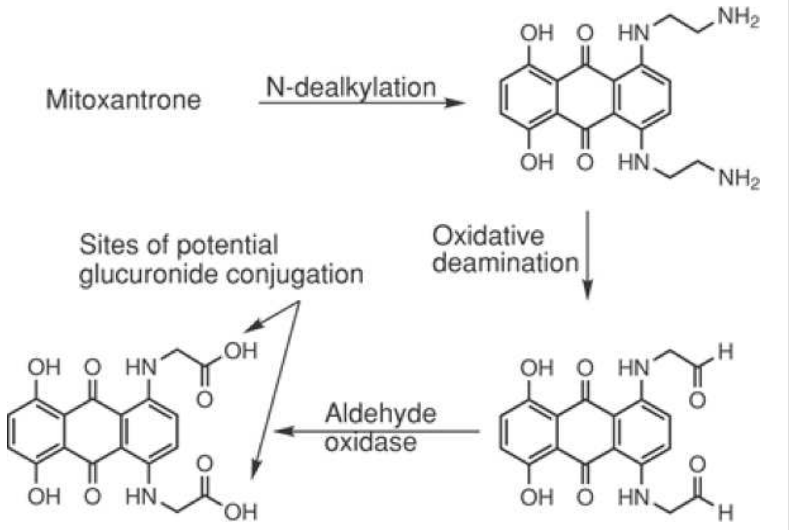


Fig. 42.20. Mitoxantrone metabolism.

Mitoxantrone is used in combination with other agents during the initial treatment of acute nonlymphocytic leukemia and hormone-refractory prostate cancer. Recent studies have shown that mitoxantrone also decreases the rate of relapse and disease progression in patients with multiple sclerosis (49). Although too toxic for use in patients with primary progressive disease, it is available for the treatment of chronic progressive, progressive relapsing, or deteriorating relapsing-remitting multiple sclerosis.

Miscellaneous Antibiotics

Dactinomycin

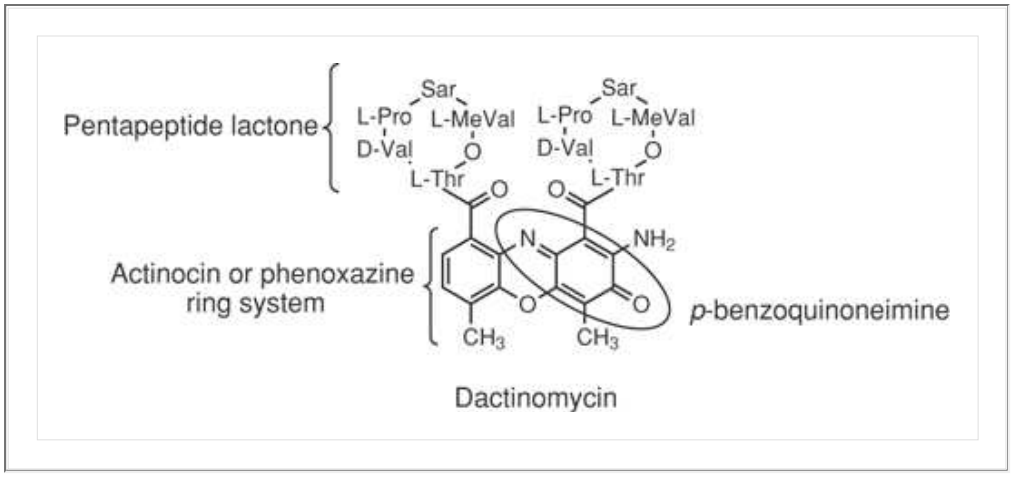
Dactinomycin (Fig. 42.17) has two pentapeptide lactones attached to an aromatic (and, therefore, flat) actinocin (or phenoxazinone) structure. It is capable of intercalating DNA and binds preferably between guanine and cytosine residues on a single DNA strand. This interaction results in DNA elongation and distortion, commonly referred to as a point mutation. When sliding between adjacent DNA base pairs, the actinocin orients itself perpendicular to the main DNA axis, allowing the pentapeptide lactone units to bind to residues in the minor groove of DNA through hydrophobic and hydrogen bonds. An affinity-enhancing bond between the threonine carbonyl oxygen and a protonated C_2-amino group of guanine also forms. Other hydrogen, hydrophobic, and van der Waals (π-stacking) interactions form between the lactone and DNA residues, particularly guanine and cytosine.

The binding of the actinocin and polypeptide lactone portions of dactinomycin to DNA is cooperative, meaning that the binding of one unit facilitates the binding of the other, most likely by promoting an optimal

orientation. This significantly enhances drug-DNA affinity. The binding of dactinomycin to DNA, although noncovalent, is much stronger than that observed with the anthracyclines. Drug dissociation from DNA is slow, leading to a pseudoirreversible effect. As a result of very strong DNA binding interactions, topoisomerase II is inhibited, which results in nonrepairable double-strand breaks in DNA. Transcription and translation processes are blocked,

resulting in a decrease in de novo RNA (especially mRNA) and protein synthesis.

The *p*-benzoquinoneimine segment of dactinomycin renders the molecule vulnerable to NADPH/CYP450 reductase. Free radicals can be generated, and additional single-strand DNA breaks can result. The loss of either aromatic methyl group results in a loss of activity. The reason for this profound impact on pharmacological action and therapeutic utility is unknown.



Dactinomycin is used for the treatment of various solid tumors and muscle-related cancers. It induces severe side effects, and nausea and vomiting can be use-limiting. Myelosuppression also is common and, most often, is the dose-limiting toxic effect. The drug usually is given by the IV route, but toxicity can be limited if the tumor can be perfused with drug (assuming minimal distribution into the general circulation). Dactinomycin is a severe blistering agent, and extravasation can cause irreversible and profound tissue damage. The side effects of radiation therapy are significantly exaggerated by the concurrent use of dactinomycin. The drug's 36-hour half-life is the result of a very high affinity for DNA, a large volume of distribution, and minimal metabolic breakdown. Dactinomycin is photosensitive and must be protected from light.

Mitomycin

As shown in Figure 42.21, mitomycin is activated through a bioreductive process utilizing NADPH/CYP450 reductase and/or NAD(P)H quinone oxidoreductase 1 (NQ 01 reductase), an enzyme expressed in many neoplastic cells (50,51). Through these enzymes, the quinone ring of mitomycin is readily reduced to the hydroquinone, generating superoxide radicals in the process that ultimately will be converted to cytotoxic hydroxyl radicals through the Fenton reaction. As previously discussed, hydroxyl radicals induce single-strand breaks in DNA. Formation of the hydroquinone is followed by aromatization to the indole ring through the loss of methanol. Both the electrophilic aziridine ring and the δ^+ methylene group adjacent to the carbamate ester are vulnerable to attack by DNA nucleophiles, such as the 2-NH_2 group of guanine or the 4-NH_2 group of cytosine, resulting in cross-linked DNA and cell death.

Mitomycin is administered IV in the treatment of disseminated adenocarcinoma of the stomach or pancreas, and it has been used intravesically in superficial bladder cancer. Biotransformation pathways are saturable, and approximately 10% of an administered dose is eliminated unchanged via the kidneys. Myelosuppression is the major use-limiting side effect of this drug, which is slow to manifest but quite prolonged in duration. Severe skin necrosis can occur on extravasation, and potentially fatal pulmonary toxicities have been noted as well. Mitomycin can induce hemolytic uremia accompanied by irreversible renal dysfunction and thrombocytopenia, and the drug should not be administered to patients with serum creatinine levels greater than 1.7 mg/dL. Severe bronchospasm also has been noted in patients treated with vinca alkaloids who also are receiving (or who have previously received) mitomycin.

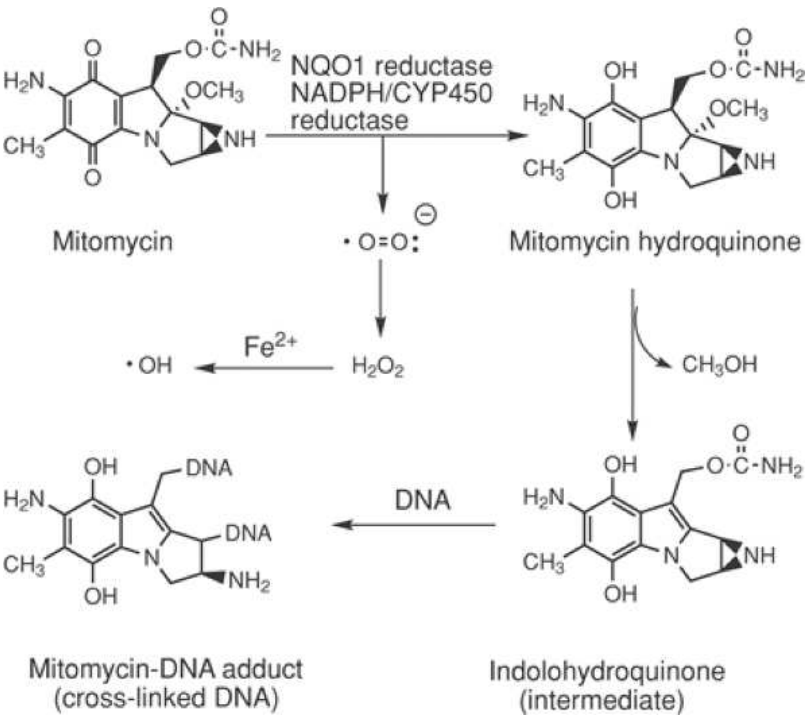


Fig. 42.21. Mitomycin metabolism.

Bleomycin sulfate

The commercially available bleomycin drug product is a mixture of naturally occurring glycopeptides, predominantly bleomycin A_2 (Fig. 42.17). The aromatic bithiazole ring system can intercalate DNA, but unlike most of the antibiotics discussed thus far, the molecule does not inhibit topoisomerase II. Rather, intercalation positions bleomycin for DNA destruction via cytotoxic free radicals. The disaccharide, polyamine, imidazole, and pyrimidine structures are very electron rich and readily chelate intracellular Fe^{2+}. Once chelated, Fe^{2+} is oxidized to Fe^{3+}, with a concomitant reduction of bound oxygen, and both superoxide and hydroxyl radicals are generated. The free radicals cleave deoxyribose and cause single-strand breaks in DNA, most commonly between guanine-cytosine or guanine-thymine residues. When the cyclic deoxyribose sugar breaks, it forms a highly electrophilic base propenal that inactivates essential cellular proteins by alkylating nucleophilic Cys residues (Fig. 42.22). Reduced glutathione is proposed to serve a protective role by acting as propenal scavenger and, until depleted, saves cellular proteins from alkylation (52).

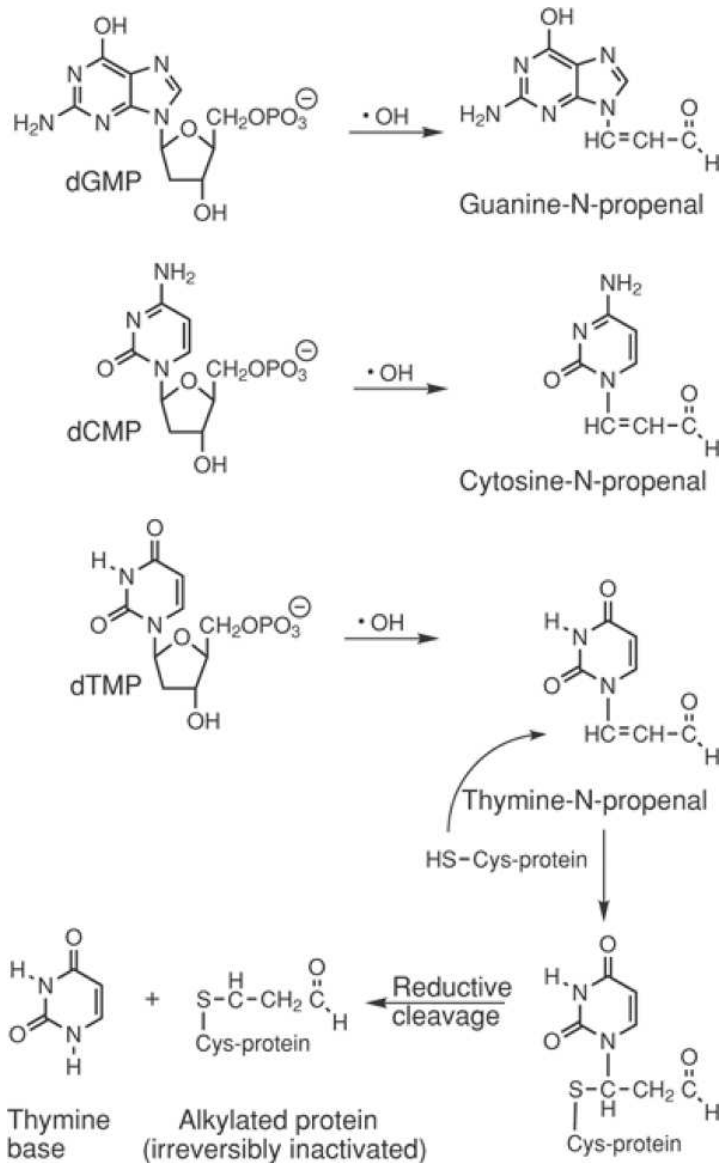

Fig. 42.22. Alkylation of Cys residues by hydroxyl radical–generated base propenals.

Bleomycin is a natural product isolated from *Streptomyces verticillus*. It *normally is chelated with* Cu^{2+}*, which must be removed via catalytic reduction before marketing. This increases the cost of the drug, but it frees up the critical bleomycin functional groups for chelation with intracellular ferrous iron.*

The action of bleomycin is terminated through the action of bleomycin hydrase, a cytosolic aminopeptidase that cleaves the terminal amide moiety to form the inactive carboxylate metabolite (Fig. 42.23). The metabolic replacement of the electron-withdrawing amide with an electron-donating carboxylate increases the pK_a of the α-amino group, which normally interacts with DNA in the un-ionized conjugate form. After hydrolysis, the ratio of ionized to un-ionized forms of this critical amine increases approximately 126-fold, destroying DNA affinity and leading to the loss of therapeutic action. Drug destruction via the bleomycin hydrase pathway is rapid, and tumors will be resistant to bleomycin if they contain high concentrations of the enzyme. Conversely, tumors that are poor in bleomycin hydrase (e.g., squamous cell carcinoma) respond well to this agent.

Bleomycin hydrase is found in all tissues except skin and lung. Approximately 10% of patients who are

administered bleomycin will experience potentially fatal pulmonary fibrosis, which can occur during therapy or several months following termination of therapy, often without warning. Some studies have shown that the copper-complexing agent tetrathiomolybdate can reduce the risk of bleomycin-induced fibrosis by inhibiting the action of copper-dependent inflammatory cytokines (53). Erythema and hypertrophic modifications in skin also are common side effects that manifest after 2 to 3 weeks of bleomycin therapy.

Bleomycin is used IV in the palliative treatment of squamous cell head and neck cancers, testicular and other genital carcinomas, and Hodgkin's and non-Hodgkin's lymphoma. It is excreted via the kidneys, and serum concentrations of active drug are increased in patients with renal disease. The elimination half-life can rise from 2 to 4 hours to more than 20 hours in renal failure, resulting in significant toxicity, especially pulmonary toxicity. Dosage adjustments are warranted. Unlike many antineoplastic agents, bleomycin does not suppress the bone marrow, and it often is given in combination with compounds that do, so that the dose of all

drugs can be optimized. Nausea and vomiting also are relatively mild, but approximately 1% of lymphoma patients who are treated with bleomycin will experience an immediate or delayed, severe idiosyncratic reaction that mimics anaphylaxis.

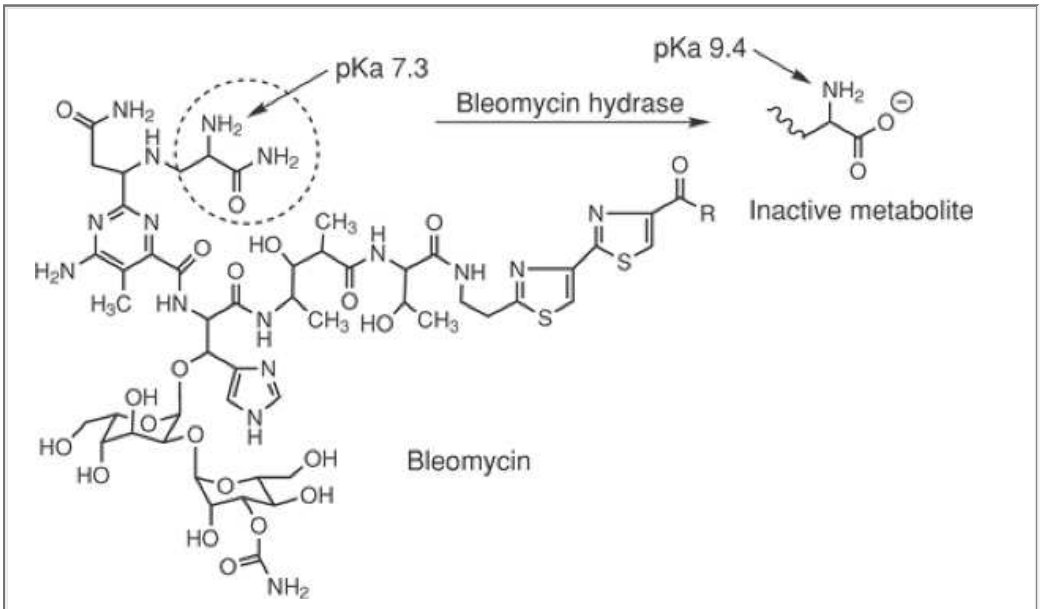

Fig. 42.23. Bleomycin hydrase mediated inactivation of bleomycin.

Antimetabolites

The antineoplastic agents discussed thus far have all damaged existing DNA and inhibited its ability to replicate. The antimetabolites, on the other hand, most commonly stop the de novo synthesis of DNA by inhibiting the formation of the nucleotides that make up these life-sustaining polymers. We will see that the rate-limiting enzymes of nucleotide biosynthesis often are the primary target for the antimetabolites, because inhibition of this key enzyme is the most efficient way to shut down any biochemical reaction sequence. Antimetabolites also are capable of inhibiting other enzymes required in the biosynthesis of DNA, and many can arrest chain elongation by promoting the incorporation of false nucleotides into the growing DNA strand.

The antimetabolites serve as false substrates for critical nucleotide biosynthesis enzymes. These enzyme inhibitors are structurally “dolled up” to look like a super attractive version of the normal (endogenous) substrate. Speaking anthropomorphically, through a form of chemical entrapment, they entice the enzymes to choose them over the endogenous substrate, and once they do, the antimetabolites bind them irreversibly. If the building block nucleotides cannot be synthesized, then DNA synthesis (and tumor growth) is stopped dead in its tracks. If tumor growth is arrested, then metastasis slows, and the patient has a fighting chance for remission and/or cure.

Antimetabolite antineoplastics are categorized by the class of nucleotide they inhibit. Purine antagonists

inhibit the synthesis of the purine-based nucleotides adenylate monophosphate (AMP) and guanylate monophosphate (GMP), and the pyrimidine antagonists stop the production of the pyrimidine-based nucleotides, primarily deoxythymidine monophosphate (dTMP).

Pyrimidine Antagonists: dTMP Synthesis Inhibitors

dTMP biosynthesis

Looked at simply, dTMP is produced via C_5-methylation of deoxyuridine monophosphate (dUMP). The rate-limiting enzyme of the dTMP synthetic pathway is the sulfhydryl-containing thymidylate synthase, with 5,10-methylenetetrahydrofolate (5,10-methylene-THF) serving as the methyl-donating cofactor. All dTMP synthesis inhibitors will inhibit thymidylate synthase either directly or indirectly, and this will result in a "thymineless death" in actively dividing cells. Without dTMP and its deoxythmidine triphosphate metabolite, DNA will fragment, and the cell will die.

To truly understand how an antimetabolite inhibits a biochemical pathway, we must first understand completely how the pathway normally functions. A quick look at the dTMP synthesis pathway (Fig. 42.24) will confirm that our "simple methylation reaction" is comprised of several important steps, each of which is analyzed in turn below.

The synthase enzyme is very large and contains a deep pocket for the binding of both substrate and cofactor.

It may be illuminating to think of this binding pocket like a big cooking pot. Once the "ingredients" are added (substrate and cofactor), the process of making the product (dTMP) can begin. The active site binding motifs for both substrate and cofactor are highly conserved among all thymidylate synthase enzymes, regardless of source (54). Whereas early studies on substrate binding were conducted with bacteria-derived synthases, the human enzyme (hTS) has now been crystallized and some binding residues identified (55). With regard to substrate binding (hTS sequence numbers given where known):

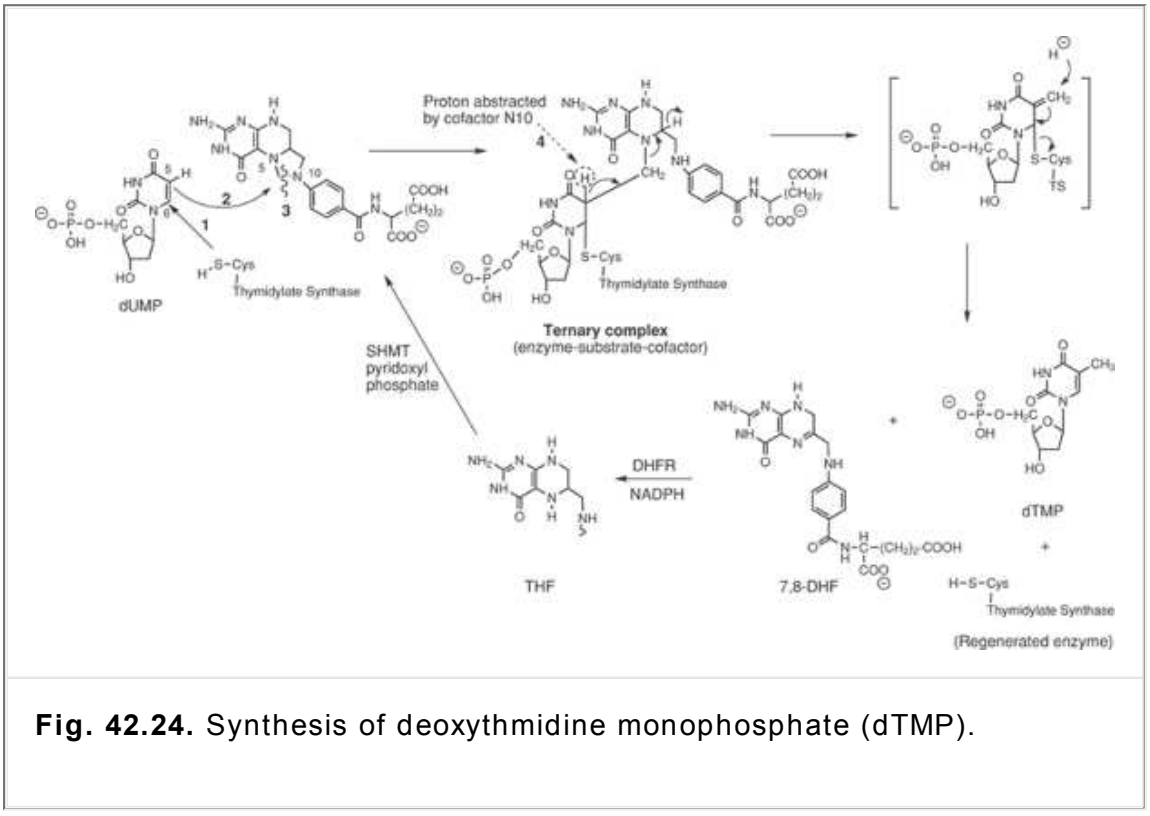

Fig. 42.24. Synthesis of deoxythmidine monophosphate (dTMP).

- Four Arg residues at positions 50, 218, 175′, and 176′ form electrostatic bonds with the anionic 5′-phosphate of the substrate.

- Tyr (H-donor) and His (H-acceptor) residues form hydrogen bonds with the deoxyribose 3′-OH.
- The main-chain amide of aspartate (Asp^{218}) forms a hydrogen bond with the pyrimidine C_2 carbonyl oxygen.
- His^{196} forms a hydrogen bond with the pyrimidine C_4 carbonyl oxygen.
- An Asn residue (H-acceptor) forms a hydrogen bond with the pyrimidine C_3-NH.
- Cys^{195} forms a transient covalent bond with C_6 of the pyrimidine ring.

The glutamate tail of 5,10-methylene-THF binds to Lys and His residues of the synthase. Oxygen atoms of leucine (Leu^{221}) and phenylalanine (Phe^{225}) interact with the *p*-aminobenzoic acid component of the folate, whereas Asp^{218}, His, and Ile residues interact with additional cofactor functional groups (55,56). The binding of both substrate and cofactor promotes a conformational change in the synthase protein and causes the N-terminal portion of the synthase to change its location, which covers the opening of the binding “pot” like a big lid. The conformational change brings the folate cofactor “face to face” with the dUMP substrate, properly orienting all key functional groups for the reaction to come.

The C_6 position of the dUMP substrate is surrounded by electron-withdrawing nitrogen and oxygen atoms, leaving it highly electrophilic (δ^+) and ready to be attacked by the nucleophilic Cys^{195} of the synthase. The Cys sulfhydryl group launches an intermolecular nucleophilic attack, forming a new covalent bond between the sulfur and C_6 of the substrate (step 1). The bond that breaks in response to this attack is the 5,6-double bond of dUMP, which attacks the methylene group of the cofactor (step 2). With the release of the N_{10} nitrogen the cofactor imidazolidine ring breaks (step 3). Taken together, steps 1 to 3 generate a ternary complex of enzyme, substrate and cofactor (Fig. 42.24).

A series of reactions involving bond breaking and bond making are shown in Figure 42.24, leading to formation of dTMP, 7,8-dihydrofolate (7,8-DHF), and regenerated thymidylate synthase. The C_5-H abstraction by N_{10} of the cofactor (step 4) is essential for synthesis of dTMP. To complete the biochemical cycle, 7,8-DHF must be reduced to THF via dihydrofolate reductase (DHFR) utilizing NADPH. Finally, THF is converted to 5,10-methylene-THF through the action of serine hydroxymethyltransferase and vitamin B_6.

With the enzyme and cofactor both regenerated, and with plenty of dUMP stored in cellular pools, the cell is ready to synthesize another molecule of dTMP. This happens at a regular pace in healthy cells and at an uncontrolled rate in tumor cells.

Direct inhibitors of thymidylate synthase (Fig. 42.25)

Fluorouracil

To bind to thymidylate synthase, this fluorinated pyrimidine prodrug must be converted to its deoxyribonucleotide form (Fig. 42.26). The active form of fluorouracil differs from the endogenous substrate only by the presence of the 5-fluoro group, which holds the key to the cell-killing action of this drug. The C_6 position of the false substrate is significantly more electrophilic than normal because of the strong electron-withdrawing effect of the C_5 fluorine. This greatly increases the rate of attack by Cys^{195}, resulting in a very fast formation of a fluorinated ternary complex (Fig. 42.27). The small size of the fluorine atom assures no steric hindrance to the formation of this false complex.

The next step in the pathway required the abstraction of the C_5-H (as proton) by N_{10} of the cofactor, but this is no longer possible. Not only is the C_5-fluorine bond stable to cleavage, the fluorine atom and N_{10} would repel one another because they are both electron rich. The false ternary complex cannot break down, no product is formed, no cofactor is released, and most importantly, the rate-limiting enzyme (thymidylate synthase) is not regenerated. Because dTMP can no longer be synthesized, the cell will die.

Fluorouracil is administered IV in the palliative treatment of colorectal, breast, stomach, and pancreatic cancers. Patients are treated for four consecutive days, followed by treatment on odd-numbered days up to a maximum of 12 days. Fluorouracil is rapidly cleared from the bloodstream, and although up to 20% of a dose is excreted unchanged in the urine, most undergoes hepatic catabolism via a series of enzymes that includes the polymorphic dihydropyrimidine dehydrogenase (Fig. 42.28). Patients who are genetically deficient in this enzyme will experience a more pronounced effect from this drug and are at significant risk for use-limiting

toxicity (57). In general, women clear fluorouracil faster than men do. Dosage adjustments usually are not required in hepatic or renal dysfunction. Major toxicities are related to bone marrow depression, stomatitis/esophagopharyngitis, and potential GI ulceration. Nausea and vomiting are common. Solutions of fluorouracil are light sensitive, but discolored products that have been properly stored and protected from light are still safe to use.

Floxuridine

This deoxyribonucleoside prodrug (Fig. 42.26) is bioconverted via 2′-deoxyuridine kinase–mediated phosphorylation to the same active 5-fluoro-dUMP structure generated in the multistep biotransformation of

fluorouracil. It is given by intra-arterial infusion for the palliative treatment of GI adenocarcinoma that has metastasized to the liver and that cannot be managed surgically.

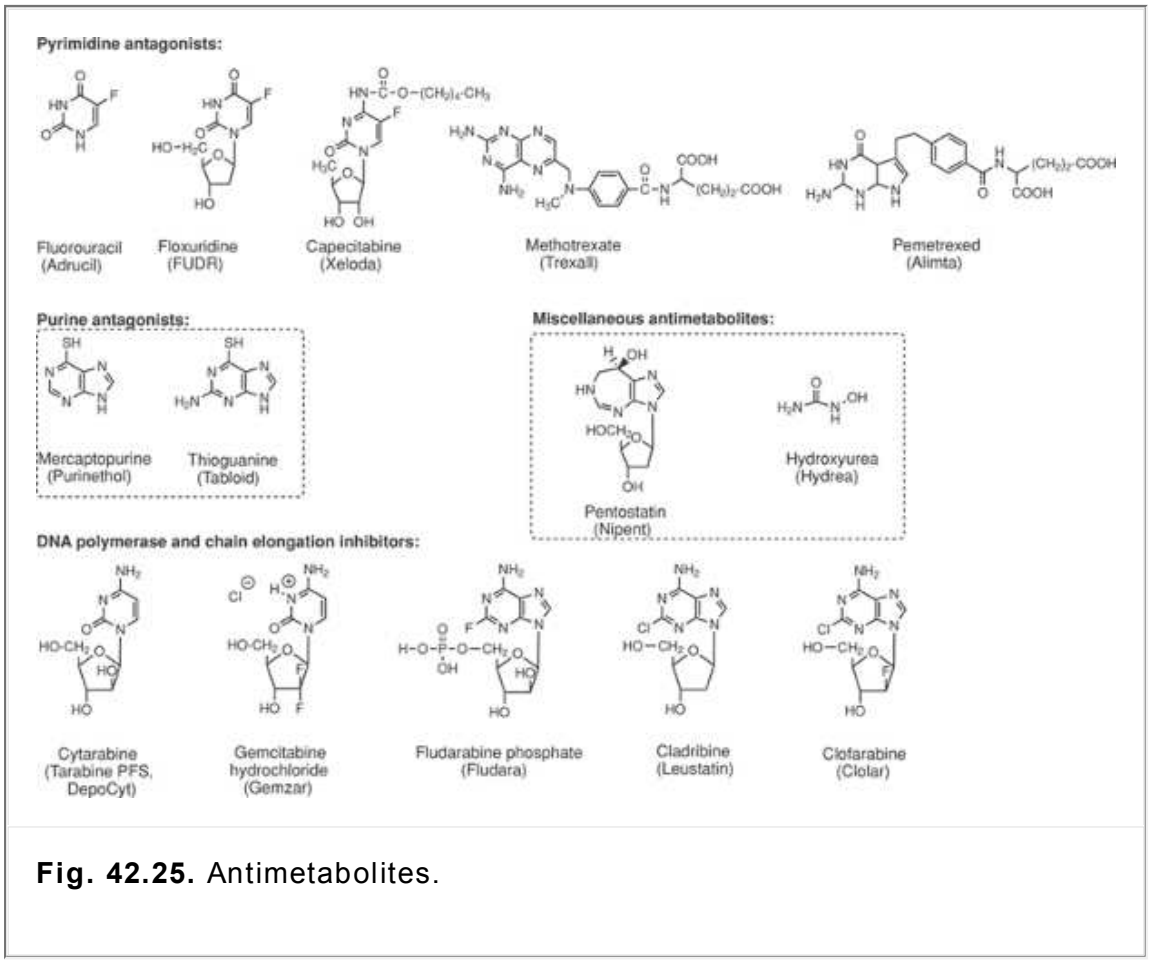

Fig. 42.25. Antimetabolites.

Capecitabine

Although capecitabine is a carbamylated analogue of cytidine (Fig. 42.29), the drug actually is another 5-fluoro-dUMP prodrug. Given orally, it is extensively metabolized to fluorouracil, which is then converted to the active fluorinated deoxyribonucleotide as previously described. Thymidine phosphorylase, an enzyme involved in this biotransformation, is much more active in tumors than in normal tissue, which improves the tumor-selective generation of fluorouracil. Levels of active drug in the tumor can be up to 3.5-fold higher than in surrounding tissue (58), leading to a lower incidence of side effects compared to fluorouracil therapy. Because capecitabine is biotransformed to fluorouracil, it follows the same catabolic and elimination pathways (Fig. 42.28) reported for 5-fluorouracil. Doses should be attenuated in moderate to severe renal impairment, and the caution relative to the augmented risk of toxicity in patients with dihydropyrimidine dehydrogenase deficiency applies.

Capecitabine is indicated for use as first-line therapy in patients with colorectal cancer. It also is used alone

or in combination with docetaxel in patients with metastatic breast cancer who have experienced disease progression or recurrence after anthracycline therapy. Given b.i.d. in tablet form, the total daily dose is calculated based on patient body surface area and is taken 30 minutes after eating to avoid food-induced decreases in absorption. In addition to bone marrow suppression, nausea, and vomiting, the drug can induce severe diarrhea and a potentially disabling disorder termed “hand-and-foot syndrome” (palmar-plantar erythrodysethesia). Capecitabine inhibits CYP2C9 and, along with competition for serum protein binding sites, results in clinically significant drug–drug interactions with both warfarin and phenytoin. The interaction with warfarin can result in potentially fatal bleeding episodes, which can appear within days of combination therapy or be delayed up to 1 month after discontinuation of capecitabine therapy.

Indirect inhibitors of thymidylate synthase

Methotrexate

Methotrexate (Fig. 42.25) is a folic acid antagonist structurally designed to compete successfully with 7,8-DHF for the DHFR enzyme. The direct inhibition of DHFR causes cellular levels of 7,8-DHF to build

up, which in turn results in feedback (indirect) inhibition of thymidylate synthase. Methotrexate also is effective in inhibiting glycine amide ribonucleotide (GAR) transformylase (see Fig. 42.31), a key enzyme in the synthesis of purine nucleotides. Take note of the structural differences between methotrexate and DHF, because these differences will be important to an understanding of the chemical mechanism of this anticancer agent.

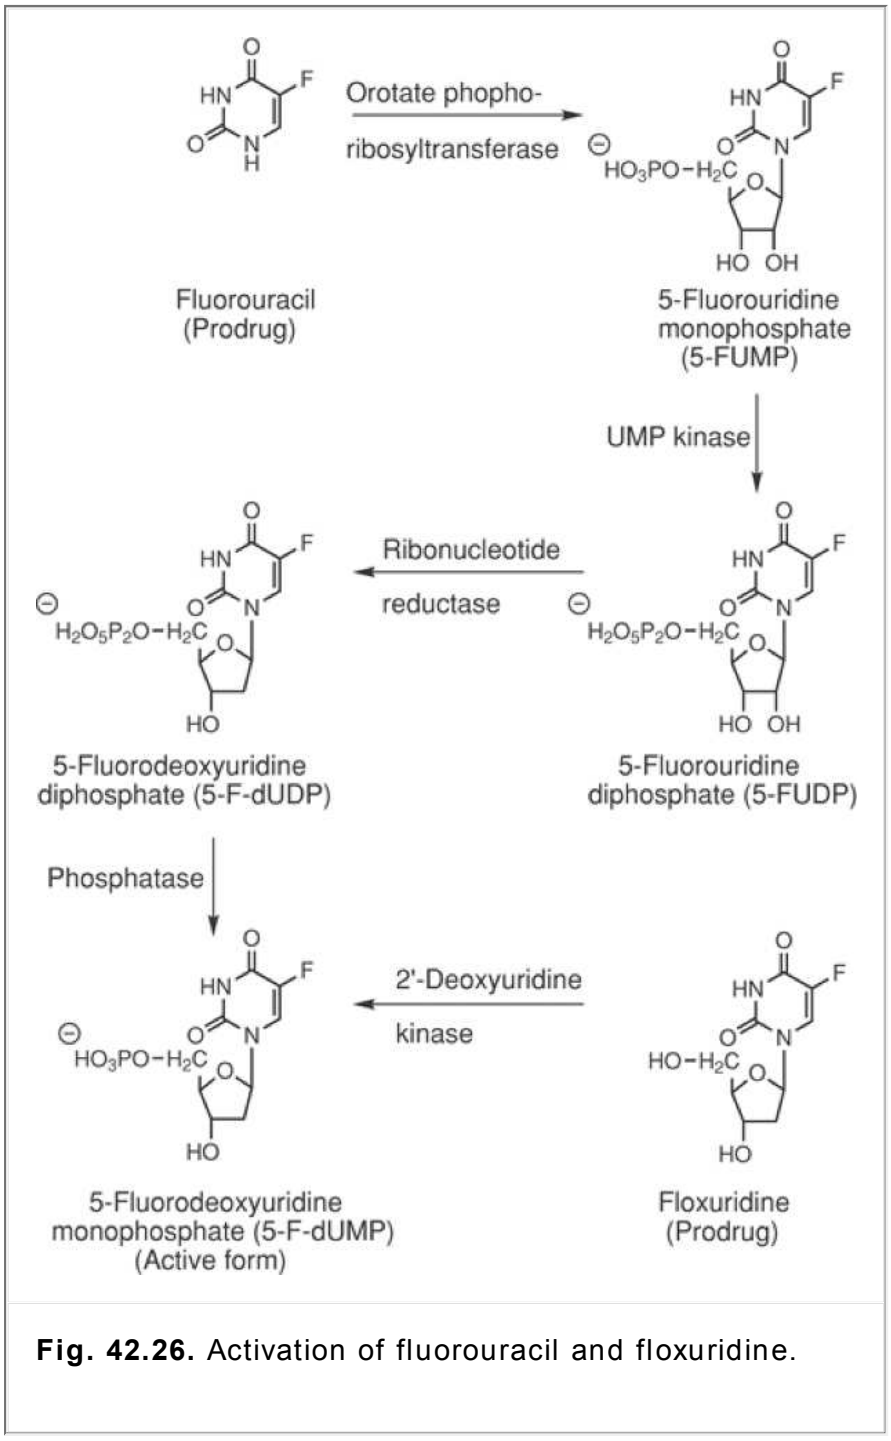

Fig. 42.26. Activation of fluorouracil and floxuridine.

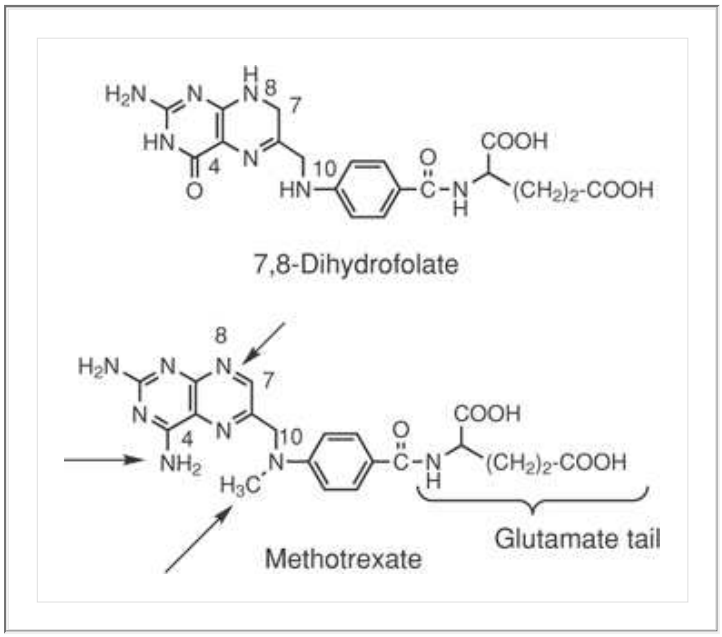

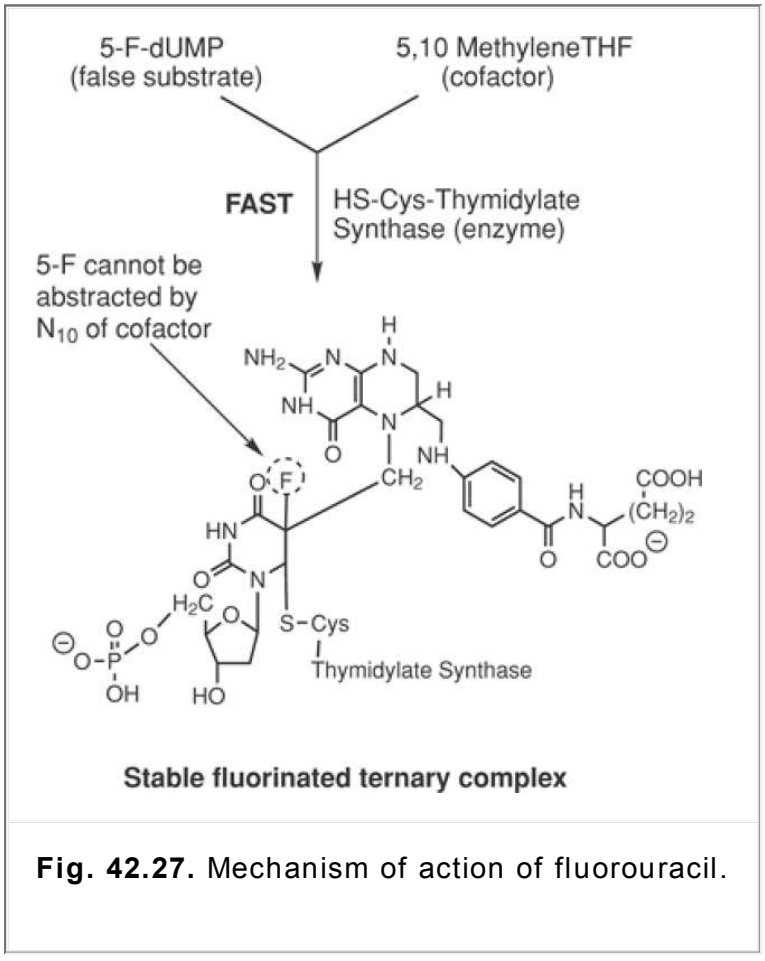

Fig. 42.27. Mechanism of action of fluorouracil.

It has been proposed that the N_5 position of DHF is protonated by a Glu^{30} of DHFR (59) and, in cationic form, binds to DHFR Asp^{27} through an electrostatic bond (Fig. 42.30). N_5 is the strongest base in the DHF structure, in part because of attenuating the impact of the C_4 carbonyl on electron density around N_1. Additional affinity-enhancing interactions between enzyme and substrate also have been identified (60,61), and once bound, the substrate 5,6-double bond is positioned close to the NADPH cofactor so that the transfer of hydride can proceed.

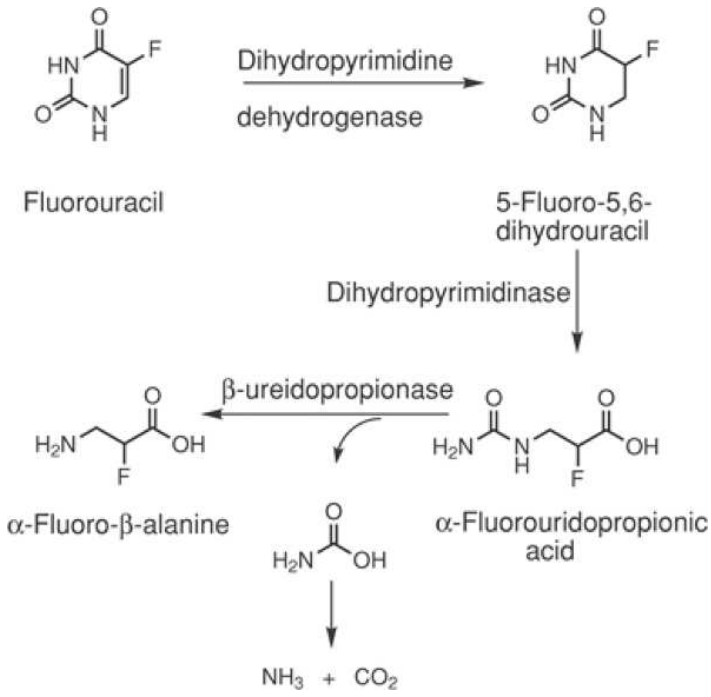

Fig. 42.28. Fluorouracil metabolism.

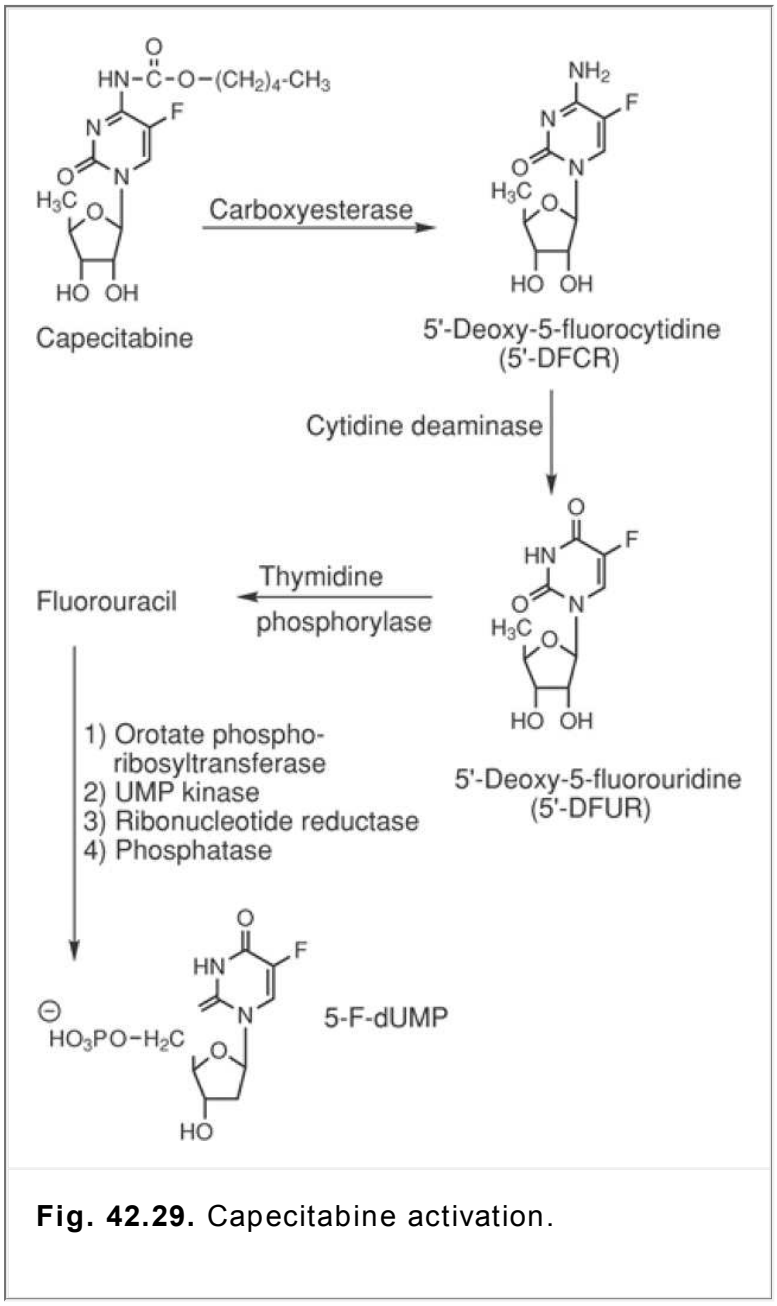

Fig. 42.29. Capecitabine activation.

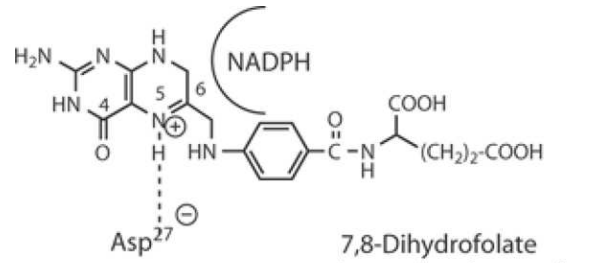
In contrast, the C_4 amino substituent of methotrexate enriches electron density at N_1 through π-electron donation, increasing its basic character between 10- and 1,000-fold and promoting protonation by Glu^{30} at the expense of N_5. Because N_1 and N_5 are across the pteridine ring from one another, the interaction of N_1 with the DHFR Asp^{27} will effectively stand the false substrate "on its head" relative to the orientation of 7,8-DHF (Fig. 42.30) (61,62). With the 5,6-double bond of methotrexate 180° away from the bound NADPH cofactor (61) and stabilized by the fully aromatic pteridine ring, the possibility for reduction is eliminated. The DHFR enzyme will be pseudoirreversibly bound to a molecule it cannot reduce, which ties up the DHFR enzyme and prevents the conversion of DHF to THF. In turn, this halts the synthesis of the 5,10-methylene-THF cofactor required for dTMP biosynthesis and causes feedback inhibition of the thymidylate synthase enzyme. The cell will die a "thymineless death."

Methotrexate can be given orally in the treatment of breast, head and neck, and various lung cancers as well as in non-Hodgkin's lymphoma. The sodium salt form also is marketed for IV, intramuscular, intra-arterial, or intrathecal injection. Oral absorption is dose-dependent and peaks at 80 mg/m^2 because of site saturation. The monoglutamate tail of methotrexate permits active transport into cells, with carrier-mediated transport predominating at serum concentration levels lower than 100 μM. Once inside the cell, methotrexate undergoes a polyglutamation reaction that adds several anionic carboxylate groups to trap the drug at the

site of action. Polyglutamation is more efficient in tumor cells than in healthy cells and, therefore, may promote selective toxicity of this drug. Cancer cells can become resistant to methotrexate over time which may involve impaired transport across tumor cell membranes, enhanced efflux from the tumor cell, and attenuated polyglutamation rates. The polyglutamated drug will be hydrolyzed back to the parent structure before renal elimination. Up to 90% of an administered dose of methotrexate is excreted unchanged in the urine within 24 hours.



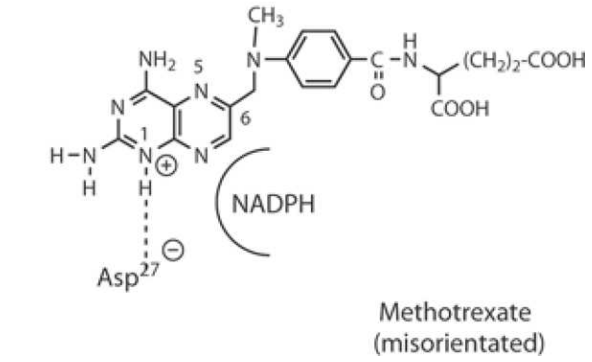


Fig. 42.30. Misorientation of methotrexate of dihydrofolate reductase (DHFR).

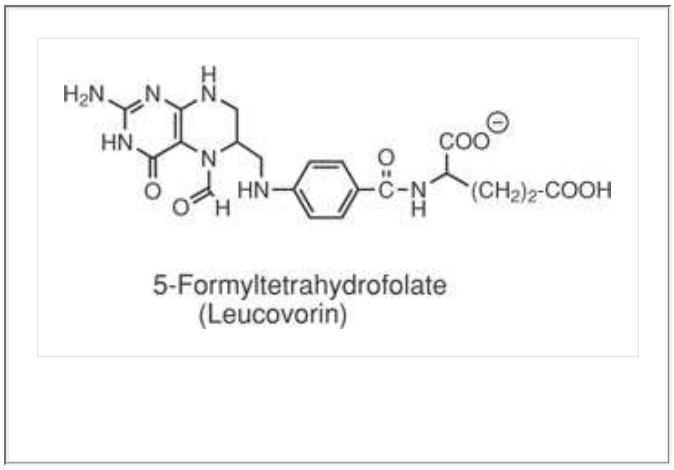
Methotrexate toxicity can occur with high doses if "third space" fluids allow drug to accumulate in ascites and pleural effusions and/or when renal excretion is impaired by kidney disease. When used in high doses, methotrexate and its 7-hydroxymetabolite (which has a three- to fivefold lower water solubility) can precipitate in the renal tubule, causing damaging crystalluria. Methotrexate- induced lung disease is a particularly critical problem, because it can arise at any time and at any dose, and it can even be fatal. Methotrexate use also can precipitate severe GI side effects, including ulcerative stomatitis and hemorrhagic enteritis, leading to intestinal perforation. Potentially fatal skin reactions are a risk as well. As a Category X teratogen, this drug should not be given to women who are pregnant or planning to become pregnant.

If severe methotrexate toxicity occurs, reduced folate replacement therapy with 5-formyltetrahydrofolate

(leucovorin) must be initiated as soon as possible. Leucovorin generates the folate cofactors needed by DHFR and GAR transformylase to ensure the continued synthesis of pyrimidine and purine nucleotides in healthy cells. "Leucovorin rescue" therapy often is given as prophylaxis after high-dose methotrexate therapy.



Pemetrexed

Pemetrexed (Fig. 42.25) is a novel multitarget antifolate used by the IV route for the treatment of advanced or metastatic nonsmall cell lung cancer and in combination with cisplatin in malignant pleural mesothelioma. Like methotrexate, it is actively transported into tumor cells through reduced folate carriers and, in polyglutamated form, inhibits the synthesis of pyrimidine and purine-based nucletotides by disrupting folate-dependent metabolic processes (63). In addition to DHFR, this pyrrolopyrimidine-based inhibitor binds tightly to thymidylate synthase and GAR transformylase (64,65). Patients on pemetrexed must take folate and vitamin B_{12} supplements to reduce the risk of bone marrow suppression (neutropenia, thrombocytopenia, and anemia) and GI side effects. Pretreatment with corticosteroids can reduce the risk of drug-induced skin rash. Pemetrexed has a half-life of 3.5 hours and is excreted primarily unchanged via the kidneys. Significant cross-resistance has been noted between pemetrexed and other pyrimidine and folate antagonists (63).

Purine Antagonists: Amidophosphoribosyl Transferase Inhibitors

AMP and GMP biosynthesis

The rate-limiting enzyme in the synthesis of purine nucleotides is amidophosphoribosyl transferase (also known as phosphoribosylpyrophosphate amido transferase), which is a major target for one of the two thiol-containing purine anticancer antimetabolites on the U.S. market.

The pathway outlining the normal synthesis of AMP and GMP is provided in Figure 42.31. It is important to recognize that the rate-limiting step is the first of the pathway; if that step is inhibited, no other step can proceed. Also, note that the rate-limiting transferase enzyme works on a phosphorylated ribose substrate. Because phosphorylated ribose is a component of every intermediate in the pathway, no enzyme in the sequence will function without its presence. Finally, note the reaction in the pathway catalyzed by GAR transformylase, which requires the methyl-donating 10-formyltetrahydrofolate. As previously mentioned, this step is inhibited by methotrexate.

Thiopurine metabolism

The two currently marketed purine anticancer agents are both 6-thio analogues of the endogenous purine bases guanine and purine, also known as inosine (Fig. 42.25). They are prodrugs and must be converted to ribonucleotides by hypoxanthine guanine phosphoribosyl transferase (HGPRT) before they can exert their cytotoxic actions. Mercaptopurine, acting through a methylated ribonucleotide metabolite, inhibits the target amidophosphoribosyl transferase enzyme, leading to the true antimetabolic effect of lowered AMP and GMP biosynthesis (Fig. 42.32). A second mechanism of antineoplastic activity for mercaptopurine (and the predominant mechanism for thioguanine) involves the incorporation of di- and triphosphate deoxy- and ribonucleotides generated within the tumor cell into DNA and RNA, respectively (66). This illicit substitution further inhibits elongation of the strands and promotes apoptosis.

Thiopurines are metabolized by S-methylation via the polymorphic enzyme thiopurine methyl transferase (TPMT) with S-adenosylmethionine serving as cofactor. The methylated thiopurine bases cannot react with HGPRT and, therefore, cannot form the active false ribonucleotides. Drug manufacturers take this into

account when establishing dosing regimens. The active false ribonucleotide 6-thioinosinic acid also is subject to extensive TPMT-catalyzed methylation. The S-methyl-6-thioinosinic acid metabolite is a potent inhibitor of the amidophosphoribosyl transferase enzyme and contributes to the cytotoxic action of the parent drug (Fig. 42.32). In contrast, little or no 6-methylthioguanylic acid is produced inside the cell (66,67).

Thiopurine methyl transferase is polymorphic in humans, and some individuals do not express this protein to any significant extent (68). Patients who are poor TPMT metabolizers (e.g., 10% of Caucasians, but also evident in other races) will not experience the activity-attenuating metabolic effect and will generate more active ribonucleotide per dose than patients with normal or excessive levels of the enzyme will. The TPMT genotype of patients should be assessed before initiating thiopurine therapy, because poor metabolizers are at a high risk of life-threatening myelosuppression from elevated levels of false ribonucleotides, even when standard doses are administered (67). In addition, the accumulation of mutagenic thiopurine-based ribonucleotides puts these patients at higher risk for secondary malignancies (66). Thiopurines can still be used in poor TPMT metabolizers, but the dose should be decreased significantly (e.g., 10- to 15-fold) and white blood cell counts monitored vigilantly.

Extensive TPMT metabolizers, who represent up to 90% of patients on thiopurine therapy, will form lower amounts of apoptotic 6-thiolated ribonucleotides. In the case of mercaptopurine, the molecules of ribonucleotide generated will be methylated very rapidly to the antimetabolic 6-methylthioinosinic acid, thus enhancing sensitivity to the drug (67). In contrast, extensive TPMT metabolizers show a decreased sensitivity to thioguanine,

because there is no compensatory increase in the formation of methylated ribonucleotide to offset the decreased production of 6-thioguanylic acid (66).

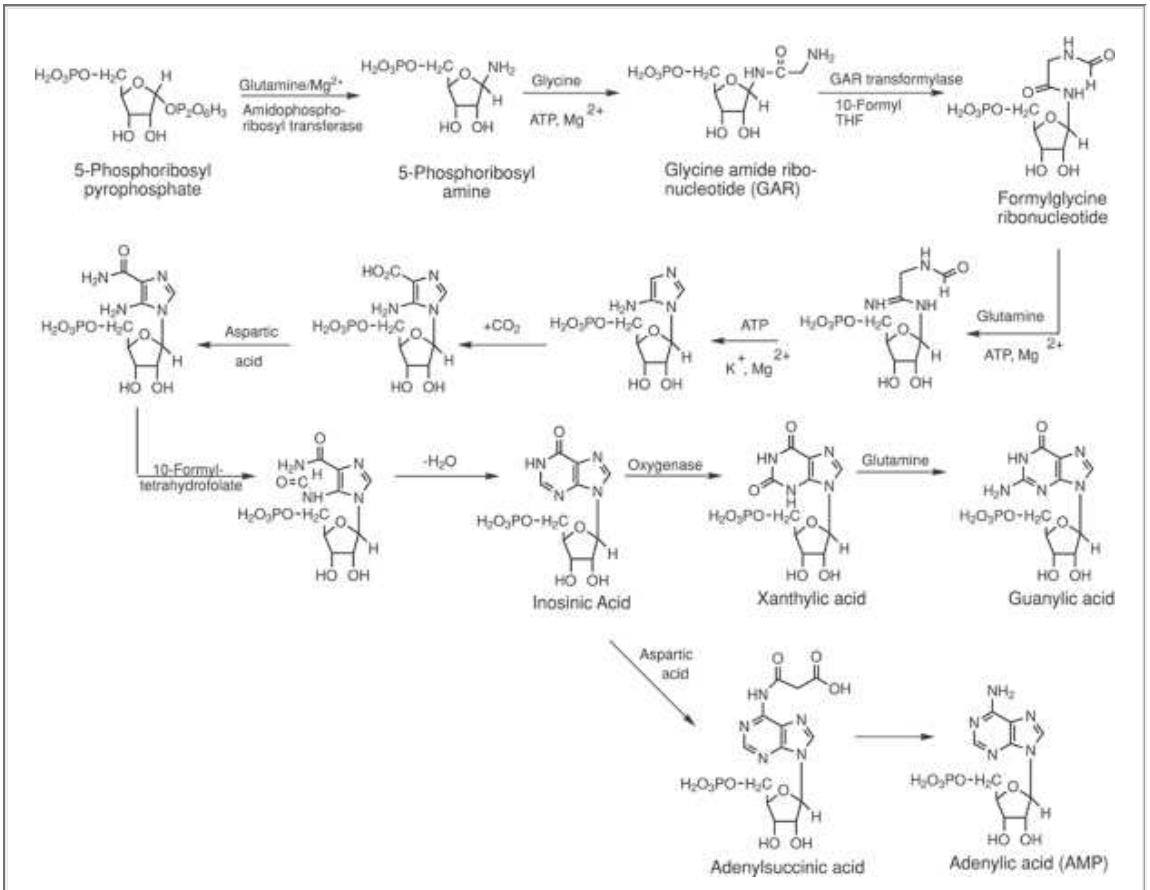


Fig. 42.31. Biosynthetic scheme for the synthesis of purines.

Xanthine oxidase competes with TPMT for mercaptopurine (but not for thioguanine) and converts it to

inactive 6-thiouric acid, which is excreted in the urine (Fig. 42.33) (68). 6-Thioinosinic acid also is subject to metabolism via the xanthine oxidase pathway, ultimately forming the same inactive metabolite. Allopurinol, which inhibits xanthine oxidase and increases levels of active 6-thioinosinic acid, can be coadministered with mercaptopurine to increase its duration of action and effective antineoplastic potency. The dose of mercaptopurine can be cut approximately in half when coadministered with allopurinol. Coadministration of allopurinol with thioguanine is not warranted, because the impact of xanthine oxidase on its metabolic degradation is minor.

Specific drugs

Mercaptopurine

Mercaptopurine (Fig. 42.32) is used in the treatment of acute lymphatic and myelogenous leukemias. It is available in an oral dosage form, but absorption can be erratic and is reduced by the presence of food. The drug is extensively metabolized on first pass and excreted by the kidneys. Bone marrow suppression is the major use-limiting toxicity, although the drug can be hepatotoxic in high doses. Dosage adjustments should be considered in the face of renal or hepatic impairment. Because the major mechanism of action of mercaptopurine is inhibition of de novo purine nucleotide biosynthesis rather than apoptosis secondary to the incorporation of false nucleotides into DNA, there is a lower risk for mutagenesis and secondary malignancy compared to thioguanine (66).

Thioguanine

Thiogunanine (Fig. 42.32) is administered orally in the treatment of nonlymphocytic leukemias. Like mercaptopurine, absorption is incomplete and variable, and the toxicity profiles are similar except where previously noted.

DNA Polymerase/DNA Chain Elongation Inhibitors

Five halogenated and/or ribose-modified DNA nucleoside analogues are marketed for the treatment of a wide

variety of hematologic cancers and solid tumors (Fig. 42.25). These agents have complex and multifaceted mechanisms. All include inhibition of DNA polymerase and/or DNA chain elongation among their actions, however, and all must be converted to triphosphate nucleotides before activity is realized. As nucleosides, they are actively taken up into cells via a selective nucleoside transporter protein, so tumors deficient in this transporter system will be resistant to these anticancer agents. Once inside the cell, specific kinases conduct the essential phosphorylation reactions. In active triphosphate form, they can be mistakenly incorporated into the growing DNA chain, thus arresting further elongation, and/or inhibit enzymes essential for DNA synthesis.

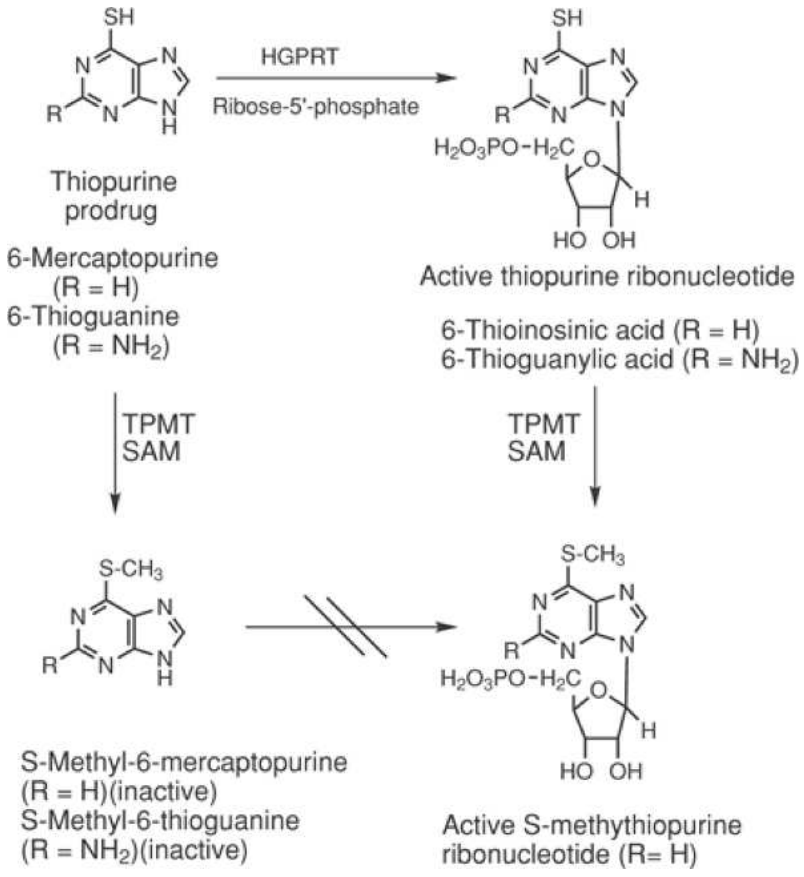

Fig. 42.32. Thiopurine metabolism leading to activation and inactivation.

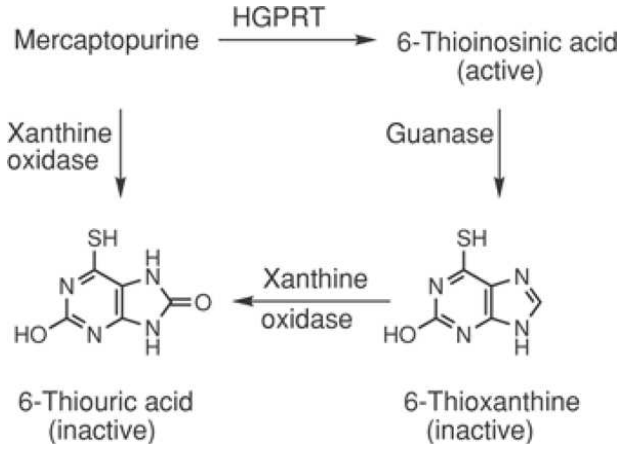

Fig. 42.33. Xanthine oxidase inactivation of mercaptopurine and 6-thioinosinic acid.

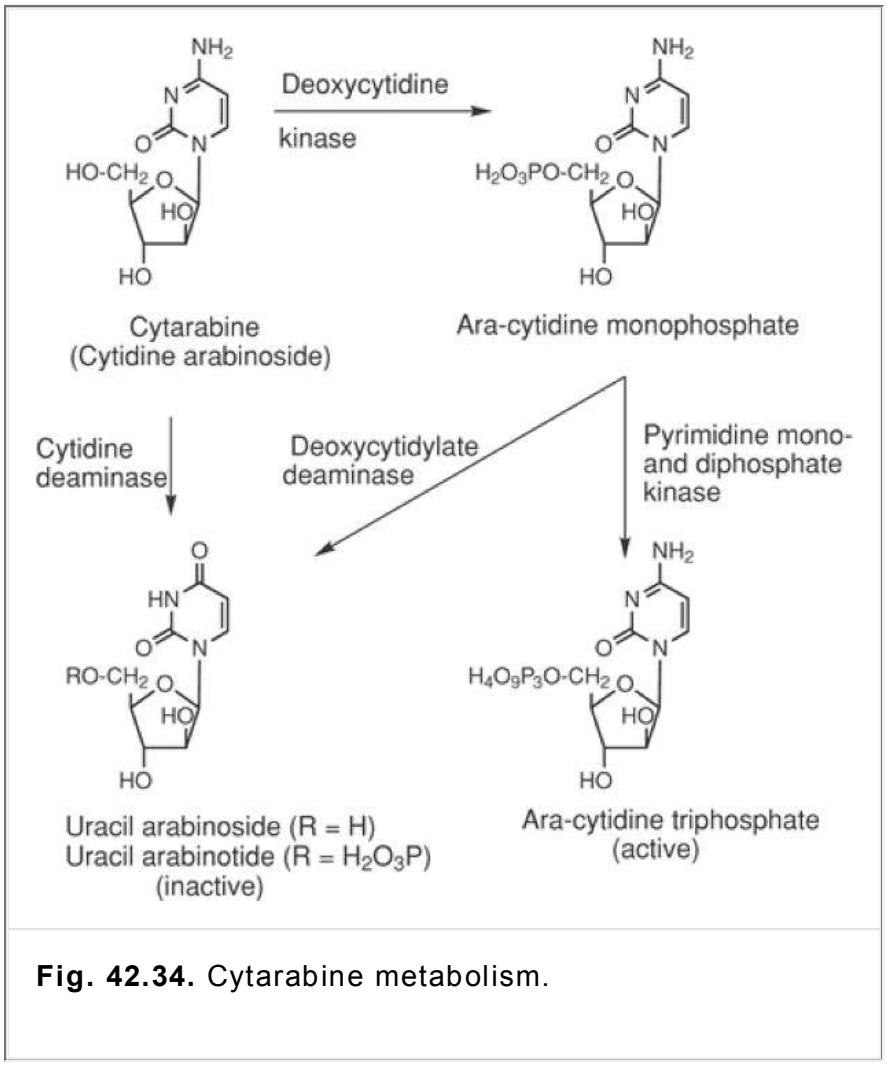

Fig. 42.34. Cytarabine metabolism.

All drugs in this group are administered IV, are excreted via the kidneys, and induce myelosuppression as their major use-limiting side effect.

Cytarabine and Gemcitabine

Both of these cytidine-based anticancer agents (Fig. 42.25) undergo initial phosphorylation by deoxycytidine kinase to the monophosphate with subsequent phosphorylations catalyzed by pyrimidine monophosphate and diphosphate kinases. Cytaribine, an arabinoside, is catabolized by cytidine and deoxycytidylate (deoxycytidine monophosphate) deaminases to inactive uracil analogues (Fig. 42.34). The significantly longer half-life of gemcitabine (19 hours) compared to conventional cytarabine (3.6 hours) is caused by the inhibitory action of the difluorodeoxycytidine triphosphate metabolite on the potentially degradative deoxycytidine monophosphate deaminase enzyme (58). Gemcitabine elimination is gender-dependent, with women having the greater risk for toxicity because of lower renal clearance.

Gemcitabine is indicated in the treatment of breast, pancreatic, and nonsmall cell lung cancers. Cytarabine, which can be administered subcutaneously and intrathecally in addition to IV, is used in the treatment of various leukemias. A liposomal formulation of cytarabine is available for the treatment of lymphomatous meningitis.

Fludarabine, cladribine, and clofarabine

Like their pyrimidine counterparts, these 3-halogenated adenosine-based nucleosides undergo conversion to the active triphosphate nucleotides (Fig. 42.25) after active transport into tumor cells. All are initially phosphorylated by

deoxycytidine kinase, and cells with high levels of this enzyme should respond well to these agents. The C_2-halogen renders the molecules relatively resistant to the degradative action of adenosine deaminase, and a significant fraction of the dose is eliminated unchanged via the kidneys. Fludarabine, an arabinoside, actually is marketed as the monophosphate nucleotide to enhance water solubility for IV administration, but this group is cleaved rapidly in the bloodstream, allowing the free nucleoside to take advantage of the nucleoside-specific transporting proteins.

Cladribine is indicated in the treatment of hairy cell leukemia, whereas fludarabine phosphate is utilized in chronic lymphocytic leukemia. In addition to myelosuppression, fludarabine phosphate can induce hemolytic anemia, and severe CNS toxicity has been noted with high doses.

Clofarabine is used in acute lymphoblastic leukemia patients of 21 years or less who have failed with at least two previous regimens. In addition to inhibiting DNA chain elongation, this drug also inhibits ribonucleotide reductase and facilitates the release of proapoptotic proteins from mitochondria. The rapid attenuation of leukemia cells after administration of this agent can result in a condition known as tumor lysis syndrome, and respiratory and cardiac toxicities can occur secondary to cytokine release. Toxicity can progress to potentially fatal capillary leak syndrome and organ failure, and patients should receive IV fluids for the entire 5-day course of therapy to minimize risk of serious adverse events.

Miscellaneous Antimetabolites

Pentostatin

Pentostatin (Fig. 42.25) is a ring-expanded purine ribonucleoside that inhibits adenosine deaminase and is used in the treatment of hairy cell leukemia. The elevated levels of deoxyadenosine triphosphate that result from inhibition of this degradative enzyme inhibit the action of ribonucleotide reductase (the enzyme that converts ribose diphosphate to deoxyribose diphosphate), thus halting DNA synthesis within the tumor cell.

Hydroxyurea

Hydroxyurea (Fig. 42.25) blocks the synthesis of DNA by trapping a tyrosyl free radical species at the catalytic site of ribonucleotide reductase, thereby inhibiting the enzyme that converts ribonucleotide diphosphates into their corresponding deoxyribonucleotides. It is used orally for the treatment of melanoma, metastatic or inoperable ovarian cancer, resistant chronic myelocytic leukemia, and as an adjunct to radiation in the treatment of squamous cell carcinoma and cancer of the head and neck. Hydroxyurea increases the effectiveness of radiation therapy through its selective toxicity to cells in the radiation-resistant S phase and by stalling the cell cycle in the G_1 stage, in which radiation therapy does the greatest damage. It addition, hydroxyurea thwarts the normal damage-repair mechanisms of surviving cells.

Hydroxyurea has excellent oral bioavailability (80–100%), and serum levels peak within 2 hours of consuming the capsules. If a positive response is noted within 6 weeks, toxicities generally are mild enough to permit long-term or indefinite therapy on either a daily or every-3-day basis. Leukopenia and, less commonly, thrombocytopenia and/or anemia are the most serious adverse effects. Excretion of the unchanged drug and the urea metabolite is via the kidneys. The carbon dioxide produced as a by-product of hydroxyurea metabolism is excreted in the expired air.

Mitosis Inhibitors

The mitotic process depends on the structural and functional viability of microtubules (polymeric heterodimers consisting of isotypes of α- and β- tubulin proteins). These distinct but nearly identical 50-kDa proteins lie adjacent to one another within the tubule and “roll up” to form an open, pipe-like cylinder akin to a hollow peppermint candy stick. A γ-tubulin protein is found at the organizational center of the microtubule. The nature of the tubulin isotypes found in the microtubule are conserved throughout specific tissues within a given species and will impact the cell's sensitivity to mitosis inhibitors.

During cell division, tubulin undergoes intense, sporadic, and alternating periods of structural growth and erosion known as “dynamic instability.” The proteins alternatively polymerize and depolymerize through guanosine triphosphate– and Ca^{2+}-dependent processes. Polymerization involves the addition of tubulin dimers to either end of the tubule, although the faster-growing (+)-end is more commonly involved. Polymerization results in tubular elongation, whereas depolymerization results in the shortening of the

structure. The frenetic alteration in structure, facilitated by microtubule-associated proteins (MAPs), ultimately allows the formation of the mitotic spindle and the attachment to chromosomes that is a prerequisite to cell division. Inhibiting the essential hyperdynamic changes in microtubular structure results in mitotic arrest and apoptosis. Two classes of mitosis inhibitors currently are marketed for the treatment of cancer, taxanes, and vinca alkaloids.

Taxanes

Anticancer taxanes initially were isolated from the bark of the Pacific yew (*Taxus brevifolia*) but are now produced semisynthetically from an inactive natural precursor found in the leaves of the European yew (*Taxus baccata*) a renewable resource. Taxanes bind to polymerized (elongated) β-tubulin at a specific receptor site located within the tubular lumen. At standard therapeutic doses (which should lead to intracellular concentrations of 1–20 μM), taxane-tubulin binding renders the microtubules resistant to depolymerization and prone to polymerization (69). This promotes the elongation phase of microtubule dynamic instability at the expense of the shortening phase, and it inhibits the disassembly of the tubule into the mitotic spindle. In turn, this interrupts the normal process of cell division. At these concentrations, extensive polymerization causes the formation of large and

dense aberrant structures, known as asters, that contain stabilized microtubule bundles.

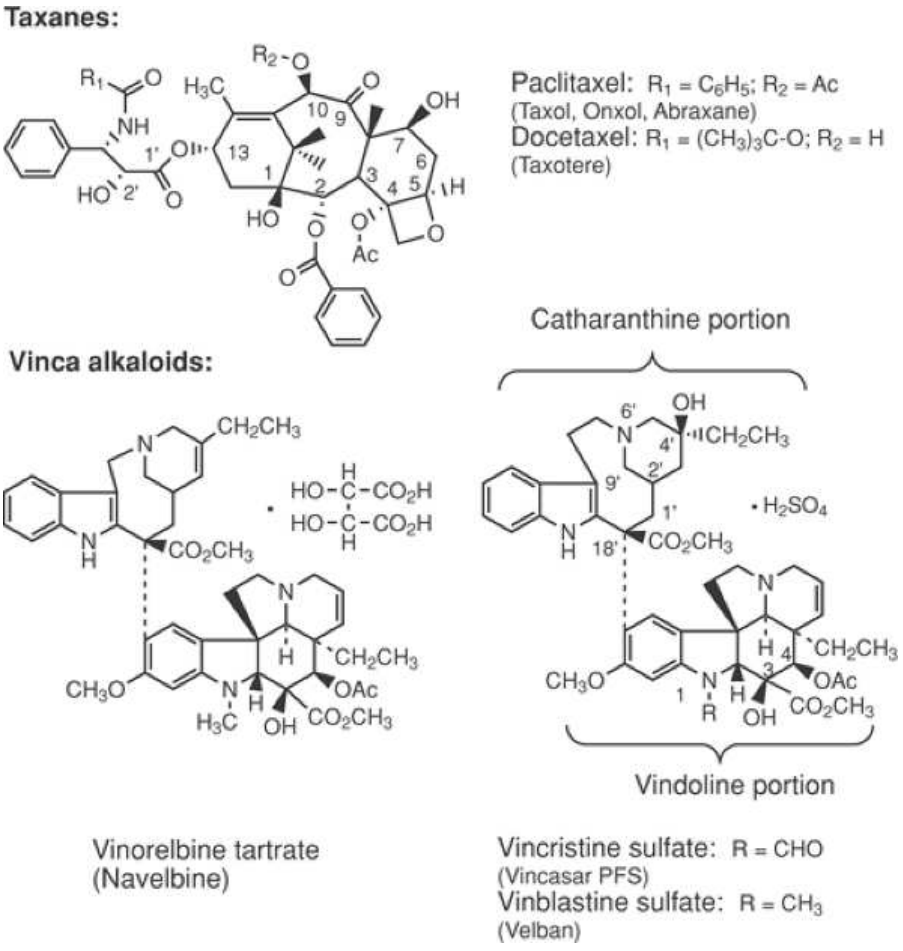

Fig. 42.35. Mitosis inhibitors.

Chemistry and receptor binding

Chemically, diterpenoid taxanes consist of a 15-membered tricyclic taxane ring system

(tricyclo[9.3.1.0]pentadecane) fused to an oxetane (D) ring and contain an esterified β-phenylisoserine side chain at C_{13}. As shown in Figure 42.35, the two marketed taxane antineoplastics differ in substitution pattern at C_{10} (acetate ester or secondary alcohol) and C_{13} (benzamido or *t*-butoxycarboxamido). The taxane ring system often is conceptualized as having "northern" and "southern" halves. The "southern" segment is critical to receptor binding, whereas the "northern" section ensures the proper conformation of essential functional groups, including the C_{13}-isoserine side chain (with its C_1-carbonyl, free C_2-(R)-OH and C_3-(S)-benzamido or *t*-butoxycarboxamido groups), the benzoyl and acetyl esters at C_2 and C_4, respectively, and the intact oxetane ring (70,71,72).

The key taxane-tubulin binding interactions are identified in Table 42.7, utilizing paclitaxel as ligand (70,73,74). Paclitaxel interacts at the β-tubulin binding site in a folded ("T" or "butterfly") conformation, that places C_2-benzoyl and the C_3-benzamido groups in close proximity (70). Their independent intermolecular engagement with a critical β-tubulin His residue, however, which is perfectly positioned between them, keeps them from interacting with one another. The oxetane ring of taxanes, although capable of enhancing receptor affinity through hydrogen bonding (72,73), is believed to serve a more critical role in properly orienting the C_4-acetyl moiety for

interaction within its hydrophobic binding pocket (71). The C_1-OH also promotes conformational stability through intramolecular interaction with the carbonyl oxygen of the C_2 benzoyl moiety (70). The areas of the paclitaxel structure where steric influences are most critical to receptor binding have been identified (72).

Table 42.7. Paclitaxel–β-Tubulin Binding Interactions (70,73,74)

Paclitaxel Functional Group	β-Tubulin Binding Residues	Interaction
C_2-benzoyl phenyl	Leu^{217}, Leu^{219}, His^{229}, Leu^{230}	Hydrophobic
C_2-benzoyl carbonyl	Arg^{278}	Hydrogen bond
$C_{3'}$-benzamido-NH	Asp^{26}	Hydrogen bond
$C_{3'}$-benzamido carbonyl	His^{229}	Hydrogen bond
$C_{3'}$-phenyl	Ala^{233}, Ser^{236}, Phe^{272}	Hydrophobic
C_4-acetyl	Leu^{217}, Leu^{230}, Phe^{272}, Leu^{275}	Hydrophobic
C_7-OH	Thr^{276}, Ser^{277}, Arg^{278}	Hydrogen bond
C_{12}-CH_3	Leu^{217}, Leu^{230}, Phe^{272}, Leu^{275}	Hydrophobic

$C_{2'}$-OH	Arg^{369}, Gly^{370} (NH)	Hydrogen bond
$C_{1'}$-carbonyl	Gly^{370} (NH)	Hydrogen bond
Oxetane oxygen	Thr^{276} (NH)	Hydrogen bond

Taxane metabolism

The taxanes are metabolized to significantly less cytotoxic metabolites by CYP450 enzymes. In humans, CYP2C8 bioconverts paclitaxel to 6α-hydroxypaclitaxel, the major metabolite, which is 30-fold less active than the parent structure (75,76,77). CYP3A4 mediates the formation of additional minor *p*-hydroxylated metabolites of the benzamido and benzoyl at $C_{3'}$ and C_2 respectively (Fig. 42.36), and the 10-desacetyl metabolite has been documented in urine and plasma. Docetaxel is oxidized exclusively by CYP3A4/5, with CYP3A4 having a 10-fold higher affinity for the drug than CYP3A5. The major metabolite, known as hydroxydocetaxel, is the hydroxymethyl derivative of the 3′-*t*-butoxycarboxamide side chain (77). Hydroxydocetaxel is further oxidized and cyclized to isomeric oxazolidinediones before excretion. The elimination of taxanes is predominantly biliary.

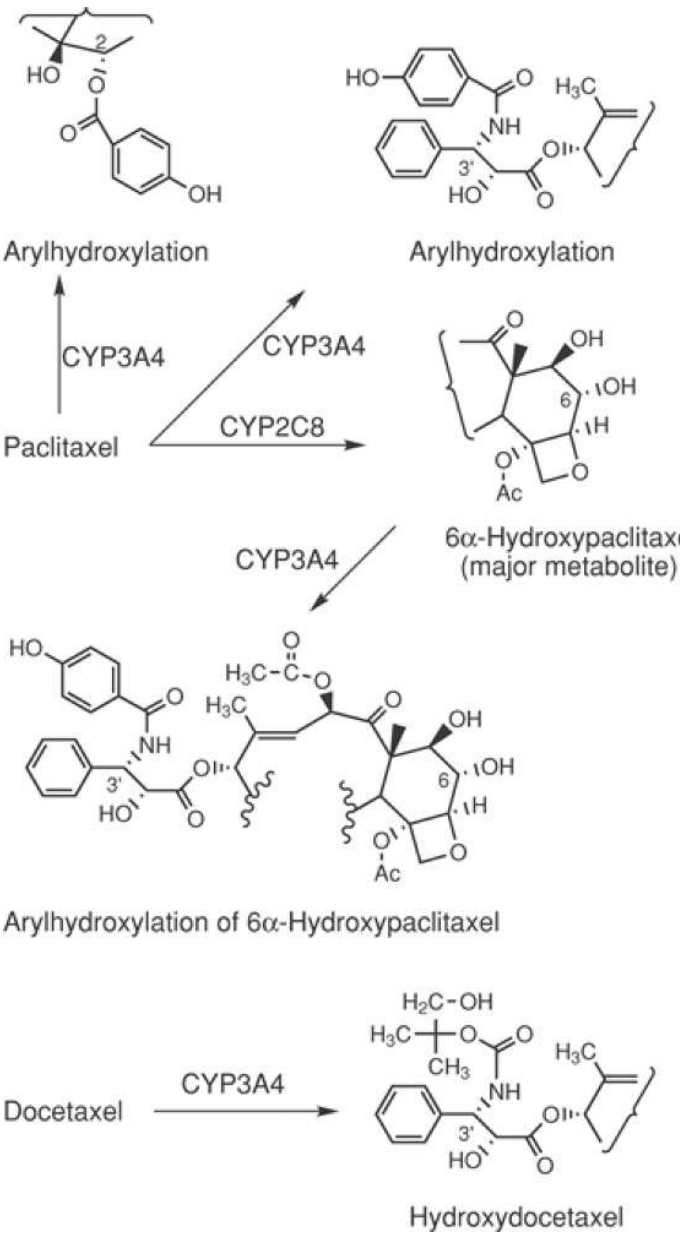

Fig. 42.36. Taxane metabolism.

The metabolic patterns of these closely related structures are distinct, and it has been hypothesized that the C_{13} side chain plays a major role in positioning the compounds in the catalytic site of CYP450 enzymes. Specifically, the 3′-phenyl ring of paclitaxel has been proposed to properly orient C_6 for hydroxylation through π-stacking interactions with CYP2C8 active site residues while decreasing affinity for CYP3A4 binding groups. The hydrophobic character of the 10-acetoxy group, found in paclitaxel, enhances CYP450-mediated hydroxylation two- to fivefold by facilitating substrate binding or augmenting catalytic capability. Both isoforms are impacted by the presence of this ester, often to the same extent (77).

Epothilones

Low water solubility is a significant drawback to the therapeutic utility of the taxanes. This is particularly true of paclitaxel, which has a more lipophilic acetate moiety at C_{10} compared to docetaxel's more polar hydroxyl group. Paclitaxel must be administered in a vehicle of 50% alcohol/50% polyoxyethylated caster oil, which can lead to an enhanced risk of hypersensitivity reactions (dyspnea, hypotension, angioedema, and uticaria)

in patients not pretreated with H_1 and H_2 antagonists and dexamethasone (78). In addition, high P-glycoprotein–mediated cellular efflux of both taxane anticancer agents can result in drug resistance. To overcome these problems, epothilone B (Fig. 42.37), a 16-membered macrolide structurally unrelated to the taxanes but with functional groups properly positioned to mimic critical tubulin-binding groups, is being actively investigated for use in a variety of solid tumor and hematologic cancers. Epothilone B binds with very high affinity to the taxane binding site on polymerized β-tubulin, and it acts through the same cytotoxic

mechanism. In addition to enhanced water solubility and a lack of P-glycoprotein affinity, epothilone is more efficiently produced through fermentation with the myxobacterium *Sorangium cellulosum* and has a higher antineoplastic potency (74,79,80).

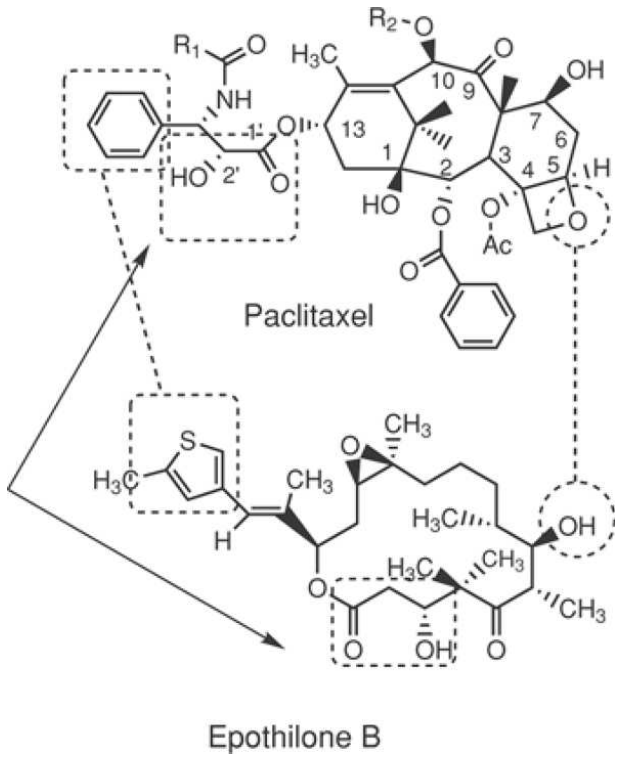

Fig. 42.37. Receptor binding-matched epothilone B and paclitaxel functional groups.

Specific drugs

Paclitaxel

Paclitaxel (Fig. 42.35), which is claimed to be “the best-selling anticancer drug in history” (70), is indicated for IV use in combination with cisplatin as first-line therapy for advanced ovarian and nonsmall cell lung cancer. It also is used alone or in combination with the fluorouracil prodrug capecitabine in anthracycline-resistant metastatic breast cancer. Paxclitaxel's ability to up-regulate thymidine phosphorylase, one of capecitabine's activating enzymes, is the rationale behind the combination therapy (81). Solution (Taxol, Onxol) and albumin-bound (Abraxane) formulations are available and cannot be used interchangeably. Abraxane also has been employed in various solid tumors of the GI and genitourinary tracts. Solution-based infusions generally are administered over 3 to 24 hours and can be passed through an in-line, 0.22-μm filter to reduce vehicle-related cloudiness. The albumin-bound form is given over 30 minutes and should be well-mixed (but not filtered) to ensure complete suspension of the protein–drug particles.

The major use-limiting adverse effect of paclitaxel is dose-dependent myelosuppression, particularly

neutropenia, and first doses may need to be decreased in patients with hepatic dysfunction. Subsequent dose reductions, if any, should be tailored to individual response. The drug should not be given to patients who have baseline neutrophil counts below 1,500 cells/mm^3. The albumin-bound formulation also is associated with sensory neuropathy. As noted above, all patients receiving solution-based paclitaxel should be pretreated with antihistamines and a corticosteroid to minimize the risk of potentially fatal hypersensitivity reactions. Paclitaxel is a Category D teratogen and carries a high risk of fetal intrauterine mortality. Both male and female patients are advised not to attempt conception while on this drug. Due caution should be observed when coadministering paclitaxel with drugs that inhibit or compete for metabolizing enzymes, particularly CYP2C8 (e.g., 17α-ethinylestradiol and diazepam).

Docetaxel

The indications for docetaxel (Fig. 42.35) generally mirror those of paclitaxel, although docetaxel is not used in ovarian cancer. It has greater water solubility than paclitaxel because of presence of the free C_{10}-OH group, and it is formulated with polysorbate 80 rather than with polyoxyethylated castor oil. Hypersensitivity reactions are still possible, and all patients should receive corticosteroid premedication. In addition to neutropenia and teratogenicity, this taxane can induce significant fluid retention, and 2-kg weight gains are not uncommon. Although rare, onycholysis also has been reported. Drug–drug interactions have been noted when docetaxel is coadministered with drugs that inhibit or compete for CYP3A4 enzymes (e.g., "azole" antifungals, erythromycin, and cyclosporine) (82).

Vinca Alkaloids

Several alkaloids found naturally in *Catharanthus roseus* (periwinkle) have potent antimitotic activity. In opposition to the taxoids, vinca alkaloids halt cell division by inhibiting polymerization. They bind at the interface of two heterodimers within the inner tubular lumen at a single high-affinity site on the (+)-end of the tubules and attenuate the uptake of the guanosine triphosphate essential to tubule elongation (83). Simultaneous binding to α- and β-tubulin results in protein cross-linking, which promotes a stabilized protofilament structure (84). Inhibition of microtubule elongation occurs at "substoichiometric" concentrations, at which alkaloid occupation of only 1 to 2% of the total number of high-affinity sites can result in up to a 50% inhibition of microtubule assembly (85). At high concentrations, when alkaloid binding to high-affinity sites becomes stoichiometric and lower-affinity binding sites on the tubule wall also are occupied, microtubular depolymerization is stimulated, leading to the exposure of additional alkaloidal binding sites and resulting in dramatic changes in microtubular conformation. Spiral aggregates, protofilaments, and highly structured crystals form, and the mitotic spindle ultimately disintegrates (69,81). The loss of the directing mitotic spindle promotes chromosome "clumping" in unnatural shapes (balls and stars), leading to cell death (78). Other nonmitotic toxicities related to the microtubule-disrupting action of the vinca alkaloids include inhibition of axonal transport and secretory processes and disturbances in platelet structure and function (85).

Chemistry

The specific chemical nature of the vinca binding site remains elusive because of difficulties encountered in binding assay development and implementation as well as in data analysis. It is known that the active site is close to residue 339 and residue 390 on α- and β-tubulin, respectively (86). Of the three marketed vinca alkaloids (vincristine, vinblastine, and vinorelbine), vincristine binds most tightly, whereas vinblastine has the lowest affinity (85). Because vinca alkaloids enter cells by simple passive diffusion, unbound vinorelbine and vinblastine (being more lipophilic than vincristine) may be more extensively taken up into tissues. Vincristine, however, is cleared more slowly from the system and has the longest terminal half-life of the three agents, resulting in a more prolonged tumor cell exposure (69,85). Like the taxanes, tumor resistance to vinca alkaloids is mediated through P-glycoprotein.

The vinca alkaloids are complex structures composed of two polycyclic segments known as catharanthine (or velbanamine) and vindoline (Fig. 42.35), both of which are essential for high-affinity tubulin binding. The three commercially available anticancer alkaloids differ in the

length of the alkyl chain bridging positions 6′ and 9′ of the catharanthine moiety (methylene or ethylene), in the substituents at position 4′ (olefin or tertiary alcohol), and in the N_1 vindoline indole nitrogen (methyl or formyl). Although subtle, these structural changes lead to significant differences in clinical spectrum,

potency, and toxicity. For example, vincristine's relative lack of bone marrow toxicity at standard therapeutic doses makes it popular in combination therapy with more myelosuppressive anticancer agents, whereas vinblastine's relative lack of neurotoxicity permits its coadministration with cisplatin. It is known that acetylation of either hydroxyl group destroys antineoplastic activity. Reduction of the vindoline olefinic linkage greatly attenuates action (78). The $C_{18'}$-methoxycarbonyl, as well as the stereochemistry at positions 18′ and 2′, also are believed to be critical to activity (87).

Vinca alkaloids undergo O_4-deacetylation to yield metabolites equally or more active than the parent drug. They also are subject to extensive CYP3A4-mediated metabolism before biliary excretion, although the structures of these metabolites are currently unknown (88,89,90).

Specific drugs

Vincristine

Vincristine (Fig. 42.35) is marketed as the sulfate salt and is given by the IV bolus or continuous infusion routes in the treatment of acute leukemia and various Hodgkin's and non-Hodgkin's lymphomas. Toxicity often is more pronounced by the latter route. Elimination is triphasic, with the first phase (5 minutes) representing rapid uptake into tissues and the last phase (85 hours) representing release back to the plasma from tubulin-containing cells. Because the drug is extensively metabolized in the liver, patients with hepatic dysfunction are at an increased risk for toxicity, and dosage reductions should be considered. The most significant dose-limiting adverse effect is neurotoxicity, which can manifest initially as numbness and painful paresthesias in the extremities and progress to muscular pain, severe weakness, and loss of coordination. Patients can experience constipation secondary to intestinal neurotoxicity, which may require treatment with cathartics. Myelosuppression is not particularly problematic, because it occurs at doses higher than those that can be tolerated. As previously noted, coadministration with mitomycin can induce acute or delayed pulmonary toxicity characterized by severe bronchospasm.

All vinca alkaloids are severe vesicants that can induce necrosis, cellulitis, and/or thrombophlebitis. Proper needle placement before administration should be assured to eliminate the risk of extravasation. Unlike the tissue damage caused by the vesicant action of nitrogen mustards and antibiotic antineoplastics, cold exacerbates tissue destruction. If extravasation occurs, apply heat for 1 hour fours time a day for 3 to 5 days, coupled with local hyaluronidase injections. Vinca alkaloids are all Category D teratogens and are fatal if administered by the intrathecal route.

Vinblastine

In addition to the hematologic indications that it shares with vincristine, vinblastine sulfate (Fig. 42.35) has found utility in the treatment of advanced testicular carcinoma (often in combination with bleomycin), advanced mycosis fungoides, Kaposi's sarcoma, and histiocytosis X. Leukopenia is the dose-limiting side effect, and dose reductions are warranted in patients with serum bilirubin levels greater than 3 mg/dL. The drug-related impact on erythrocyte and thrombocyte levels usually is insignificant. Like vincristine, it is administered as an IV bolus or infusion. The initial elimination half-life of 3.7 minutes is similar to vincristine, but the 24.8-hour terminal half-life is significantly shorter.

Vinorelbine

Vinorelbine tartrate (Fig. 42.35) is used alone or in combination with cisplatin for first-line treatment of nonsmall cell lung cancer. This semisynthetic alkaloid is unique in having oral bioavailability (85), but it currently is available only for IV injection. The initial phase elimination half-life is on par with that observed for vincristine and vinblastine, and the terminal phase half-life is between 28 and 44 hours. Although dose-limiting granulocytopenia is the major adverse effect, potentially fatal interstitial pulmonary changes have been noted, and patients with symptoms of respiratory distress should be promptly evaluated. As with all vinca alkaloids, elimination is primarily hepatobiliary, and dosage reduction should be considered in patients with liver dysfunction.

Estramustine

Because this anticancer agent contains a carbamylated nitrogen mustard moiety (Fig. 42.3), it is most commonly classified as a DNA alkylator; however, it is now known that its primary mechanism of

antineoplastic action is inhibition of mitosis. Estramustine binds to MAP-4, prompting dissociation of this protein from the microtubule and promoting depolymerization and disassembly. It also can bind directly to α- and β-tubulin at a site distinct from the vinca alkaloid and taxane binding sites, although paclitaxel exerts a noncompetitive inhibition of estramustine binding to tubulin. A specific estramustine binding protein in prostate tissue is believed to facilitate its action in the treatment of metastatic carcinoma of the prostate. Estramustine has a low affinity for the β_m tubulin isotype, which often is overexpressed in estramustine-resistant prostatic neoplasms as one defense against this therapeutic intervention (81,91).

Topoisomerase Poisons

Epipodophyllotoxins

The epipodophyllotoxins (Fig. 42.38) are semisynthetic glycosidic derivatives of podophyllotoxin, the major component of the resinous podophyllin isolated from the dried roots of the American mandrake or mayapple plant (*Podophyllum peltatum*). Although these compounds are capable of binding to tubulin and inhibiting mitosis, their primary mechanism of antineoplastic action is poisioning topoisomerase II, a mechanism that they share

with anthracyclines and dactinomycin (discussed with the antibiotic antineoplastics under *Antibiotics*). Topoisomerase IIα has two distinct DNA-independent binding sites for the epipodophyllotoxins, one within the catalytic domain and a second within the N-terminal ATP-binding domain (92). Once bound, the toxins stabilize the cleavable ternary drug-enzyme-DNA complex, stimulating DNA ligation but inhibiting resealing. The DNA-topoisomerase fragments accumulate in the cell, ultimately resulting in apoptosis. The RNA transcription processes also are disrupted by the interaction of epipodophyllotoxins with topoisomerase IIα (93).

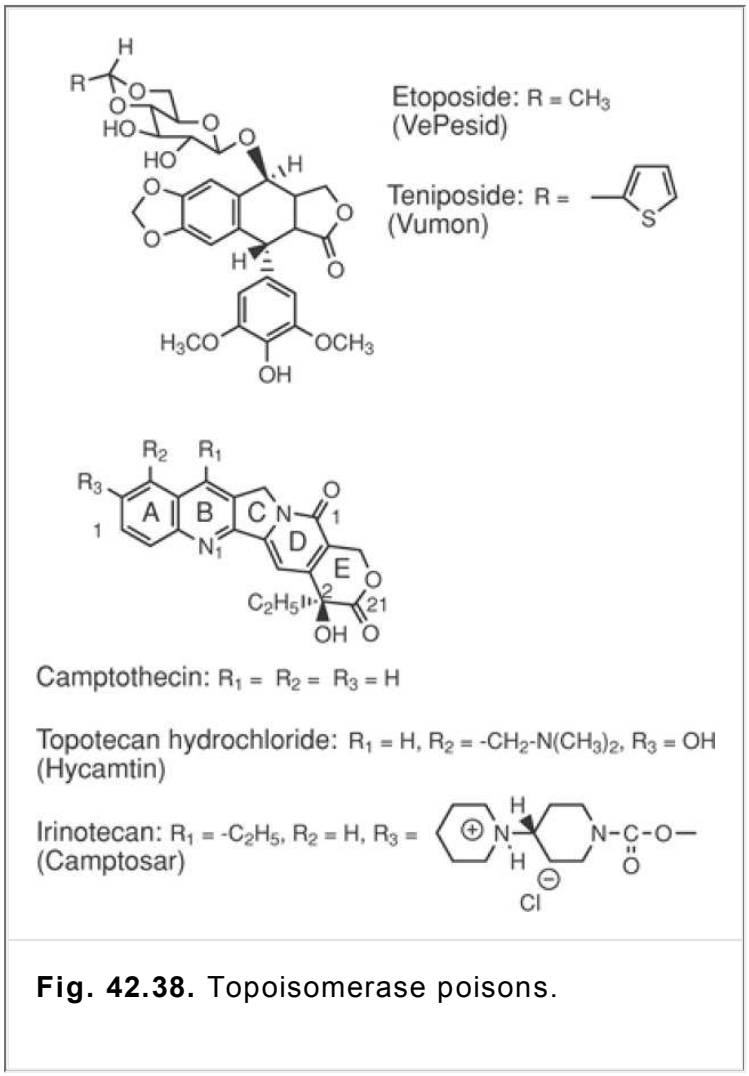

Fig. 42.38. Topoisomerase poisons.

Epipodophyllotoxins are cell-cycle specific and have their most devastating impact on cells in the S or early G_2 phase. For this reason, doses are divided and administered over several days. Resistance is multifaceted and involves down-regulation of topoisomerase IIα, attenuation of enzymatic activity levels, development of novel DNA repair mechanisms, and P-glycoprotein–mediated cellular efflux.

Chemistry

Structurally, the two marketed epipodophyllotoxins, etoposide and teniposide, differ only in the nature of one β-D-glucopyranosyl substituent (methyl or thienyl, respectively). Both are highly water insoluble, but teniposide's higher lipophilicity facilitates cellular uptake and results in a 10-fold enhancement of potency (93). The need for solubility enhancers, such as polysorbate 80 (Tween, etoposide) or polyoxyethylated castor oil (Cremophor EL, teniposide), in IV formulations puts patients at risk for hypersensitivity reactions that can manifest as hypotension and thrombophlebitis. Epinephrine, antihistamines, and corticosteroids often are coadministered to minimize risk. A water-soluble phosphate ester analogue of etoposide can be administered in standard aqueous vehicles, permitting higher doses than the oil-modified formulations would allow. The phosphate ester is rapidly cleaved to the free alcohol in the blood.

Metabolism

Epipodophyllotoxins are subject to metabolic transformation before renal and nonrenal elimination (Fig. 42.39). Etoposide is stable enough for oral administration, although a dose approximately twice that of the IV formulation must be administered. Teniposide is more extensively metabolized, presumably because of its enhanced ability to penetrate into hepatocytes, and no oral dosage form is marketed. Both drugs undergo lactone hydrolysis to generate the inactive hydroxy acid as the major metabolite, but the parent drugs also can be transformed by CYP3A4-catalyzed O-demethylation and Phase II glucuronide or sulfate conjugation.

Phase II metabolism accounts for between 5 to 22% of the dose. Clinically significant interactions between epipodophyllotoxins and CYP3A4 inducers, such as phenytoin, phenobarbital, and St. John's wort, have been documented, and coadministration can enhance antineoplastic drug clearance by as much as

77%. Conversely, CYP3A4 inhibitors, such as cyclosporine or macrolide antibiotics, can decrease clearance, leading to unwanted toxicity.

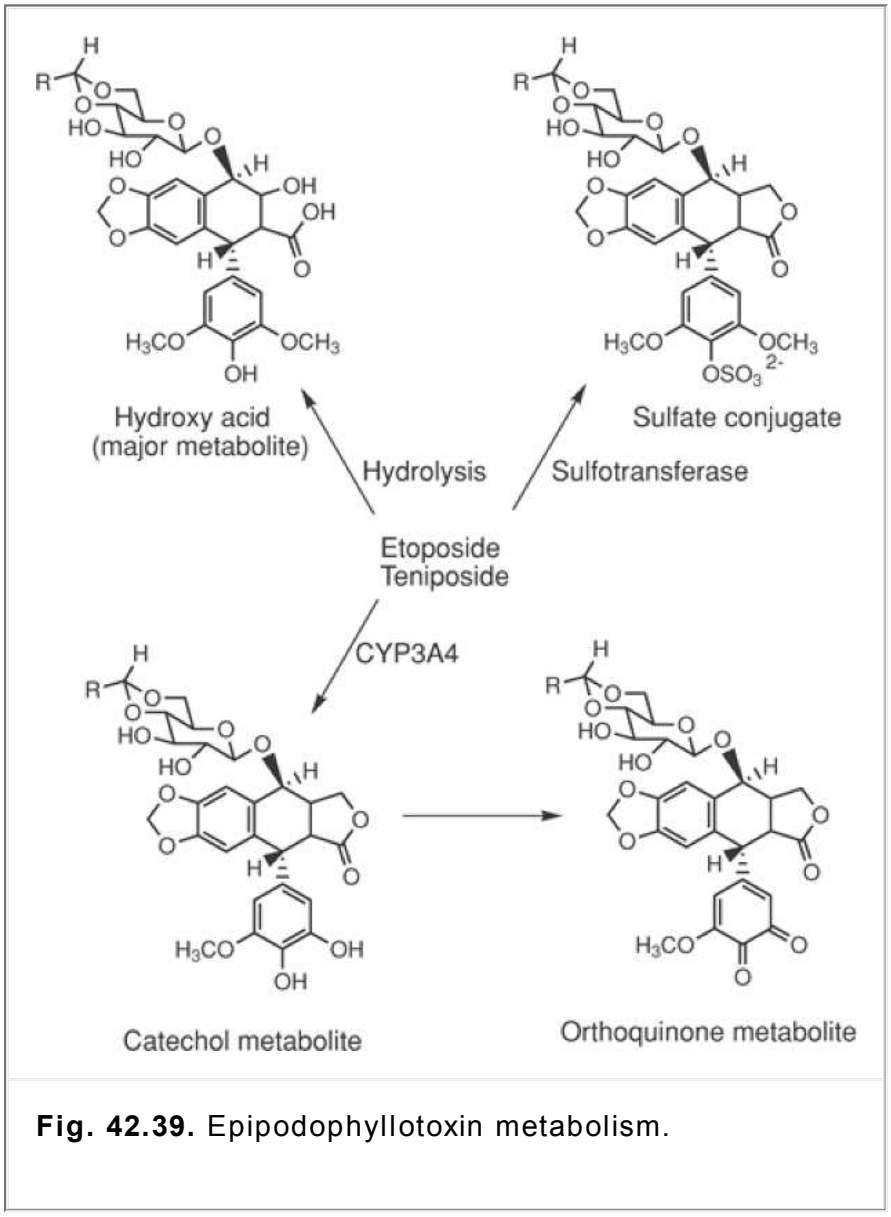

Fig. 42.39. Epipodophyllotoxin metabolism.

The catechol metabolite can oxidize to a reactive orthoquinone, and both have been proposed to promote topoisomerase-mediated DNA cleavage, potentially enhancing the risk of the translocations that result in therapy-induced acute myeloid leukemia in children treated with these drugs. Epipodophyllotoxin-induced leukemia occurs in 2 to 12% of patients and is believed to result from translocation of the *MLL* gene at chromosome band 11q23. The mean latency period of 2 years is shorter than the 5- to 7-year latency for leukemia induced by DNA alkylators, and the drug-induced cancer often is resistant to standard treatment (including bone marrow transplantation) (94). Other serious adverse effects include dose-limiting mucositis and myelosuppression, particularly leukopenia. Alopecia is common, and nausea and vomiting, most noticeable with the oral dosage form, generally are mild.

Specific drugs

Etoposide

Etoposide (Fig. 42.38) is utilized in the treatment of small cell lung cancer and in combination with other agents in refractory testicular cancer. Both IV and oral formulations are available. Oral bioavailability is concentration dependent and runs approximately 50% for the 50-mg capsule. Little first-pass metabolism is noted with the gelatin capsule dosage form. The drug is more than 96% protein bound, undergoes biphasic elimination, and has a terminal half-life of 4 to 11 hours. Approximately 35 to 45% of a dose is eliminated via the kidneys, with less than 6% excreted in feces. The drug should be used with caution in patients with renal or liver disease. Specifically, doses should be decreased in patients with creatinine clearance of less than 50 mL/min or bilirubin levels of greater than 1.5 mg/dL, and the drug should not be used in patients with bilirubin levels of greater than 3.1 mg/dL. Organoplatinum anticancer agents (e.g., cisplatin) decrease etoposide clearance, especially in children. If used in combination, administration must be separated by at least 2 days.

Teniposide

Teniposide (Fig. 42.38) is used in combination with other agents for the treatment of refractory childhood acute lymphoblastic leukemia. Compared to etoposide, it is more tightly protein bound (>99%), more extensively metabolized, more slowly cleared (terminal half-life, 5–40 hours), and less dependent on renal elimination (10–21%). Exposure to heparin can cause teniposide to precipitate, so lines must be thoroughly flushed before and after teniposide administration. The drug also can spontaneously precipitate, particularly if solutions are overagitated, and patients receiving 24-hour infusions should be monitored for blockage of access catheters. Teniposide and etoposide are Category D teratogens and, if at all possible, should not be used in women of childbearing years.

Camptothecins

Mechanism of action

Camptothecins are chiral, extensively conjugated, amine-containing pentacyclic lactones (Fig. 42.38). The biological target of camptothecins is topoisomerase I (rather than the topoisomerase II enzyme that serves as the receptor for the anthracyclines, dactinomycin and epipodophyllotoxins), but the mechanism of antineoplastic action is qualitatively similar (stabilization of a cleavable ternary DNA-enzyme complex that does not permit the resealing of nicked DNA). Although the fragmented DNA is capable of resealing in the absence of drug, when DNA replication forks encounter the fragmented DNA, a double-stranded DNA break occurs, killing the cell.

The binding of camptothecins occurs in such a way as to stabilize a covalent DNA-topoisomerase bond at the point of single-strand breakage (Tyr^{723} on the human enzyme). The binding pocket, located within the DNA strand, is revealed only after the normal DNA nicking has occurred, explaining why these poisons preferentially bind to the enzyme-DNA complex rather than to unoccupied DNA or enzyme. The flat camptothecin ring system intercalates DNA at the site of cleavage, mimicking a DNA base pair (95). The crystal structures of human ternary complexes involving the parent camptothecin alkaloid, camptothecin, and the semisynthetic analogue, topotecan (Fig. 42.38), have been solved, and important drug–protein interacting entities are noted in Table 42.8 (95,96). The bulky substituents at C_7, C_9, and C_{10} of the marketed compounds, which project into the major groove of DNA, do not hinder binding.

Camptothecins are most potent in cells undergoing active DNA replication and cell division (e.g., they are S-phase specific). Mechanisms of resistance are similar to those discussed for other drugs and include down-regulation or mutation of the target enzyme, down-regulation of enzymes needed for drug activation, and cellular efflux. Breast cancer resistance protein and multidrug resistance (MDR)-associated proteins, such as MAP-2 and MAP-3, rather than P-glycoprotein, appear to mediate resistance to these agents (78,93).

Chemistry

The parent camptothecin alkaloid, isolated from bark of *Camptotheca acuminate*, has antitumor activity, but its limited water solubility necessitated delivery as

the sodium salt of the significantly less active hydrolyzed lactone. Lactonization of the hydroxy acid in acidic urine was significant, and elevated levels of active intact alkaloid in the kidney accounted for the hemorrhagic cystitis induced by this compound. Currently marketed analogues have a basic side chain incorporated at either C_9 (tocotecan) or C_{10} (irinotecan), allowing the formation of water-soluble salts of the

intact semisynthetic alkaloid. At pH 7.4, the active lactone exists in equilibrium with the hydroxy acid hydrolysis product, with the direction dictated by the extent of binding to serum albumin. The preferential protein binding of the lactone, which occurs with irinotecan, shifts the equilibrium to favor the production of the more active lactone, thus enhancing potency.

Table 42.8. Topotecan–Topoisomerase I Interactions (95,96)

Topotecan Functional Group	Topoisomerase I Residue
Pyridine N_1	Arg^{364}
C_{10}-OH	Enzyme associated water (H-bond)
C_{17}-pyridone carbonyl	Asn^{722}
C_{20}-OH	Asp^{533} (H-bond)
C_{21}-lactone carbonyl	Tyr^{723}-phosphate, Lys^{532}

Specific drugs

Irinotecan Hydrochloride

In combination with fluorouracil, this prodrug camptothecin (Fig. 42.38) analogue is considered to be first-line therapy in the treatment of metastatic colorectal cancer. It also has shown efficacy in small cell and nonsmall cell lung cancers when used in combination with cisplatin. Given IV, the drug is slowly bioactivated in the liver through hydrolysis of the C_{10}-carbamate ester. The catalyzing enzyme is a saturable carboxylesterase known as irinotecan-converting enzyme. Levels of active metabolite, known as SN-38 (Fig. 42.40), are 50- to 100-fold lower than the parent drug, but preferential protein binding of the lactone (95%) permits significant plasma levels of the optimally active SN-38 compared to the hydroxy acid metabolite. SN-38 has a terminal half-life of 11.5 hours (compared to 5.0–9.6 hours for the prodrug parent) and is glucuronidated at the C_{10} phenol before elimination. CYP3A4 also cleaves the terminal piperidine ring through oxidation at the α-carbons, followed by hydrolysis of the resultant amides, producing inactive metabolites. Excretion of the parent drug and metabolites is renal (14–37%) and, to a lesser extent, biliary.

Delayed diarrhea induced by irinotecan is dose-limiting and potentially fatal, and vigorous loperamide therapy should be instituted at the first sign of symptoms. Acute diarrhea is attributed to the drug's ability to inhibit acetylcholinesterase and can be addressed through anticholinergic pretreatment. Pretreatment also helps patients to avoid “cholinergic syndrome,” a collection of annoying side effects that include flushing, sweating, blurred vision, lacrimation, and less commonly, bradycardia. Camptothecins also are myelosuppressive, and neutropenia can be severe, particularly in patients with elevated bilirubin levels. Extensive biotransformation also demands cautious use of irinotecan in patients with hepatic dysfunction. Prophylactic antiemetic therapy should be given at least 30 minutes before the administration of irinotecan to minimize the nausea and vomiting associated with this anticancer agent.

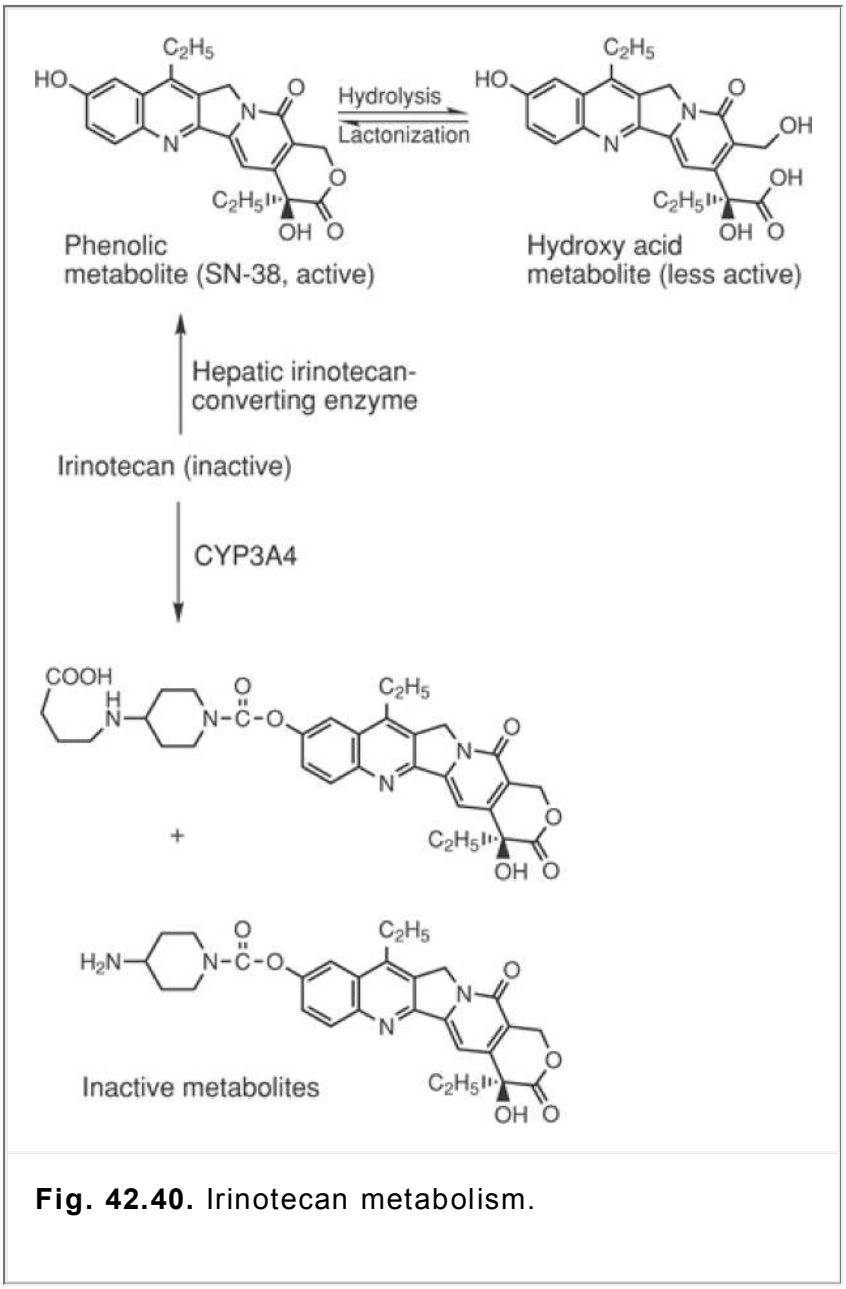

Fig. 42.40. Irinotecan metabolism.

Topotecan Hydrochloride

This active camptothecin analogue (Fig. 42.38) is used by the IV route in the treatment of ovarian and small cell lung cancer that has not responded to first-line therapy. Myelosuppression, particularly neutropenia, is use-limiting and has precluded combination therapy with other bone marrow-suppressing drugs. Thrombocytopenia and anemia occur in approximately one-third of treated patients. Schedules that call for daily (for 5 days) administration also can result in serious mucositis and diarrhea.

Topotecan elimination is biphasic, with a terminal half-life of 2.0 to 3.5 hours. Lactone hydrolysis is rapid, and binding to serum proteins is limited to between 25 and 40%. CYP3A4-mediated N-dealkylation to mono- and didealkylated metabolites occurs to a limited extent, and the O-glucuronides that form at multiple points along the metabolic path are excreted via the kidney (Fig. 42.41). Extensive renal clearance demands dosage adjustment in patients with kidney disease.

Because both topotecan and irinotecan are metabolized by CYP3A4, the potential for drug–drug interactions must be evaluated. Reduced clearance was noted when azole antifungal agents and cyclosporine were coadministered with irinotecan, and accelerated clearance

was observed when topotecan was coadministered with CYP3A4 inducers, such as phenobarbital and phenytoin.

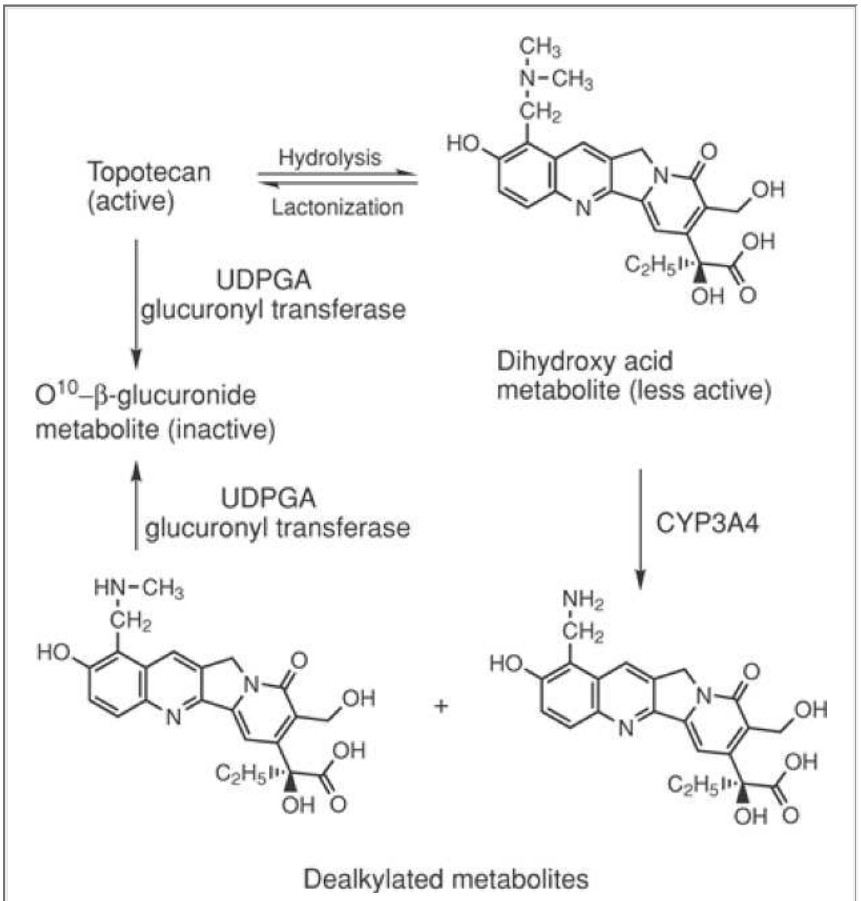

Fig. 42.41. Topotecan metabolism.

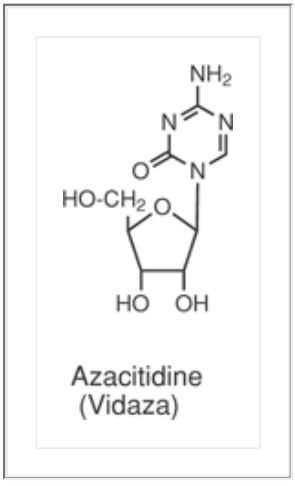
Miscellaneous Anticancer Agents: DNA Demethylators



Azacitidine

In contrast to the DNA alkylating agents discussed earlier in this chapter, one nucleic acid–based chemotherapeutic agent, azacitidine, blocks abnormal cellular proliferation by dealkylating (specifically

demethylating) DNA residues on genes responsible for differentiation and growth. The hypomethylation effect some- times can restore normal gene function while selectively killing cells that have stopped responding to the body's cellular proliferation control processes. Azacitidine is given subcutaneously for the treatment of myelodysplastic syndrome, and serum levels generally are maximized within 30 minutes. The parent drug and its metabolites are excreted in the urine. Azacitidine is carcinogenic and teratogenic in rodents, and leukopenia, thrombocytopenia, and neutropenia are the most common reasons for drug discontinuation or dosage reduction.

Other Chemotherapeutic Approaches

Hormone Therapy

Glucocorticoids (e.g., prednisone and methylprednisolone) commonly are administered with anticancer agents to suppress lymphocytic activity and to enhance the chance of success in the treatment of leukemias and lymphomas. In addition, some tumors, such as estrogen-dependent breast cancer, endometrial cancer, and metastatic cancer of the prostate, depend on the presence of sex hormones for viability. In these neoplastic diseases, the use of steroid receptor antagonists, synthesis inhibitors, or gonadotropin secretion inhibitors, either alone or in combination with other antineoplastic drugs, is a common approach to chemotherapeutic care. Antiestrogens (e.g., tamoxifen), antiandrogens (e.g., flutamide), progestins (e.g., megestrol acetate), aromatase inhibitors (e.g., exemestane), and luteinizing hormone–releasing hormone agonists (e.g., leuprolide acetate) are all available for use in managing hormone-dependent tumors and often are employed after surgery, radiation therapy, and/or other chemotherapy. (Readers are referred to Chapters 45 and 46 for a more detailed discussion of the hormone agonists and antagonists currently used in the treatment of cancer.)

Enzyme Therapy

Exogenous asparagine is essential to the survival of malignant lymphocytic leukemia cells, because these cells lack asparagine synthetase enzymes. L-Asparaginase (also known as L-asparagine amidohydrolase) or its derivatives can be added to the chemotherapeutic regimen of patients with leukemia to deplete serum asparagine by hydrolysis to aspartate and ammonia. Being deprived of this avenue for asparagine acquisition, tumor cells die from an inability to synthesize essential proteins. Normal cells, which contain asparagine synthetase, are able to synthesize this essential nutrient and can withstand therapy.

Biological Response Modifiers

Several human or recombinant antiproliferative proteins are currently in use for the treatment of cancer. Interleukin-2, interferons, BCG vaccine, tyrosine kinase, epidermal growth factor, proteasome inhibitors, and several monoclonal antibodies directed against tumor cell antigens now augment the cancer chemotherapeutic arsenal. (Readers are directed to Chapter 5 for a more in-depth discussion of the peptides and proteins available for the treatment of neoplastic disease.)

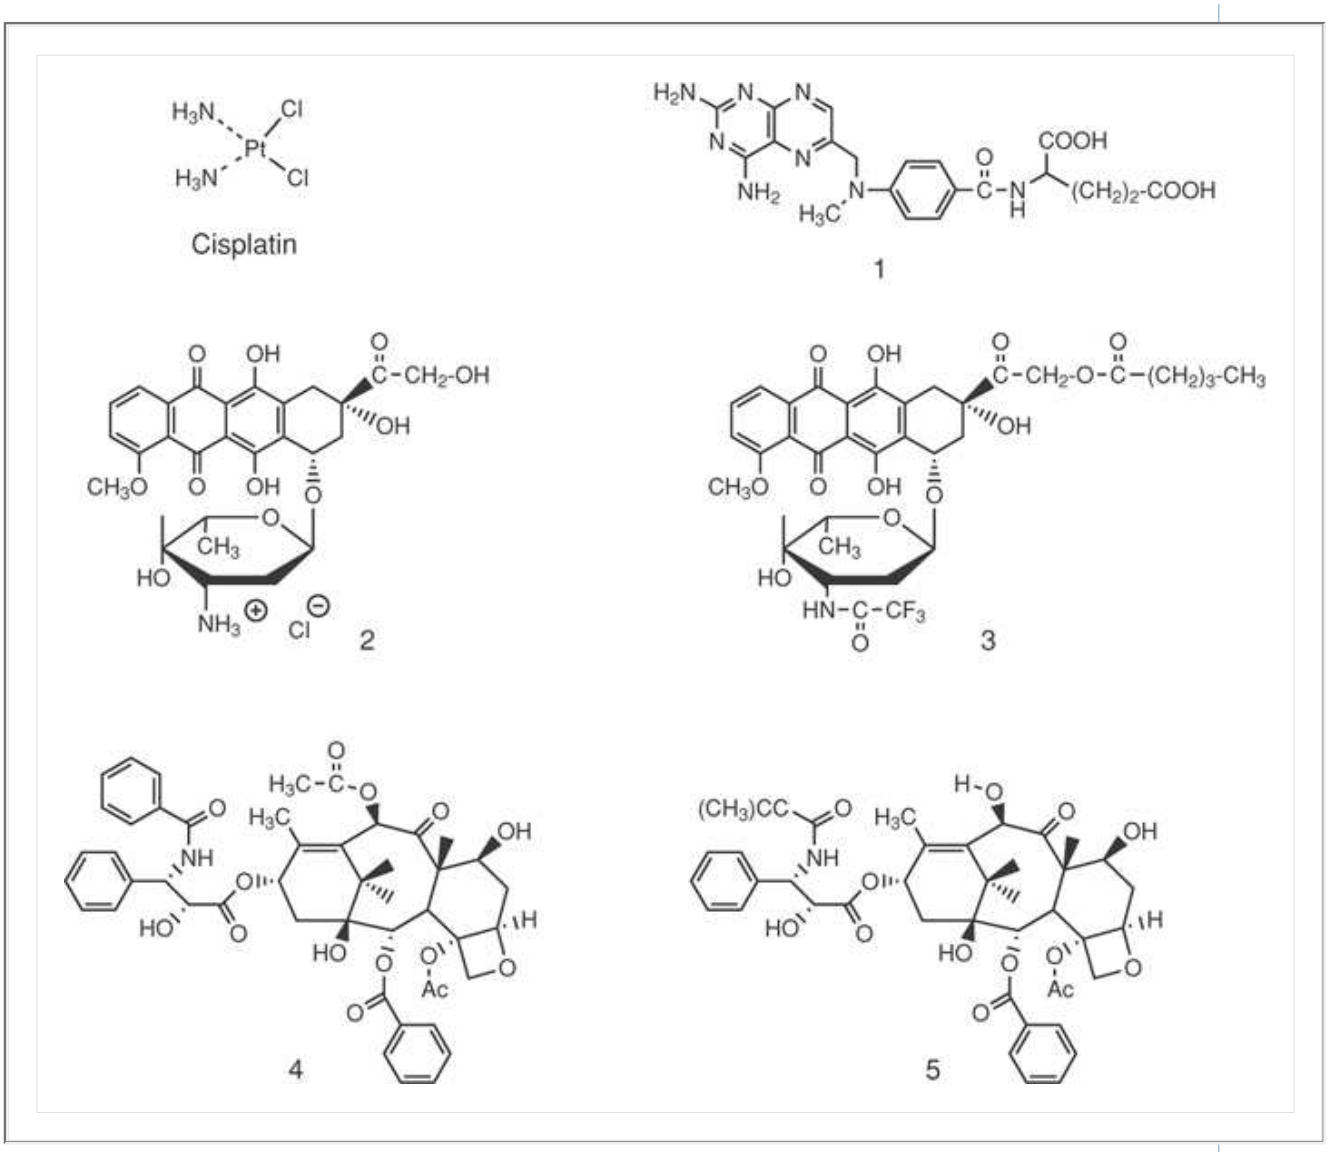
Case Study

Victoria F. Roche

S. William Zito

PR is a 37-year-old Portuguese man who survived Wilms' tumor during his childhood. Unfortunately, the chemotherapy used to treat his neoplasm induced a delayed and drug-resistant cardiomyopathy that ultimately resulted in a successful heart transplant when he was 25. Although he was managing fairly well, PR was recently dealt another health-related blow with a diagnosis of bladder cancer. The cancer was discovered last week and, although aggressive, appears to still be localized to the bladder. He is deemed not to be a candidate for surgery.

PR's current pharmacotherapy includes cyclosporine (an immunosuppressant that is metabolized predominantly by, and also inhibits, CYP3A4) and low-dose prednisone. In addition to the organoplatinum complex cisplatin, his oncologist wants to construct a chemotherapeutic regimen that combines an antimetabolite, a topoisomerase II inhibitor, and a mitosis inhibitor. Review the structure–activity relationships of the following five antineoplastic structures in preparation for your recommendation.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient, and advise the physician.

Chapter 43

Antiviral Agents and Protease Inhibitors

Patrick M. Woster

Drugs covered in this chapter:

Acyclovir

Adefovir dipivoxil

Amantadine

Cidofovir

Cytarabine

Famciclovir

Fomivirsen

Foscarnet

Ganciclovir

Idoxuridine

Interferon

Ribavirin

Rimantadine

Trifluorothymidine

Valacyclovir

Vidarabine

Neuraminidase inhibitors

- Enfuvirtide
- Oseltamivir phosphate
- Zanamivir

Antiretroviral agents

- Nucleoside reverse transcriptase inhibitors
  - Abacavir
  - Didanosine
  - Emtricitabine
  - Lamivudine
  - Stavudine
  - Tenofovir disoproxil
  - Zalcitabine
  - Zidovudine
- Nonnucleoside reverse transcriptase inhibitors
  - Delavirdine
  - Efavirenz
  - Nevirapine
- Protease inhibitors

- Amprenavir
- Atazanavir
- Fosamprenavir
- Indinavir
- Lopinavir/ritonavir
- Nelfinavir
- Ritonavir
- Saquinavir

Tipraqnavir

Introduction

Viruses are the smallest of the human infectious agents, ranging in size from approximately by 20 to 300 nm in diameter (1,2). They contain one kind of nucleic acid, either RNA or DNA, as their entire genome, which codes for a variety of enzymes and other proteins used in replication and transmission of the organism. It can be argued that a virus does not qualify as a true life form, because it is nothing more than a nucleic acid strand with associated proteins and cannot move under its own power. When it attaches itself to a host cell, however, it internalizes itself and forces the host to make additional copies of the virus, demonstrating a clear reproductive plan. During replication, it utilizes host cellular biochemicals and processes and, thus, in a sense, takes in “nutrients” to survive and multiply. In some cases, viruses respond to external conditions and escape the immune response by integrating into the host DNA, demonstrating the ability to respond to external stimuli. Although viruses are simple organisms, they are a significant causative agent for numerous human diseases and, as such, represent one of the major challenges in the area of drug discovery. Agents that are used clinically for a variety of viral diseases act by targeting processes that are specific to the virus, such as a unique viral enzyme, or a necessary process, such as transcription. To date, however, no drug has been discovered that is truly curative for viral infection. In addition, because viruses have the ability to undergo mutations, resistance to existing therapies can develop. The discovery of new antiviral agents is thus an important ongoing effort in medicinal chemistry.

Virus Structure and Classification (1,2)

Numerous species of virus that infect bacteria, plants, and animals have been identified, and they exhibit a remarkable range of diversity. All viruses exist as obligate cellular parasites, and as such, they do not need to possess the complex biochemical machinery that is characteristic of higher organisms. They do, however, have a defined macromolecular structure that is designed to protect them from the environment and to facilitate their entry into cells. The basic subunit of a virus is its genome, which can be made up of either DNA or RNA. The nucleic acid portion of a virus can be single or double stranded and may be present in linear or circular form. Viral genomic DNA or RNA often is associated with basic nucleoproteins and may be surrounded by a symmetrical protein known as a capsid. The capsid is made up of repeating structural units known as protomers, which themselves are made up of nonidentical protein subunits. The combination of the nucleic acid core and the capsid is called the nucleocapsid, and in some cases, this comprises the entire virus. In other cases, the nucleocapsid structure is surrounded by a lipid-containing membrane that is derived during viral maturation, when the virus undergoes budding through the host cell membrane. The complete viral particle, with

or without an envelope, is called the virion. Viral architecture can be grouped into three types based on the arrangement of morphologic subunits, and each virus exhibits cubic (icosahedral) symmetry, helical symmetry, or a complex structure. Icosahedral virions are symmetrical structures that contain 20 surfaces, each of which is an equilateral triangle. A sufficient number of capsid structural units must be employed in the icosahedron to make a capsid large enough to encapsulate the viral genome. Morphologic units called capsomeres are seen on the surface of icosahedral viral particles. These structures are clusters of polypeptides, but they do not necessarily correspond to the chemically defined

structural units. Some viruses arrange their structural subunits into a standard helical formation. In viruses with helical symmetry, protein subunits systematically bind to the viral nucleic acid, ultimately forming a nucleocapsid helix. The filamentous nucleocapsid is then coiled inside a lipid-containing envelope. Unlike icosahedral virions, the regular, periodic interaction between capsid protein and viral nucleic acid prevents the formation of "empty" helical particles. Finally, some viral particles, such as the large and complex poxviruses, do not exhibit cubic or helical symmetry but, instead, form more complicated structures that can be spherical, brick-shaped, or ovoid. A subset of complex viruses are called pleomorphic viruses, in that they assume multiple, complex morphologies.

Clinical Significance

Antiviral agents include diverse compounds with varied actions. A thorough clinical understanding about most of these compounds is dependent on a basic appreciation of biochemistry and medicinal chemistry. Viruses are mainly composed of either RNA or DNA nucleic acid strands. As such, one of the most ideal targets for treating viral pathogens has been the inhibition of viral replication. Successful viral replication is dependent on enzyme-mediated transcription of viral RNA or DNA. A significant number of antiviral agents, including HIV nucleoside reverse transcriptase inhibitors and a majority of antiherpes agents, are designed to be "false" substrates of viral transcription enzymes. It is through competitive inhibition that these agents are able to fulfill their intended effect. Their chemical structures are similar to naturally occurring substrate nucleoside purines (adenosine and guanosine) and pyrimidines (thymidine and cytidine). Their incorporation, however, will lead to termination of replication. These nucleoside antiviral agents typically require triphosphorylation to become active intracellularly. It is important to recognize that resistance to these antiviral medications can develop when genetic mutations alter the ability of viral enzymes to phosphorylate the drugs. Drugs like cidofovir and tenofovir are nucleotide analogues, which means they are already monophosphorylated. As a result, these agents can maintain activity against viruses that have developed resistance to other nucleoside agents through certain resistant mutations.

In clinical practice, HIV antiretroviral regimens usually require a pair of nucleoside reverse transcriptase inhibitors in the regimen. It is of paramount importance that combinations of "like" nucleosides analogues (i.e., two thymidines, two cytosines, etc.) are not used together, because they have displayed antagonism and reduced viral load suppression. Nonnucleoside reverse transcriptase inhibitors are not structurally related to nucleic purines and pyrimidines; therefore, they do not act as substrates of the target enzyme.

Protease inhibitors, which are the most potent antiretroviral agents currently available, were the end result of coordinated chemical design and structure-based computational analysis of the protease enzyme. With identification of the protease crystalline structure and identification of active binding sites, scientists were able to create compounds that would fit the protease enzyme with strong affinity and cause an inhibition of protease function. The clinical impact of these man-made drugs is regarded by many as being the greatest single advance in the treatment of HIV infection.

Viral taxonomy is complex, and viruses are classified according to a number of factors, including morphology, properties of the genome (i.e., DNA versus RNA, single strand versus double strand, linear or circular, and sense or antisense), physicochemical properties, structure of associated proteins, replication strategy, and so on. Viruses are separated into major groups called families, with names that end in the suffix -viridae, and then into genera that end in -virus. Thus, poxviruses are in the family Poxviridae and in the genus *Poxvirus*. A comparison of the genetic and structural features of viral families with members that can infect humans appears in Table 43.1.

Viral Replication, Cellular effects, and Pathogenesis (2,3)

As mentioned above, all viruses exist as obligate intracellular parasites, and as such, they rely on the cellular machinery of the host for their growth, development, and replication. To synthesize the proteins needed for viral replication, the organism must be capable of producing usable mRNA in sufficient quantities to compete with host mRNA for protein synthesis. During viral replication, all of the macromolecules required by the virus are synthesized in a highly organized sequence. The replication cycle (Fig. 43.1) begins when the intact virion binds to a host cell through electrostatic adsorption to a specific "receptor"

P.1195

P.1196

site. This process is known as the attachment phase. Attachment is most likely a fortuitous event resulting from structural complementarity between the exterior structure of the virion and a normal cell surface structure on the host cell. For example, HIV binds to the CD4 receptor on cells of the immune system, rhinoviruses bind ICAM-1, and Epstein-Barr virus (EBV) recognizes the CD21 receptor on B cells. When attachment has been achieved, the virion enters the penetration phase, the process by which it gains entry into the host cell. Penetration may occur by receptor-mediated endocytosis, fusion of the viral envelope with the cell membrane, or in some cases, direct penetration of the membrane. Following penetration of the cell, viruses must be uncoated, resulting in either the naked nucleic acid or the nucleocapsid form, which usually contains polymerase enzymes. After they have been uncoated, viruses are no longer infectious.

Table 43.1. Characteristics of Virus Families Containing Membe

Family	Examples	Genome	Capsid Symmetry	Size (nr
Parvoviridae	Parvovirus B19	ssDNA, sense or antisense	Icosa	18–26
Papillomaviridae	Human papilloma (wart)virus; polyoma virus; SV 40	dsDNA, circular DNA	Icosa	55
Adenoviridae	Multiple types (40 adenoviruses/mastadenovirus)	dsDNA	Icosa	70–90
Hepadnaviridae	Hepadnavirus, hepatitis B virus	dsDNA, circular, one ss region	Icosa	40–48
Herpesviridae	Herpes simplex I and II; varicella-zoster; herpes zoster; cytomegalovirus; Epstein-Barr virus	dsDNA	Icosa	150–2

Poxviridae	Variola; vaccinia	dsDNA	Comp	230–4
Picornaviridae	Hepatitis A virus; poliovirus; enterovirus; rhinovirus, coxsackie virus A and B	ssRNA, sense	Icosa	28–30
Astroviridae	Astrovirus	ssRNA, sense	Icosa	28–30
Caliciviridae	Norwalk virus	ssRNA, sense	Icosa	27–40
Togaviridae	Rubella virus; alphavirus, arbovirus	ssRNA, sense	Icosa	50–70
Flaviviridae	Hepatitis C virus; arbovirus; yellow fever virus; dengue virus; West Nile virus	ssRNA, sense	Comp	40–60
Coronaviridae	Coronavirus	ssRNA, sense	Comp	120–1
Retroviridae	HIV-I and -II; lentavirus; human T-cell lymphotropic viruses	ssRNA as dimer	Comp	80–10
Arenaviridae	Arenavirus	ssRNA, antisense	Comp	50–30
Orthomyxoviridae	Influenza virus A, B, and C	ss RNA, antisense	Hel	80–12
Bunyaviridae	Hantavirus	ssRNA, antisense	Hel	80–12

Rhabdoviridae	Rhabdovirus; rabies virus; encephalitis virus	ssRNA, antisense	Hel	75–18
Paramyxoviridae	Syncytial virus; parainfluenza virus	ssRNA, antisense	Hel	150–3
Filoviridae	Marburg virus; Ebola virus	ssRNA, antisense	Hel	80–80
Reoviridae	Rheovirus; rotavirus; orbivirus	dsRNA, in 10–12 pieces	Icosa	60–80
Prion	Prion proteinaceous material	None	NA	NA

ds, double-stranded; ss, single-stranded; Icos, icosahedral; Comp, complex; Hel, heli

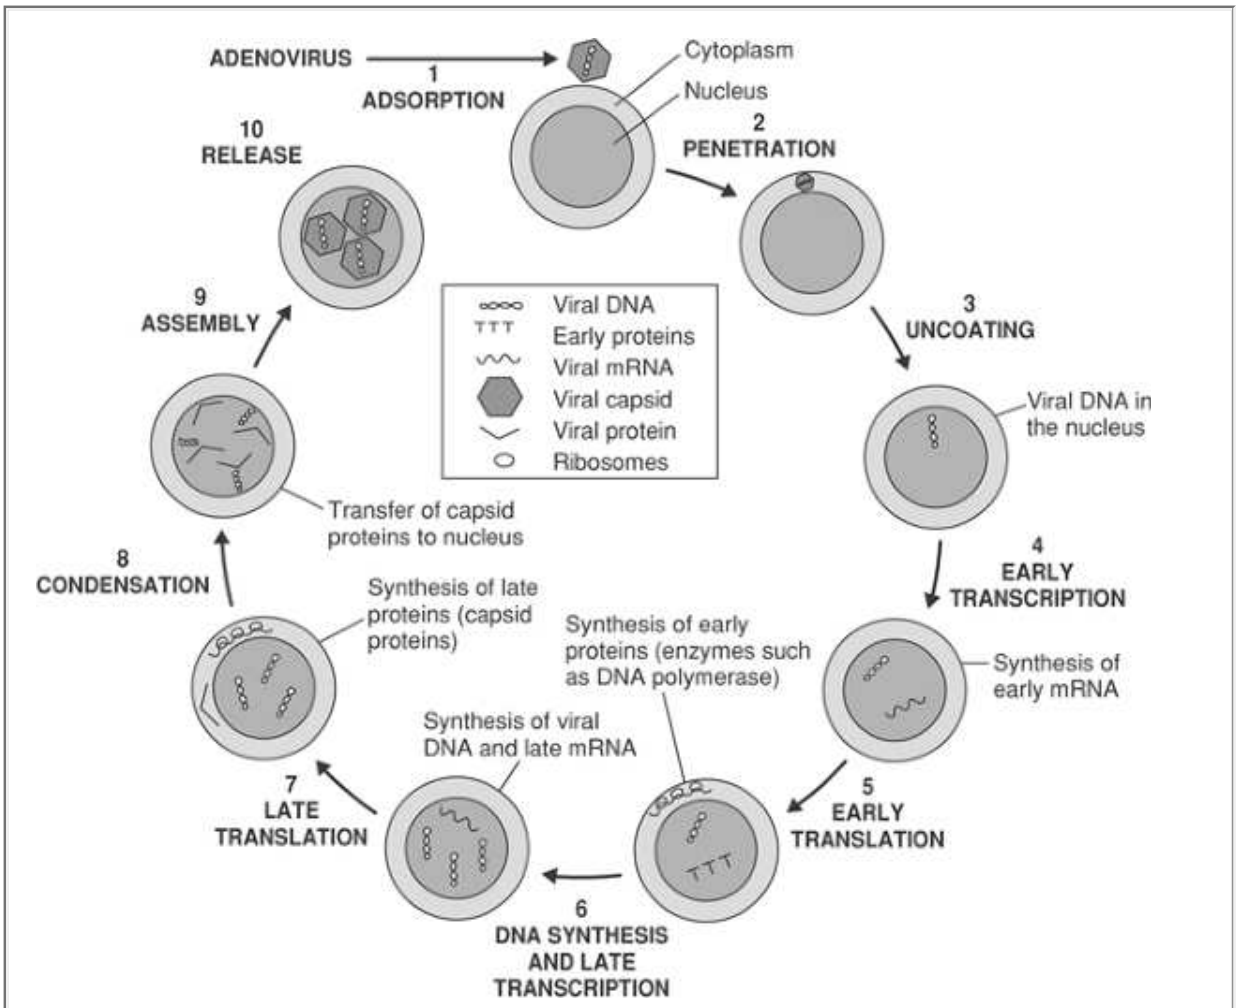

Fig. 43.1. Steps involved in the viral life cycle. (Adapted from Brooks GF, Butel JS, Morse SA, et al. Jawetz, Melnick, and Adelberg's Medical Microbiology. 23rd Ed. New York: McGraw-Hill, 2004; with permission. Copyright 2004 The McGraw-Hill Companies, Inc.)

Once the virus has penetrated the cell and uncoated, it enters a segment of its life cycle known as the eclipse period, the length of which varies with the type of virus. During this time, the virus utilizes host resources to replicate and produce necessary viral proteins. Cells that can support viral reproduction are called permissive. As a result, the infection is known as a productive infection, because it results in new viral particles. When new infectious viral particles are produced, host cellular metabolism may be completely directed toward the production of viral products, resulting in destruction of the cell. In other cases, host cell metabolism is not dramatically altered, and the infected cell can survive. During viral reproduction, up to 100,000 new virions can be produced, and the replication cycle can vary from a few hours to more than 3 days. Some cells types, called nonpermissive, are unable to support the reproduction of an infective virion, resulting in an abortive infection. Abortive infections also occur when the virus itself is defective. Either situation can lead to a latent infection, where the viral genome may persist in a surviving host cell. As will be described below, such an infection can lead to the transformation of a cell from normal to malignant.

DNA Virus

The strategies used by various viruses to replicate vary widely, but all are characterized by the need to transcribe mRNA that is suitable for translation of viral proteins. Several pathways lead to the required

mRNA, after which the host enzymes and raw materials are used to make viral proteins. Early viral proteins used in replication are synthesized immediately after infection, whereas late proteins used to produce the complete virion structure are synthesized after viral nucleic acid synthesis. Most DNA viruses contain double-stranded DNA as their genome and, thus, can replicate using host cell machinery to

produce mRNA directly. Papillomavirus, adenovirus, and herpesvirus are replicated in the host nucleus and, thus, use transcriptional enzymes of the host (i.e., DNA-dependent RNA polymerase) to synthesize mRNA. This mRNA is then translated to form proteins needed by the virus, including enzymes (e.g., DNA-dependent DNA polymerase) used to produce progeny DNA copies. These progeny DNA strands are infectious. By contrast, poxviruses replicate in the cytoplasm using a mechanism that is not well understood, wherein the genome initially is transcribed by a viral enzyme in the virion core. Parvoviruses contain a single-stranded DNA genome and must synthesize double-stranded DNA in the host nucleus before synthesis of mRNA and translation of proteins. This process may or may not require a helper virus, such as herpes simplex. The hepatitis B viral genome, comprised of double-stranded DNA, contains numerous gaps that must be repaired using a DNA polymerase packaged in the virion before transcription to form mRNA.

RNA Virus

Compared to DNA viruses, those viruses with RNA-based genomes have evolved a wide variety of reproductive strategies. The single-stranded RNA viruses may be divided into three groups that differ in the method by which the RNA genome is utilized. In all three groups, the RNA genome must serve two functions: to be translated to form protein, and to be replicated to form progeny RNA strands. The first group is comprised of viruses such as picornaviruses, flaviviruses, and togaviruses that have an RNA genome that can be used directly as mRNA. Viral RNA that can be used as mRNA is by convention termed (+) or sense-strand RNA. In most cases (e.g. picornaviruses), this sense-strand RNA binds to the host ribosome shortly after entering the cell, where it is read and used to produce a single polypeptide called the polyprotein. The polyprotein is then processed by autocatalysis and various proteolytic enzymes to produce the required viral proteins. In some cases (e.g. togaviruses), only a portion of the RNA genome is available to be translated by the host ribosome. Following the initial translation of the sense strand, it serves a second function—namely, to serve as a template for the synthesis of a (–) or antisense strand via an RNA-dependent RNA polymerase. This antisense strand then can be used to produce additional sense-strand RNAs that are infectious and also can serve as mRNA. These progeny sense-strand RNAs are then packaged into an intact virion before transmission to another host cell.

The second group of single-stranded RNA viruses, including orthomyxoviruses, bunyaviruses, arenaviruses, paramyxoviruses, filoviruses, and rhabdoviruses, all contain an antisense RNA genome that can be used only for transcription of new RNA. All antisense RNA viruses contain an RNA transcriptase as part of their virion, because the host cell does not have this type of RNA-dependent RNA polymerase. During the first round of genome expression, a series of short sense-strand RNAs are made, which are then translated to form the required viral enzymes for replication. Ultimately, these enzymes are used to produce a full-length sense RNA strand, which is then used to make multiple copies of the antisense viral genome. The progeny antisense DNA strands by themselves are not infectious, because they have not yet been packaged with the required RNA transcriptase. When the progeny antisense RNA has been synthesized, it is packaged into an intact virion, in which form it becomes infectious before transmission to another cell.

The third group of RNA viruses are the retroviruses, in which single-stranded RNA exists as a dimer of a sense and an antisense strand. The genomic RNA strands can be base-paired, although the structure of this complex is not well understood, or the strands can be hydrogen-bonded to other macromolecules in the virion. Retroviral genomic RNA serves a single function—namely, to act as a template for the formation of double-stranded viral DNA. Host cells do not contain an enzyme that can form DNA from viral RNA; thus, the virion of a retrovirus must contain a reverse transcriptase (RT) enzyme as well as various host tRNA molecules. Transcription of the genome begins when a complex of RT and tRNA binds to the viral genome. A complimentary DNA strand is then synthesized using one of the host tRNAs as a primer, and the original RNA strand is digested by RNAse H and viral ribonuclease packaged in the virion. A

complimentary DNA strand is then synthesized, and the resulting double-stranded DNA is translocated to the nucleus, where viral enzymes incorporate genome-length viral DNA into the host genome. In some cases, the viral portion of the genome can remain dormant for long periods, or it may be immediately used to make progeny viral RNA, a process that is catalyzed by host RNA polymerase II. Transcription produces both shortened segments that are used to make polyproteins and full-length progeny RNA. The polyproteins are processed to form various viral proteins, whereas the full length RNA is packaged into an infectious virion.

Virus Protein

In addition to replication of the viral genome, a number of other structures associated with the complete virion also can be made. A number of viral proteins may be synthesized that have important functions in the structure, transmission, and survival of the virus. These proteins can protect the genetic material in the virus from destruction by nucleases, participate in the attachment process, and provide structure and symmetry to the virion. In addition, in certain cases where the virus requires an enzymatic process for which there is no host enzyme, a virion may include enzymes, such as RNA polymerases or a RT. Some viruses require a lipid envelope that contains transmembrane proteins specifically coded for by the virus and which envelopes the genetic material

during viral budding. Viral envelopes contain glycoproteins that are involved in cell recognition during attachment to the host cell. These glycoproteins often reflect the composition of glycoproteins in the host cell. They are a determinant of the antigenic nature of viruses and, thus, facilitate recognition by the immune system of the host. Depending on their composition, however, they also can help the virus to elude neutralization by the immune system.

Cellular Egress

Viruses use one of two strategies for exiting infected cells. Nonenveloped viruses (e.g., picornaviruses and rheoviruses) complete their maturation by assembling into their corresponding virion within the cell nucleus or the cytoplasm. For example, picornaviruses assemble by clustering 60 copies of each of three viral proteins, called VP0, VP1, and VP3, into a structure called a procapsid. Viral RNA is then packaged into the procapsid, and proteolytic cleavage of VP0 produces two new viral proteins, called VP2 and VP4. The resulting conformational change produces a stable and symmetrical structure that shields the genome from degradation by host nucleases. In most cases, destruction of the host cell is required when the virion exits. Enveloped viruses (i.e., all antisense RNA viruses, togaviruses, flaviviruses, coronaviruses, hepadnaviruses, herpesviruses, and retroviruses) contain proteins that carry signal sequences and markers that cause them to be inserted into the inner and outer surfaces of the host cell cytoplasmic membrane. Viral proteins on the outer surface are glycosylated using host enzymes, then displace host cell surface proteins and collect into patches. Viral nucleocapsids that recognize proteins on the inner surface of the membrane, where they bind, are engulfed by the patch area of the membrane. The completed virion exits the cell by budding and release into the extracellular space. Viral egress can have a variety of effects on the host cell, ranging from destruction of the cell to minimal noncytolytic effects. Herpesviruses differ from other enveloped viruses in the manner in which they form their envelope. The nucleocapsid is formed in the nucleus, and final maturation of the virion occurs only on the inner surface of the host cell membrane, forming vesicles that are stored in between the inner and outer aspect of the cell membrane. Egress of the herpesvirus vesicle always occurs through destruction of the host cell.

Virus Pathogenesis

A complete discussion of viral pathogenesis is beyond the scope of this chapter. In general, however, the symptoms of a viral infection may be considered to arise from the response to viral replication and cell injury in the host. These responses range from asymptomatic or subclinical to severe clinical manifestations, and they may be either local or systemic. Understanding the biochemical events that produce viral diseases can aid in the design of effective and specific therapies. Not surprisingly, viral pathogenesis occurs in distinct steps: 1) viral entry into the host and primary viral replication, 2) viral spread, 3) cellular injury and host immune response, 4) viral clearance or establishment of persistent

infection, 5) and viral shedding. Most viruses enter the host through the respiratory or gastrointestinal (GI) tract, but they also may penetrate the skin, urogenital tract, or conjunctiva. In a few cases, viral particles can enter through direct injection (e.g., HIV and hepatitis) or through insect bites (arboviruses). When a local infection occurs, the virus replicates near the site of entry, and the underlying tissue is not affected. Some viruses, however, are able to migrate to other sites, usually through the bloodstream or lymphatic system, to produce systemic infections. When infection occurs at a remote site, most viruses demonstrate tissue or organ preference (e.g. herpesvirus localizes in nerve ganglia, and the rabies virus migrates to the central nervous system [CNS]). Localization of a virus in a particular tissue can be the result of cell receptor specificity or can arise because a virus may be activated by proteolytic enzymes in a specific cell type.

Clinical disease develops through a complex series of events when virus-infected cells are destroyed or their function is impaired, and some symptoms, such as malaise and anorexia, can result from host responses, such as cytokine release. Disease-mediated damage may become chronic when cell types that do not regenerate (e.g., brain tissue) are involved. Ultimately, the host either succumbs to the infection; develops a chronic, latent, or subclinical infection; or completely recovers. In chronic infections, the virus can be continuously detected at low levels, and either mild or no clinical symptoms may present. By contrast, latent infections are those in which the virus persists for extended periods of time in an inactive form or a location not exposed to the immune response. Intermittent flare-ups of clinical disease can occur, during which time infectious virus can be detected. Subclinical infections are those that give no overt sign of their presence. Humoral and cell-mediated immunity, interferon and other cytokines, and other host defense factors, depending on the type of virus, are common mediators of recovery and begin to develop very soon after infection. Infiltration with mononuclear cells and lymphocytes is responsible for the inflammatory reaction in uncomplicated viral lesions. Virus-infected cells can be lysed by T lymphocytes through recognition of viral polypeptides on the cell surface, and humoral immunity protects the host against reinfection by the same virus. Neutralizing antibodies that are directed against capsid proteins can prevent viral infection by disrupting viral attachment or uncoating. Interestingly, viruses have evolved a variety of survival tactics that serve to suppress or evade the host immune response. Because viruses are obligate intracellular parasites, a method of transmission from one host to another is required for survival of the species. Thus, during an active infection, shedding of the infectious virion into the environment is

a required step in the life cycle of the virus and ensures transmission of the virus to new hosts. Shedding usually occurs at the same site where the infection was initiated and can occur at various stages in the disease course.

Viral Diseases

HIV (4,5)

The human immunodeficiency virus (HIV-1) was first identified in 1979 and was found to be the cause of acquired immune deficiency syndrome (AIDS) in 1981. Since that time, AIDS had become a serious worldwide epidemic that continues to expand. The Joint United Nations Program on HIV/AIDS estimated that by the end of 2005, a total of 40.3 million people worldwide were living with HIV/AIDS, the majority having been infected through heterosexual contact. It is estimated that in 2005, more than 3.1 million people died of AIDS, and 4.9 million new cases of HIV were diagnosed, including more than 700,000 children (6). The incidence of the disease varies by location, with sub-Saharan Africa having the highest incidence. Because it is sexually transmitted, a high percentage of infected individuals are young adult workers, and as such, the disease has a significant economic impact in some regions. In addition, infected mother-to-fetus transmission occurs between 13 and 40% of the time. Although a variety of drugs have been developed for treating patients with AIDS, none has proven to be successful in curing the disease. The basic difficulty experienced with this viral infection is the ability of virus to mutate, leading to rapid drug resistance.

The HIV-1 genome consists of two identical, 9.2-kb, single-stranded RNA molecules within the virion, each of which contains information for only nine genes. Following infection of the host cell, the persistent form of the HIV-1 genome is proviral double-stranded DNA. Mature HIV virions are spherical and consist

of a lipid bilayer membrane surrounding a nucleocapsid that contains genomic RNA, a viral protease, RT, an integrase, and some other cellular factors. The HIV life cycle is depicted in Figure 43.2, and begins when the viral extracellular protein gp120 attaches to the CD4 receptor on T lymphocytes. Following attachment, the viral envelope and host cell membrane are fused, and the nucleocapsid is released into the cytoplasm. The nucleocapsid is uncoated, and the resulting RNA serves as a substrate for RT, producing a proviral double-stranded DNA that migrates to the nucleus and is incorporated into host DNA by integrase. This DNA is not expressed in resting T lymphocytes, but when the cell is activated, proviral DNA is transcribed by host RNA polymerase II. The viral RNA and proteins are transported to the cell membrane, where they assemble, form a viral bud, and are released from the lymphocyte membrane. This produces an immature virion, and processing of the viral surface proteins by HIV protease then affords the mature, infectious virus. Approximately 50% of HIV infections are asymptomatic, whereas the other 50% produce flu-like symptoms within 4 weeks. During this initial phase, viral titers are very high but then decline as specific antibodies are formed. The latent period is mediated by factors that are not well understood and can last several years. During this time, viral replication continues, and the level of CD4-positive T lymphocytes steadily declines. Eventually, the patient's immune system becomes compromised, resulting in a variety of opportunistic infections. RT sometimes makes mistakes reading the viral RNA sequence, leading to mutations in the virus and changes in the structure of the surface proteins. Thus, vaccines, which induce the production of antibodies that recognize and bind to very specific viral surface molecules, are

unlikely to be effective in HIV therapy. As will be discussed below, other viral processes, such as reverse transcription and proteolytic processing, are viable targets for small molecule therapy.

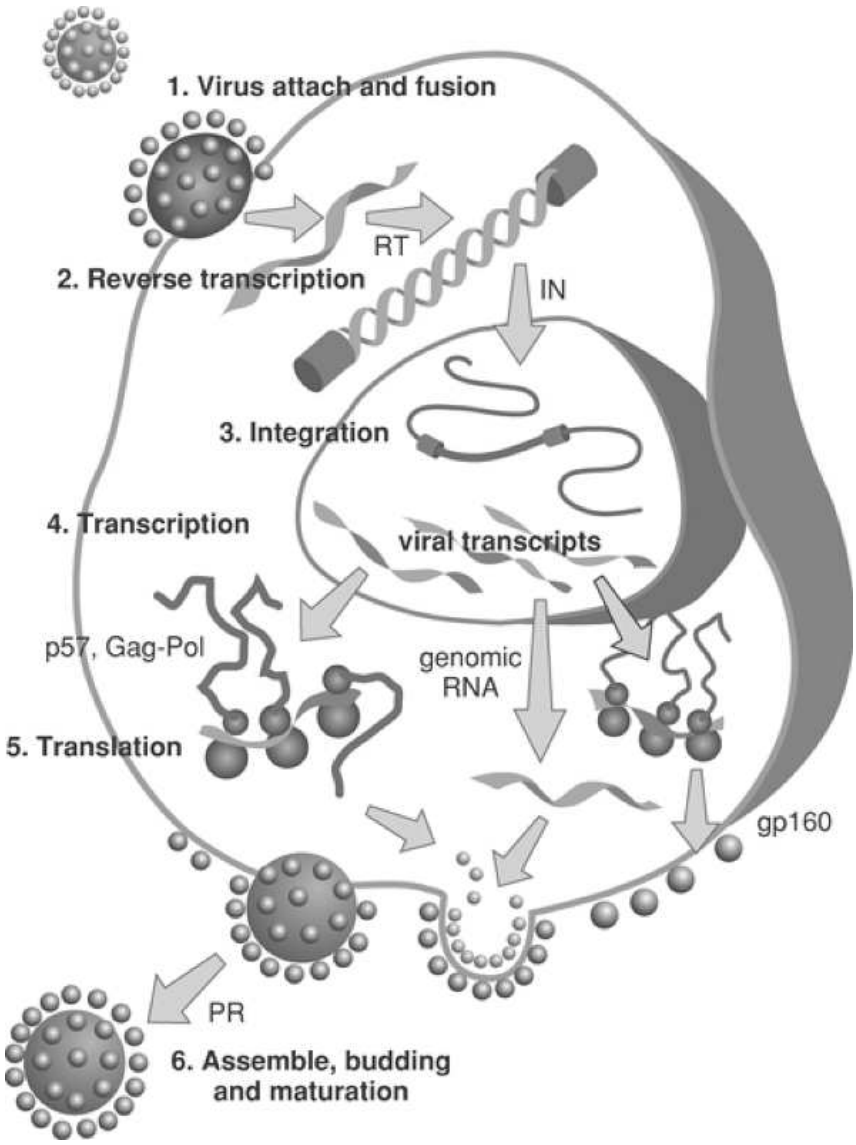

Fig. 43.2. Replicative cycle of HIV. (1) The virus gp120 protein binds to CD4 resulting in fusion of the viral envelope and the cellular membrane and the release of viral nucleocapsid into the cytoplasm. (2) The nucleocapsid is uncoated, and viral RNA is reverse transcribed by reverse transcriptase (RT). (3) The resulting double-stranded proviral DNA migrates into the cell nucleus and is integrated into the cellular DNA by integrase (IN). (4) Proviral DNA is transcribed by the cellular RNA polymerase II. (5) The mRNAs are translated by the cellular polysomes. (6) Viral proteins and genomic RNA are transported to the cellular membrane and assemble. Immature virions are released, and polypeptide precursors are processed by the viral protease (PR) to produce mature vital particles. (Adapted from Sierra S, Kupfer B, Kaiser R. Basics of the virology of HIV-1 and its replication. J Clin Virol 2005;34:233; with permission from Elsevier.)

Kaposi's sarcoma is a common complication of AIDS and has been shown to arise from a complex interaction between HIV and the human herpesvirus (HHV)-8. This disease presents as a reddish or purple lesion on various areas of the skin and, in the advanced state, may involve the lungs or GI tract.

HHV-8 does not work alone but, rather, in combination with a patient's altered response to cytokines and the HIV-1 transactivating protein Tat, which promotes the growth of endothelial cells. HHV-8 can then encode interleukin-6 viral proteins, which are specific cytokines that stimulate cell growth in the skin. HHV-8 further destroys the immune system by directing a cell to remove the major histocompatibility complex (MHC-1) proteins that protect it from invasion. These proteins are then transferred to the interior of the cell and are destroyed, leaving the cell unguarded and vulnerable to pathogens that normally would be cleared by the immune system. It recently has been discovered that xCT, the 12-transmembrane light chain of the human cystine/glutamate exchange transporter system, serves as a receptor for internalization of HHV-8 (7).

Herpesvirus (2)

The herpesvirus family contains several of the most important human pathogens and are responsible for causing a spectrum of common diseases. A common and significant feature of the herpesviruses is their ability to establish lifelong, persistent infections in their hosts and to undergo periodic reactivation. Herpesviruses possess a large number of genes, and some of the resulting proteins are targets for antiviral chemotherapy. The herpesviruses that commonly infect humans include herpes simplex virus (HSV)-1 and -2, varicella-zoster virus (VZV), cytomegalovirus (CMV), EBV, HHV-6 and -7, and Kaposi's sarcoma–associated HHV-8 (also known as KSHV). Herpesviruses are large viruses that have identical morphology and consist of a core of linear, double-stranded DNA surrounded by a protein coat that exhibits icosahedral symmetry and has 162 capsomeres. The genome is large and encodes at least 100 different proteins, including polypeptides involved in viral structure, the viral envelope, and enzymes involved in nucleic acid metabolism, DNA synthesis, and protein regulation. Oral cold sores and genital herpes infections are caused by HSV-1 and -2, respectively. These viruses can establish a latent infection in the ganglia of nerves that supply the site of the primary infection, and the latent disease is reactivated by a number of stress factors. It is estimated that virtually 100% of adult humans are infected with HSV-1, although many infections are subclinical and asymptomatic. The varicella virus is the cause of chickenpox, and the herpes zoster virus is responsible for shingles. Human CMV infection rarely causes disease in healthy people, but when infection occurs in adulthood, it may cause an infectious mononucleosis–like illness. Primary infection with the EBV is the cause of infectious mononucleosis, and this virus is thought to be a factor in the development of Burkitt's lymphoma and other malignancies. Human herpesvirus-6 is thought to cause roseola and mononucleosis, whereas HHV-7 probably is not involved in any human diseases. The role of HHV-8 in the pathogenesis of Kaposi's sarcoma has been discussed above.

Hepatitis (2)

Viral hepatitis is a systemic disease but primarily involves the liver. Hepatitis A virus (HAV) is responsible for infectious hepatitis, and hepatitis B virus (HBV) is associated with serum hepatitis. Hepatitis C virus (HCV) is a common cause of posttransfusion hepatitis. Another viral agent, hepatitis E virus (HEV), causes an enterically transmitted form of hepatitis. On occasion, disease can arise from hepatic infection with yellow fever virus, CMV, EBV, HSV, rubella virus, and the enteroviruses. Viral hepatitis usually involves acute inflammation of the liver, fever, nausea, vomiting, and jaundice, and all forms of hepatitis produce identical histopathologic lesions in the liver during acute disease. HAV is a member of the picornavirus family and carries a single-stranded RNA genome; only one strain of the virus exists. The onset of HAV hepatitis occurs within 24 hours, in contrast to the slower onset of clinical symptoms with HBV and HCV infection. Complete recovery occurs in most cases of hepatitis A, and chronic infection never occurs. HBV is classified as a hepadnavirus with a double-stranded, circular DNA genome. The outcome of HBV infection ranges from complete recovery to progression to chronic hepatitis and, rarely, death. HBV establishes chronic infections, especially in infants; 80 to 95% of infants and young children infected with HBV become chronic carriers and are at high risk of developing hepatocellular carcinoma. In adults, 65 to 80% of infections are asymptomatic, and 90 to 95% of all patients recover completely. HCV is a positive-stranded RNA flavivirus and exists in at least six major genotypes. Most cases of posttransfusion hepatitis are caused by HCV, and these infections usually are subclinical, with minor elevation of liver enzymes and a low incidence of jaundice. However, 70 to 90% of HCV-infected patients develop chronic hepatitis, and many are at risk of progressing to chronic active hepatitis and cirrhosis decades later. HEV is transmitted enterically and occurs in epidemic form in developing countries, where

water supplies sometimes are contaminated with feces. The disease is more severe in adults than in children, who usually are asymptomatic.

Influenza (2)

Respiratory illnesses commonly known as colds and flu account for more than half of all acute illnesses in the United States each year. Influenza viruses belong to the orthomyxoviridae family and are a major source of

morbidity and mortality caused by respiratory disease. Outbreaks of infection can occur in global epidemics that have resulted in millions of deaths worldwide. Genetic mutations often cause antigenic changes in the structure of viral surface glycoproteins, making influenza viruses extremely difficult to control. Three immunologic types of influenza viruses are known and are termed influenza A, B, and C. Antigenic changes are very common in influenza A, which is responsible for the majority of influenza epidemics. Influenza B undergoes more infrequent antigenic changes and is less often the cause of an influenza epidemic, whereas influenza C are antigenically stable and cause only mild illness in immunocompetent individuals. The viruses carry a single-stranded, negative-sense RNA genome that has eight segments in influenza A and B. Influenza C contains only seven segments of RNA and lack a neuraminidase gene (see below). The complete virion in each type contains nine different structural proteins. A nucleoprotein associates with viral RNA to form a ribonucleoprotein structure that makes up the viral nucleocapsid. Three other large proteins are bound to the viral ribonuclear protein and are responsible for RNA transcription and replication. A matrix protein also is included in the virion that forms a shell underneath the viral lipid envelope and comprises approximately 40% of all viral protein.

The influenza virion structure also includes a lipid envelope derived from the host cell. This envelope contains two viral surface glycoproteins called hemagglutinin and neuraminidase (NA). Mutations cause antigenic changes in the structure of these two surface glycoproteins; thus, they are the main determinants of antigenicity and host immunity. The ability of the virus to change the structure of hemagglutinin on the virus surface primarily is responsible for the continual evolution of new strains, sometimes leading to subsequent influenza epidemics. Neuraminidase is an enzyme that removes sialic acid from surface glycoproteins during viral maturation and is required to produce infectious particles and lower the viscosity of the mucin layer of the respiratory tract. Influenza virus spreads through airborne droplets or contact with contaminated hands or surfaces and has an incubation period that varies from 1 to 4 days. Transmission of the virus, however, begins to occur 24 hours before to the onset of symptoms. Interferon is detectable in respiratory secretions at the onset of symptoms, and the host response to interferon response contributes to recovery. Antibodies and other cell-mediated responses are seen 1 to 2 weeks after infection. It is well established that secondary infections from other viruses or bacteria can occur, and Reye's syndrome, an acute encephalopathy occurring in children and adolescents, is a rare complication of influenza B, influenza A, herpesvirus, and VZV infections. The chances of contracting Reye's syndrome are increased when salicylates are used in children suffering from influenza and related respiratory diseases.

Tumor Viruses (2,8,9,10,11,12)

Viruses are etiologic factors in the development of several types of human tumors, most notably cervical cancer and liver cancer. At least 15% of all human tumors worldwide have a viral cause. Tumor viruses can be found in both the RNA and DNA virus kingdoms (13). The list of human viruses presently known to be involved in tumor development includes four DNA viruses (EBV, certain papilloma viruses, HBV, and the Kaposi's sarcoma–associated HHV-8), and two RNA viruses (adult T-cell leukemia virus [HTLV-1] and HCV). Tumor viruses alter cellular behavior through the use of a small amount of genetic information, employing two general strategies. The tumor virus either introduces a new “transforming gene” into the cell (direct- acting), or the virus alters the expression of a preexisting cellular gene or genes (indirect-acting). In both cases, normal regulation of cellular growth processes is lost. Viruses alone cannot act as carcinogens, and other events are necessary to disable regulatory pathways and checkpoints to produce transformed, malignant cells. The processes used in the transformation of host cells by human tumor viruses are very diverse.

Cellular transformation may be defined as a stable, heritable change in the growth control of cells that

results in tumor formation. Transformation from a normal to a neoplastic cell generally requires the retention of viral genes in the host cell. In the majority of cases, this is accomplished by the integration of certain viral genes into the host cell genome. Retroviruses incorporate their proviral DNA, formed through the action of RT, into host cell DNA. By contrast, DNA tumor viruses integrate a portion of the DNA of the viral genome into the host cell chromosome.

All RNA tumor viruses are members of the retrovirus family and belong to one of two classes (9,10,12). Class I RNA viruses are direct-transforming and carry an oncogene obtained through accidental incorporation from the host cell. No class I RNA viruses are known to produce tumors in humans. Class II or chronic RNA tumor viruses are weakly transforming and do not carry host cell–derived oncogenes. The two known cancer-causing retroviruses in humans act indirectly. They often act by inserting their proviral DNA into the immediate neighborhood of a host cellular oncogene. HTLV-1 acts in this manner, thus increasing the number of preneoplastic cells and facilitating secondary cellular changes leading to transformation.

DNA tumor virus strains exist among the papilloma-, polyoma-, adeno-, herpes-, hepadna-, and poxvirus groups (11). DNA tumor viruses encode viral oncoproteins that are important for viral replication but also affect cellular growth control pathways. For example, inactivation of the retinoblastoma gene (*Rb*) and the p53 pathway by viral transforming proteins is a common strategy used by papovaviruses and adenoviruses. As mentioned above, all DNA tumor viruses kill their host cell when the infectious virion is released to infect other cells. Thus, transformation and tumorigenicity are entirely dependent on a host cell interaction with the virus that does not involve viral spread to other cells, and cells transformed by DNA tumor viruses depend on the continued expression of the virally encoded oncogene.

Recent studies have revealed that the human tumor viruses EBV, HHV-8, human papillomavirus, HBV, HCV, and HTLV-1 express proteins that are targeted to the mitochondria (8). Because the mitochondria play a critical role in energy production, cell death, calcium homeostasis, and redox balance, these proteins have profound effects on host cell physiology. Further study of these proteins and their interactions with mitochondria will aid in the understanding the mechanisms of viral replication and tumorigenesis and could reveal important new targets for anti-tumor therapy.

Prion Diseases (14,15,16)

Although they are not viruses, the infective proteins known as prions have sufficient similarities to viruses to warrant their discussion in this chapter. Prions are small proteins that have been shown to cause a variety of transmissible spongiform encephalopathies, which are rare neurodegenerative disorders typified by symptoms in the CNS, such as spongiform changes, neuronal loss, glial activation, and accumulation of amyloid aggregates of an abnormally folded host protein. Human prion diseases include kuru, Creutzfeldt-Jakob disease (variant, sporadic, familial and iatrogenic), Gerstmann-Sträussler-Scheinker syndrome, and fatal familial insomnia. The disease in cattle known as bovine spongiform encephalopathy and the related disease scrapie exhibit similar pathologic features. Following exposure, prions accumulate in lymphoid tissue, such as the spleen, lymph nodes, tonsils, and Peyer's patches (specialized lymphoid follicles located in the submucosa of the small intestine). This accumulation of the infectious agent is necessary for invasion of the CNS. In humans, the incubation period of the disease can vary between 18 months and 40 years. Prions appear to be variant, improperly folded versions of a normal cellular protein called PrP^{c}, a 30- to 35-kDa protein with two sites for N-glycosylation that is anchored in the neuronal cell membrane. PrP^{c} protein contains three α-helices, a short β-pleated sheet region, and a long, unstructured portion that comprises half the molecule. The variant, infectious form of the protein is known as PrP^{sc} and is produced autocatalytically from PrP^{c}. Prion diseases are always fatal, with no known cases of remission or recovery. The host shows no inflammatory response or immune response and no production of interferon, and there is no effect on host B-cell or T-cell function. At present, there are no effective agents to treat prion diseases.

Viral Chemotherapy

General Approaches (17,18)

The principles involved in the design of antiviral agents are similar to those used in the design of all chemotherapeutic agents. Drugs in this category are targeted to some process in the virus that is not present in the host cell. The earliest examples of antiviral agents did not achieve this goal, and these drugs were toxic at therapeutic levels or had a limited spectrum of activity. A variety of factors make the design of effective antiviral agents difficult, including their ability to undergo antigenic changes, the latent period during which there are no symptoms, and their reliance on host enzymes and other processes. This problem is compounded by the facts that host immunity is not well understood and that symptoms of viral infection may not appear until replication is complete and the viral genome has been incorporated into infected cells. Nonetheless, the continuing identification of new targets for antiviral agents provides new avenues for the discovery of small molecule therapies. The following section includes information regarding currently marketed antiviral compounds that have been designed in eight general areas:

- Agents that disrupt virus attachment to host cell receptors, penetration, or uncoating
- Agents that inhibit virus-associated enzymes, such as DNA polymerases and others
- Agents that inhibit viral transcription
- Agents that inhibit viral translation
- Agents that interfere with viral regulatory proteins
- Agents that interfere with glycosylation, phosphorylation, sulfation, and so on.
- Agents that interfere with the assembly of viral proteins
- Agents that prohibit the release of viruses from cell surface membranes

The remainder of this chapter deals primarily with small molecule antiviral agents that have been approved by the U.S. Food and Drug Administration (FDA) and are clinically effective in the treatment of viral infection. Immunizing biological agents, such as vaccines as well as antineoplastic agents with antiviral activity, are not covered. Some compounds used primarily in the treatment of bacterial infections, such as rifampicin, bleomycin, adriamycin, and actinomycin, also inhibit viral replication. These antibiotics do not affect the transcription or translation of viral mRNA, however, and are only effective in high concentrations. Therefore, such antibiotics are not commonly used for viral infections. There is a continuing need for new antiviral agents, primarily because viral infections are not curable after the virus invades the host cell and begins to replicate. Vaccines are effective, but they are only able to prevent an infection, and only then in cases where specific virus strains are involved. For example, immunization against influenza, which is a yearly routine in many parts of the world, can only provide immunity against the specific strains that are represented in that preparation. New virulent strains may arise from nonhuman sources, such as the so-called swine flu or avian flu viruses, and currently available vaccines would have no effect against these new strains. With regard to small molecule antiviral agents, the ideal drug would have broad-spectrum antiviral activity, completely inhibit viral replication, maintain efficacy against mutant

viral strains, and reach the target organ without interfering with normal cellular processes or the immune system of the host.

Table 43.2. Antiviral Agents Interfering with Cellular Penetration and Early Replication

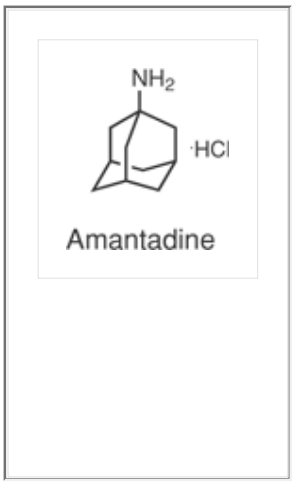
Generic Name	Trade Name	Spectrum of Activity	Dosage Form
Amantadine	Symmetrel	Influenza A	Capsule (100 mg), Syrup (50 mg/5 mL)

Rimantadine	Flumadine	Influenza A	Capsule (100 mg)
Interferon-α_{2a}	Roferon A, Alferon, Intron, Wellferon	Chronic hepatitis, CMV, HSV, papillomavirus, rhinovirus, and others	Injectable (3, 5, 10, 18, 25, and 50 million units/mL)
Interferon-α_{2b}	Interon A	Chronic hepatitis B and C, many other viruses	Injectable (3, 5, 10, 18, 25, and 50 million units/mL)
Interferon-γ	Actimmune		Injectable (100 μg/0.5 mL)
Zanamavir	Relenza	Influenza A and B	Inhaled powder (5 mg)
Oseltamivir	Tamiflu	Influenza A and B	Capsule (75 mg)
Enfurtizide	Fuzeon	HIV	Adult: 90 mg SQ b.i.d. Children (6–16 years): 2 mg/kg SQ b.i.d.

CMV, cytomegalovirus; HSV, herpes simplex virus, SQ, subcutaneous.

Agents Inhibiting Virus Attachment, Penetration, Uncoating, and Early Viral Replication (Table 43.2)

Amantadine



Mechanism of action

Amantadine hydrochloride (1-adamantanamine hydrochloride) is a symmetric, tricyclic, primary amine that inhibits penetration of RNA viral particles into the host cell (19). It also inhibits the early stages of viral replication by blocking the uncoating of the viral genome and the transfer of nucleic acid into the host cell.

Clinical application

Amantadine is clinically effective in preventing and treating all type A strains of influenza, particularly type A2 strains of Asian influenza virus, and to a lesser extent, German measles (rubella) or atoga virus. It also shows in vitro activity against influenza B, parainfluenza (paramyxovirus), respiratory syncytial virus (RSV), and some RNA viruses (murine, Rous, and Esh sarcoma viruses). Many prototype influenza A viruses of different human subtypes (H1N1; Fort Dix; H2N2, Asian type; and H3N2, Hong Kong type) also are inhibited by amantadine hydrochloride both in vitro and in animal model systems. If given within the first 48 hours of onset of symptoms, amantadine hydrochloride is effective in respiratory tract illness resulting from influenza A (but not influenza B), adenoviruses, and RSV.

Pharmacokinetics

Amantadine is well absorbed orally, and the usual dosage for oral administration is 100 mg twice daily. The drug has been approved as a capsule, tablet, and syrup for the treatment of keratoconjunctivitis caused by HSV infection. Amantadine hydrochloride oral solution should not be kept in a freezer but, rather, should be stored in a tight container at 15 to 30°C. Capsules and tablets should be protected from moisture and light. A 100 mg oral dose produces blood serum levels of 0.3 mg/mL within 1 to 8 hours. Maximum tissue concentration is reached in 48 hours when a 100 mg dose is given every 12 hours. In healthy adults receiving a 25, 100, or 150 mg dose of the drug twice daily, steady-state trough plasma concentrations were 110, 302, or 588 mg/mL, respectively. Usually, no neurotoxicity is observed if the plasma level of amantadine is no more than 1.00 mg/mL.

Amantadine crosses the blood-brain barrier and is distributed in saliva, nasal secretions, and breast milk (20). Approximately 90% of the drug is excreted unchanged by the kidney, primarily through glomerular filtration and tubular secretion, and there are no reports of metabolic products. Acidification of urine increases the rate of amantadine excretion. The half-life of the drug is 15 to 20 hours in patients with normal renal function.

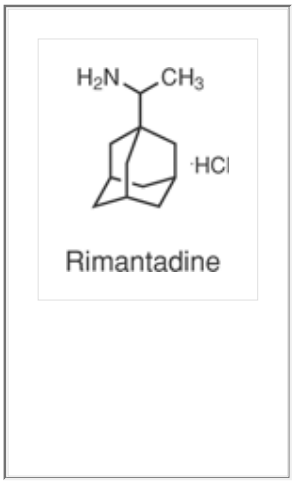
Side effects

Generally, the drug has low toxicity at therapeutic levels but may cause severe CNS symptoms, such as nervousness, confusion, headache, drowsiness, insomnia, depression, and hallucinations. The GI side effects include nausea, diarrhea, constipation, and anorexia. Convulsions and coma occur with high doses and in patients with cerebral arteriosclerosis and convulsive disorders. Chronic toxicity with

amantadine is unexpected, because few side effects have been experienced when the drug has been used in long-term therapy for Parkinson's disease. Some serious reactions, however, include depression, orthostatic hypotension, psychosis, urinary retention, and congestive heart failure. Amantadine hydrochloride should be used with caution in patients who have a history of epilepsy, severe arteriosclerosis, liver diseases, and eczematoid dermatitis. Because amantadine does not appear to interfere with the immunogenicity of inactivated influenza A vaccine, patients may continue the use of amantadine for 1 week after influenza A vaccination. A

virus that is resistant to amantadine has been obtained in cell culture and from animals, but these reports are not confirmed in humans.

Rimantadine



Mechanism of action

Rimantadine hydrochloride (α-methyl-1-adamantanemethylamine hydrochloride) is a synthetic adamatane derivative that is structurally and pharmacologically related to amantadine (21,22). It appears to be more effective than amantadine hydrochloride against influenza A, with fewer CNS side effects. Rimantadine hydrochloride is thought to interfere with virus uncoating by inhibiting the release of specific proteins. It may act by inhibiting RT or the synthesis of virus-specific RNA, but it does not inhibit virus adsorption or penetration. It appears to produce a virustatic effect early in the virus replication. It is used widely in Russia and Europe.

Clinical application

Rimantadine hydrochloride has activity against most strains of influenza A, including H1N1, H2N2, and H3N2, but it has no activity against influenza B virus. It is used for prevention of infection caused by various human, animal, or avian strains of influenza A virus in adults and children. The side effects are nightmares, hallucinations, and vomiting. The most common side effects of rimantadine are associated with the CNS and the GI tract. Rimantadine is metabolized in the liver, and approximately 20% is excreted unchanged as hydroxylated compound.

Pharmacokinetics

The half-life of rimantadine in adults ranges from 24 to 36 hours. More than 90% of rimantadine doses were absorbed in 3 to 6 hours. Steady-state plasma concentrations are from 0.10 to 2.60 mg/mL at doses of 3 mg/kg/d in infants to doses of 100 mg twice daily in the elderly. Nasal fluid concentrations of rimantadine at steady state were 1.5-fold higher than plasma concentration.

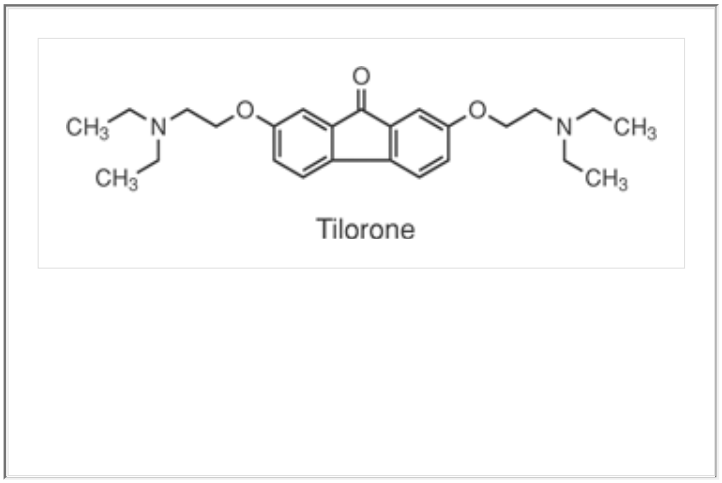
Interferon (23,24)

Isaacs and Lindenmann discovered interferon in 1957. When they infected cells with viruses, interference

with the cellular effects of viral infection were observed. Interferon was subsequently isolated and found to protect the cells from further infection. When interferon was administered to other cells or animals, it displayed biological properties such as inhibition of viral growth, cell multiplication, and immunomodulatory activities. These results led to the speculation that interferon may be a natural antiviral factor, possibly formed before antibody production, and may be involved in the normal mechanism of resistance displayed against viral infection. Some investigators relate interferon to the polypeptide hormones and suggest that interferon functions in cell-to-cell communication by transmitting specific messages. Recently, antitumor and anticancer properties of interferon have evoked worldwide interest in the possible use of this agent in therapy for viral diseases, cancer, and immunodeficiency disorders. Host cells synthesize interferons in response to various inducers.

Interferon induction

Because viruses were found to induce the release of interferon, efforts were made to induce the production or release of interferon in humans by the administration of chemical "inducers" (25). Various small molecules (substituted propanediamine) and large polymers (double-stranded polynucleotides) were used to induce interferons. Statolon, a natural double-stranded RNA produced in *Penicillium stoloniferum* culture, and a double-stranded complex of polyriboinosinic acid and polyribocytidylic acid (poly I:C) have been used as nonviral inducers for releasing preformed interferons. A modification of poly I:C stabilized with poly-L-lysine and carboxymethylcellulose (poly ICLC) has been used experimentally in humans. Clinically, it has prevented coryza when used locally in the nose and conjunctival sacs. This substance is a better interferon inducer than poly I:C. Another interferon inducer is ampligen, a polynucleotide derivative of poly I:C with spaced uridines. It has anti-HIV activity in vitro and is an immunomodulator.



Tilorone

Other chemical inducers, such as pyran copolymers, tilorone, diethylaminoethyl dextran, and heparin, also have been used. Tilorone is an effective inducer of interferon in mice, but it is relatively ineffective in humans. Initial use of interferon and its inducers instilled intranasally after rhinovirus exposure was successful in the prevention of respiratory diseases. The clinical success of interferon and its inducers has not yet been established, although they may play a significant role in cell-mediated immunity to viral infections and cancer. Disadvantages of interferon use include unacceptable side effects, such as fever, headache, myalgias, leukopenia, nausea, vomiting, diarrhea, hypotension, alopecia, anorexia, and weight loss.

Interferon structure

Interferon consists of a mixture of small proteins with molecular weights ranging from 20,000 to 160,000 daltons. They are glycoproteins that exhibit species-specific antiviral activity. Human interferons are classified into three types (26): α, β, and γ. The

α-type is secreted by human leukocytes (white blood cells and non–T lymphocytes), and the β-type is secreted by human fibroblasts. Lymphoid cells (T lymphocytes), which either have been exposed to a

presensitized antigen or have been stimulated to divide by mitogens, secrete interferon-α. Interferon-γ also is called "immune" interferon. Interferons are active in extremely low concentrations (for more details, see Chapter 6).

Clinical application

Interferon has been tested for use in chronic HBV infection, herpetic keratitis, herpes genitalis, herpes zoster, varicella-zoster, chronic hepatitis, influenza, and common cold infections. Other uses of interferon are in the treatment of cancers, such as breast cancer, lung carcinoma, and multiple myeloma. Interferon has had some success when used as a prophylactic agent for CMV infection in renal transplant recipients. The scarcity of interferon and the difficulty in purifying it have limited clinical trials. Supplies have been augmented by recombinant DNA technology, which allows cloning of the interferon gene (27), although the high cost still hinders clinical application. The U.S. FDA has approved recombinant interferon-α_{2a}, -α_{2b} and -γ for the treatment of hairy cell leukemia (a rare form of cancer), AIDS-related Kaposi's sarcoma, and genital warts (condyloma acuminatum). Subcutaneous injection of recombinant interferon-α_{2b} has been approved for the treatment of chronic hepatitis C. Some foreign countries have approved interferon-α for the treatment of cancers, such as multiple myeloma (cancer of plasma cells), malignant melanoma (skin cancer), and Kaposi's sarcoma (cancer associated with AIDS). Both interferon-β- and -γ as well as interleukin-2 may be commercial drugs of the future for the treatment of cancers and viral infections, including genital warts and the common cold.

Mechanism of action

Although interferons are mediators of immune response, different mechanisms for the antiviral action of interferon have been proposed. Interferon-α possesses broad-spectrum antiviral activity and acts on virus-infected cells by binding to specific cell surface receptors. It inhibits the transcription and translation of mRNA into viral nucleic acid and protein. Studies in cell-free systems have shown that the addition of adenosine triphosphate and double-stranded RNA to extracts of interferon-treated cells activates cellular RNA proteins and a cellular endonuclease. This activation causes the formation of translation inhibitory protein, which terminates production of viral enzyme, nucleic acid, and structural proteins (28). Interferon also may act by blocking synthesis of a cleaving enzyme required for viral release.

Pharmacokinetics

The pharmacokinetics of interferon is not well understood. Maximum levels in blood after intramuscular injection was obtained in 5 to 8 hours. Interferon does not penetrate well into cerebrospinal fluid (CSF). Oral administration of interferon does not indicate a detectable serum level, and as such, oral administration is clinically ineffective. After intramuscular or subcutaneous injection, drug concentration in plasma is dose related. Clinical use of interferon is limited to topical administration (nasal sprays) for prophylaxis and treatment of rhinovirus infections. Adverse reactions and toxicity include influenza-like syndrome of fever, chills, headache, myalgias, nausea, vomiting, diarrhea, bone marrow suppression, mental confusion, and behavioral changes. Intranasal administration produces mucosal friability, ulceration, and dryness.

Neuraminidase Inhibitors (29)

The role played by the surface glycoproteins hemagglutinin, an enzyme that is important for viral binding to host cell receptors via a terminal sialic acid residue, and neuraminidase (NA), an enzyme that is involved in various aspects of activation of influenza viruses, was discussed above. Freshly shed viral particles are coated with sialic acid residues. Neuraminidase is found in both influenza A and B viruses and is thought to be involved in catalytically cleaving glycosidic bonds between terminal sialic acid residues and adjacent sugars on hemagglutinin. The cleavage of sialic acid bonds facilitates the spread of viruses by enhancing adsorption to cell surface receptors and, thus, increases the infective level of the virus. In the absence of sialic acid cleavage from hemagglutinin, viral aggregation or inappropriate binding to hemagglutinin will occur, interfering with the spread of the infection. Neuraminidase also appears to play a role in preventing viral inactivation by respiratory mucus.

Mechanism of action

Because neuraminidase plays such an important role in the activation of newly formed viruses, it is not surprising that the development of neuraminidase inhibitors has become an important potential means of inhibiting the spread of viral infections. X-ray crystallography of neuraminidase has shown that whereas the amino acid sequence in the neuraminidase from various viruses is considerably different, the sialic acid binding site is quite similar for influenza A and B viruses. In addition, it is believed that the hydrolysis of sialic acid proceeds through a oxonium cation-stabilized carbonium ion, as shown in Figure 43.3. Mimicking the transition state with novel carboxylic derivatives of sialic acid has led to the development of transition state–based inhibitors (30). The first of these compounds, 2-deoxy-2,3-dehydro-N-acetylneuraminic acid (DANA) (Fig. 43.4), was found to be an active neuraminidase inhibitor but lacked specificity for viral neuraminidase. On determination of the crystal structure of neuraminidase, more sophisticated measurements of the binding site for sialic acid lead to the development of zanamivir and later oseltamivir.

Specific drugs

Zanamivir

Crystallographic studies of DANA (Fig. 43.4) bound to neuraminidase defined the receptor site to

which the sialic acid portion of the virus binds. These studies suggested that substitution of the 4-hydroxy with an amino group or the larger guanidino group should increase binding of the inhibitor to neuraminidase. The 4-amino derivative was found to bind to a glutamic acid (Glu^{119}) in the receptor through a salt bridge, whereas the guanidino was able to form both a salt bridge to Glu^{119} and a charge–charge interaction with Glu^{227}. The result of these substitutions was a dramatic increase in binding capacity to neuraminidase of the amino and guanidino derivatives, leading to effective competitive inhibition of the enzyme. The result has been the development of zanamivir (Fig. 43.4) as an effective agent against influenza A and B viruses.

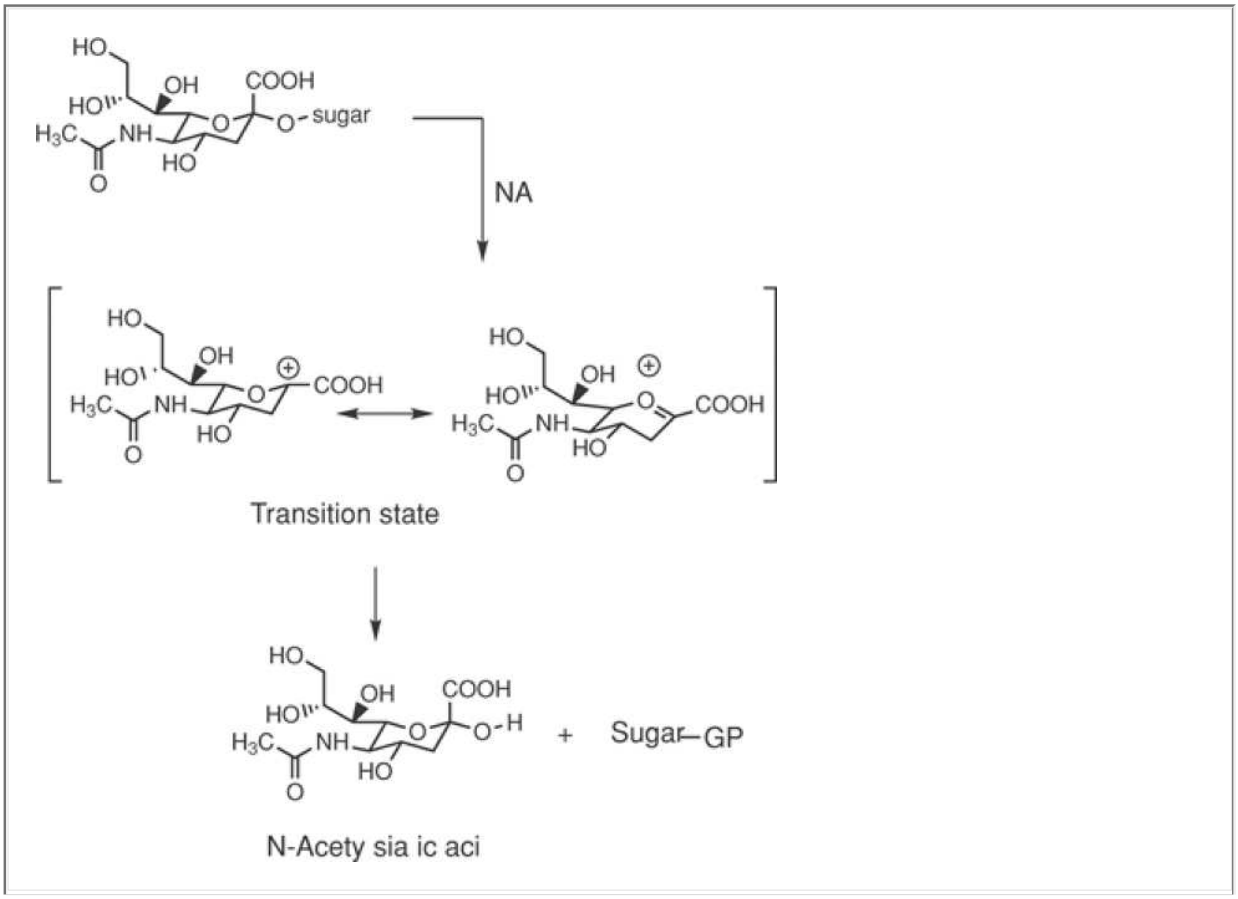


Fig. 43.3. Neuraminidase-catalyzed removal of a sialic acid residue from a glycoprotein chain. GP, glycoprotein; NA, neuraminidase.

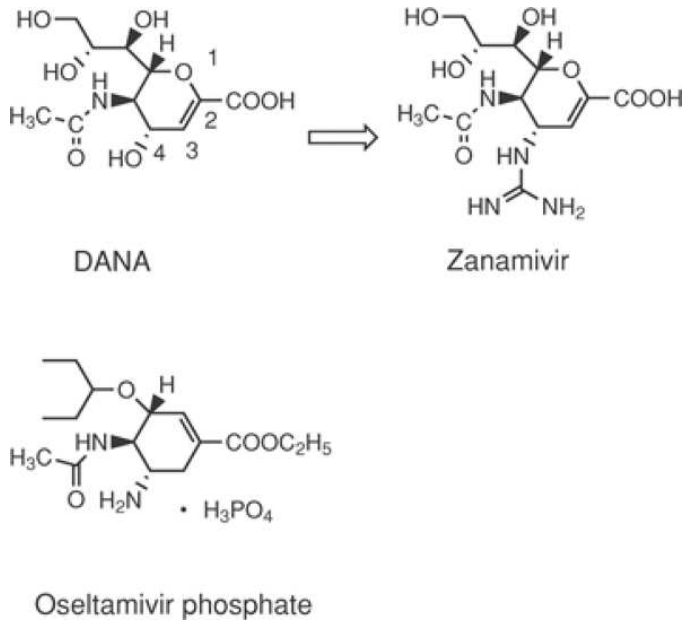

Fig. 43.4. Sialic acid derivatives 2-deoxy-2,3-dehydro-N-acetylneuraminic acid (DANA), zanamir, and oseltamivir phosphate, which act as inhibitors of neuraminidase.

Zanamirvir is effective when administered via the nasal, intraperitoneal, and intravenous (IV) routes, but it is inactive when given orally (Table 43.2). Animal studies have shown 68% recovery of the drug in the urine following intraperitoneal administration, 43% urinary recovery following nasal administration, and only 3% urinary recovery following oral administration. Human data gave results similar to those obtained in animal models. Human efficacy studies with nasal drops or sprays demonstrated that the drug was effective when administered before and after exposure to influenza A or B virus. When given before viral inoculation, the drug reduced viral shedding, infection, and symptoms. When administered beginning at either 26 or 32 hours after inoculation, there was a reduction in shedding, viral titer, and fever. Presently, the drug is available as a dry powder for oral inhalation by adults and adolescents who have been symptomatic for no more than 2 days. Zanamirvir is able to more rapidly resolve influenza symptoms and to improve recovery (from 7 days with placebo to 4 days with treatment). Additional studies have suggested the prophylactic benefit of zanamirvir when administered to family members after one member of the family developed flu-like symptoms. As a result, the manufacturer has submitted an application for the use of the drug for the prevention of influenza A and B infections.

Oseltamivir Phosphate

X-ray crystallographic studies further demonstrated that additional binding sites exist between neuraminidase and substrate involving the C-5 acetamido carbonyl and an arginine (Arg^{152}); the C-2 carboxyl and arginines at 118, 292, and 371; and the potential for hydrophobic binding to substituents at C-6 (with glutamic acid, alanine, arginine, and isoleucine). Structure–activity relationship studies showed that maximum binding occurred to neuraminidase when C-6 was substituted with the 3-pentyloxy side chain, such as the one found in oseltamivir. In addition, esterification with ethanol gave rise to a

compound that is orally effective. Oseltamivir (Fig. 43.4) was approved as the first orally administered neuraminidase inhibitor used against influenza A and B viruses (Table 43.2). The drug is indicated for the treatment of uncomplicated acute illness caused by influenza infection. Recently, the drug has been approved for prevention of influenza A and B infections in adults, adolescents, and children 1 year of age and older. The drug is effective in treating influenza if administered within 2 days after onset of symptoms. The recommended dose is 75 mg twice daily for 5 days. The prophylactic dose is 75 mg taken once daily for 7 days in adults and teenagers, with lower doses for children 1 year or older (dosed based on body weight). Oseltamivir is readily absorbed from the GI tract following oral administration. It is a prodrug that is extensively metabolized in the liver, undergoing ester hydrolysis to the active carboxylic acid

(Fig. 43.5). Two oxidative metabolites also have been isolated, with the major oxidation product being the ω-carboxylic acid (31). Side effects with oseltamivir are minor, consist of nausea and vomiting, and occur primarily in the first two days of therapy.

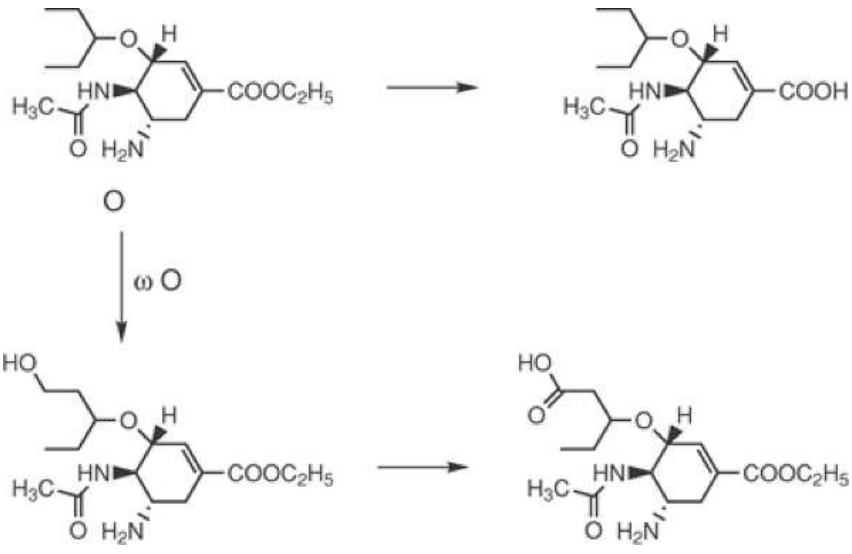

Fig. 43.5. Metabolism of oseltamivir by deethylation and ω-oxidation.

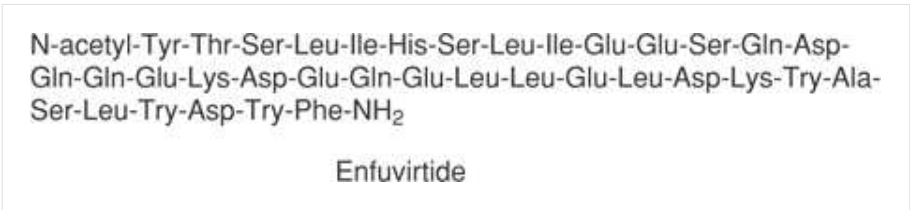
Enfuvirtide (32,33)



Entry inhibitors, also known as fusion inhibitors, are a new class of drugs for the treatment of HIV

infection, and enfuvirtide is the first compound of this family to be approved for clinical use. Enfuvirtide is an oligo peptide consisting of 36 amino acids. It is a synthetic peptide that mimics an HR2 fragment of gp41, blocking the formation of a six-helix bundle structure that is critical in the fusion of the HIV-1 virion to a CD4-positive T lymphocyte. Specifically, it binds to the tryptophan-rich region of the gp41 protein. Enfuvirtide is used in combination with other antiretrovirals and works against a variety of HIV-1 variants, but it is not active against HIV-2. Resistance to enfuvirtide can develop when the virus produces changes in a 10-amino-acid domain between residues 36 to 45 in the gp41 HIV surface glycoprotein.

Table 43.3. Antiviral Agents Interfering with Viral Nucleic Acid Replication

Generic Name	Common Name	Trade Name	Spectrum of Activity	Dosage Form
Acyclovir	Acyclo-G	Zovirax	HSV-1, HSV-2, VZV, EBV	5% Ointment, injectable (5 mg/mL), capsule (200 mg), tablet (400 and 800 mg), suspension (200 mg/5 mL)
Valacyclovir		Valtrex	HSV-1, VZV, CMV	Tablet (500 mg)
Cidofovir	HPMPC	Vistide	CMV, HSV-1, HSV-2, VZV, CMV, EBV	Injectable (75 mg/mL)
Cytarabine	Ara-C	Cytosar	Herpes zoster	Injectable (10, 20, 50, and 100 mg/mL)
Famciclovir	FCV	Famvir	HSV, VZV, EBV, chronic HBV	Tablet (125, 250, and 500 mg)
Fomivirsen		Vitravene	CMV retinitis	Injectable (6.6 mg/mL)
Foscarnet	PFA	Foscavir	CMV retinitis, HSV	Injectable (24 mg/mL)
Ganciclovir	DHPG	Cytovene, Vitrasert	CMV retinitis	Injectable (50 mg/mL), capsule (250 and 500 mg),

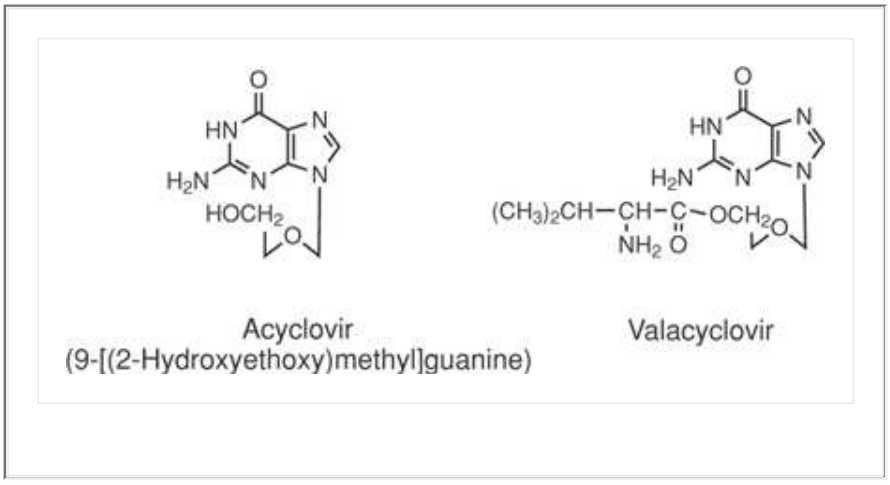
				insert (4.5 mg/insert)
Idoxuridine	5-IUDR	Herplex	HSV keratitis	0.1% Solution, 0.5% ointment
Ribavirin		Virazole	RSV, influenza A and B, HIV-1, parainfluenza	Aerosol (20 mg/mL)
Trifluorothymidine	TFT, FT3	Viroptic	HSV-1	1% Solution
Vidarabine	Ara-A	Vira A	HSV-1, HSV-2	3% Ointment (monohydrate)
Adefovir dipivoxil		Hepsera	HBV	Tablet (10 mg)

CMV, cytomegalovirus; EBV, Epstein-Barr virus; HBV, hepatitis B virus; HSV, herpes simplex virus; VZV, varicella-zoster virus.

The drug is administered twice daily as a subcutaneous injection and has a complex absorption pattern. Enfuvirtide is highly bound to plasma protein (~92%) and is prone to proteolytic metabolism. Adverse reactions are common at the site of injection (e.g., pain, erythema, and pruritus) and insomnia.

Agents Interfering with Viral Nucleic Acid Replication (Table 43.3)

Acyclovir and Valacyclovir



Mechanism of action

Acyclovir is a synthetic analogue of deoxyguanosine in which the carbohydrate moiety is acyclic (34). Because of this difference in structure as compared to other antiviral compounds (idoxuridine, vidarabine, and

trifluridine), acyclovir possesses a unique mechanism of antiviral activity. The mode of action of acyclovir consists of three consecutive mechanisms (35). The first of these mechanisms involves conversion of the drug to active acyclovir monophosphate within cells by viral thymidine kinase (Fig. 43.6). This phosphorylation reaction occurs faster within cells infected by herpesvirus than in normal cells, because acyclovir is a poor substrate for the normal cell thymidine kinase. Acyclovir is further converted to di- and triphosphates by a normal cellular enzyme called guanosine monophosphate kinase. In the second mechanism, viral DNA polymerase is competitively inhibited by acyclovir triphosphate with a lower median inhibition concentration (IC50) than that for cellular DNA polymerase. Acyclovir triphosphate is incorporated into the viral DNA chain during DNA synthesis. Because acyclovir triphosphate lacks the 3′-hydroxyl group of a cyclic sugar, it terminates further elongation of the DNA chain. The third mechanism depends on preferential uptake of acyclovir by herpes-infected cells as compared to uninfected cells, resulting in a higher concentration of acyclovir triphosphate and leading to a high therapeutic index between herpes-infected cells compared to normal cells. Acyclovir is active against certain herpesvirus infections. These viruses induce virus-specific thymidine kinase and DNA polymerase, which are inhibited by acyclovir. Thus, acyclovir significantly reduces DNA synthesis in virus-infected cells without significantly disturbing the active replication of uninfected cells.

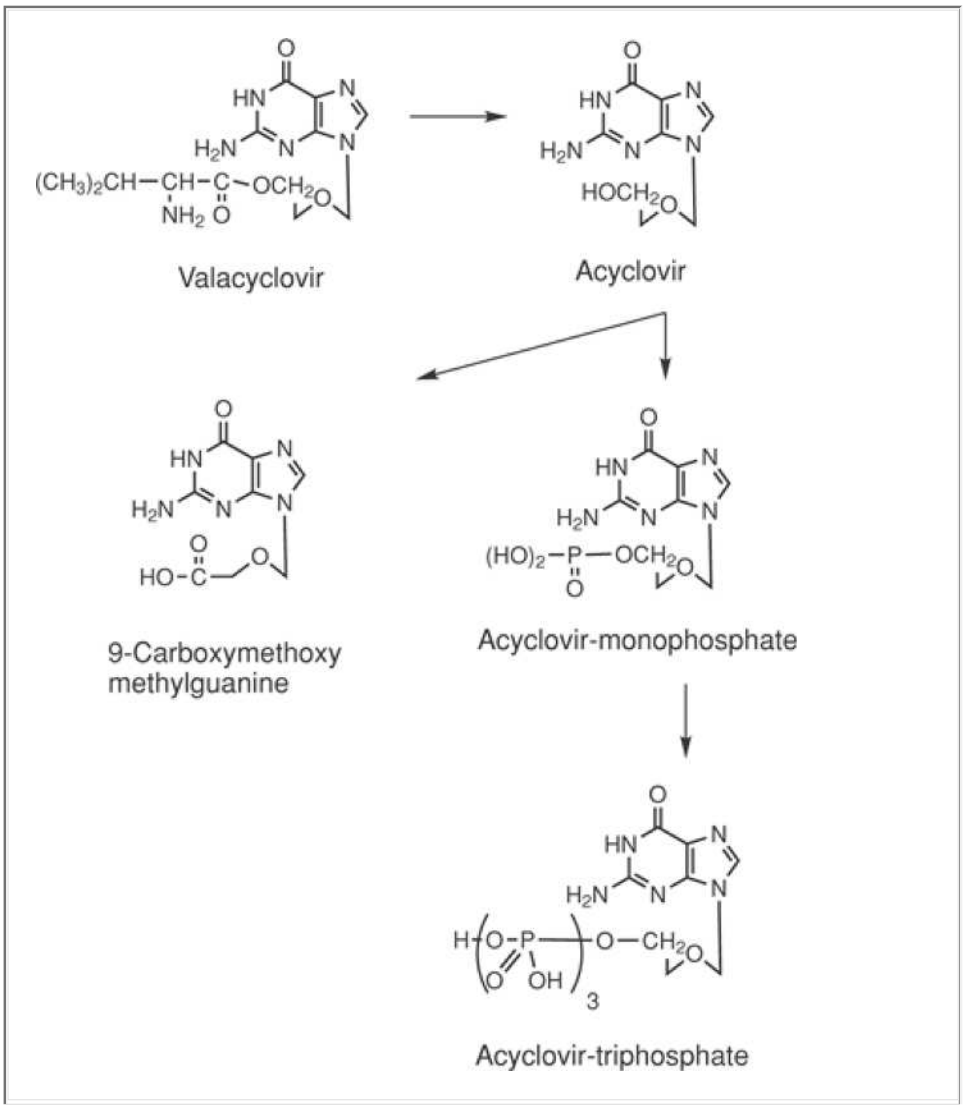


Fig. 43.6. Metabolic reactions of valacyclovir and acyclovir.

Clinical application

Acyclovir has potent activity against several DNA viruses including HSV-1, the common cause of labial herpes (cold sore), and HSV-2, the common cause of genital herpes (36). Varicella-zoster virus and some isolates of EBV are affected to a lesser extent by acyclovir. On the other hand, CMV is less sensitive to acyclovir, which has no activity against vaccinia virus, adenovirus, and parainfluenza infections. An ointment containing 5% acyclovir has been used in a regimen of five times a day for up to 14 days for the treatment of herpetic keratitis and of primary and recurrent infections of herpes genitalis. Mild pain, transient burning, stinging, pruritus, rash, and vulvitis have been noted. The U.S. FDA has approved topical and IV acyclovir preparations for initial herpes genitalis and HSV-1 and HSV-2 infections in immunocompromised patients (37). In these individuals, early use of acyclovir shortens the duration of viral shedding and lesion pain. Oral doses of 200 mg of acyclovir, taken five times a day for 5 to 10 days, have not proven to be successful because of the low bioavailability of current preparations. Oral doses of 800 mg of the drug given five times daily for 7 to 10 days have been approved by the U.S. FDA for the treatment of herpes zoster infection. This treatment shortens the duration of viral shedding in chickenpox and shingles. The IV injection of the drug (given 10 mg/kg three times a day for 10 to 12 days) has been approved for the treatment of herpes simplex encephalitis (38). Excessive and high doses of acyclovir have, however, caused viruses to develop resistance to the drug. This resistance results from reduction of virus-encoded thymidine kinase, which does not effectively activate the drug.

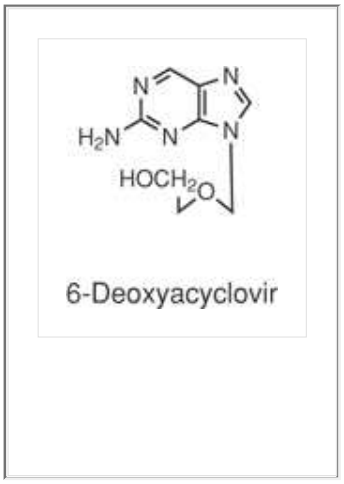
Pharmacokinetics

Pharmacokinetic studies show that IV dose administration of 2.5 mg/kg of acyclovir results in peak plasma concentrations of 3.4 to 6.8 mg/mL (39,40). The bioavailability of acyclovir is 15 to 30%, and it is metabolized to 9-carboxymethoxymethylguanine, which is inactive (Fig. 43.6). Plasma protein binding averages 15%, and approximately 70% of acyclovir is excreted unchanged in the urine by both glomerular filtration and tubular secretion. The half-life of the drug is approximately 3 hours in patients with normal renal function. In an individual with renal diseases, the half-life of the drug is prolonged. Therefore, acyclovir dosage adjustment is necessary for patients with renal impairment. Because of its low molecular weight and protein binding, acyclovir is easily dialyzed. Thus, a full dose of the drug should be given after hemodialysis. It should be infused slowly, over at least 30 minutes, to avoid acute transient and reversible renal failure. Acyclovir easily penetrates the lung, brain, muscle, spleen, uterus, vaginal mucosa, intestine, liver, and kidney. Acyclovir has relatively few side effects, except that IV injection causes reversible renal dysfunction and irritation, inflammation, and pain at the injection site. Infusion sites therefore should be inspected frequently and changed after every 72 hours. The drug is slightly toxic to bone marrow at

higher doses. Less frequent side effects are nausea, vomiting, headache, skin rashes, hematuria, arthralgia, and insomnia.

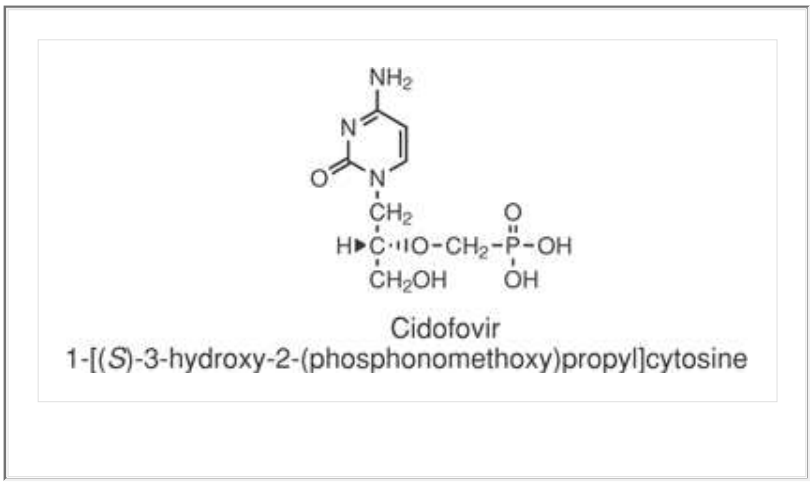
Valacyclovir hydrochloride is an amino acid ester pro-drug of acyclovir that exhibits antiviral activity only after metabolism first in the intestine walls or liver to acyclovir and then conversion to the triphosphate, as shown in Figure 43.6 (41). Structurally, it differs from acyclovir by the presence of the amino acid valine attached to the 5′-hydroxyl group of the nucleoside. Valacyclovir's benefit comes from an increased GI absorption, resulting in higher plasma concentrations of acyclovir, which normally is poorly absorbed from the GI tract. As with acyclovir, valacyclovir is active against HSV-1, VZV, and CMV (Table 43.3) because of its affinity for the viral form of the enzyme thymidine kinase. Oral valacyclovir is used for the treatment of acute, localized herpes zoster (shingles) in immunocompetent patients and may be given without meals. It also is used for the initial and recurrent episodes of genital herpes infections. The adverse effects are similar to acyclovir, which include nausea, headache, vomiting, constipation, and anorexia. The binding of valacyclovir to human plasma proteins ranges between 13.5 to 17.9%. The plasma elimination half-life of acyclovir is 2.5 to 3.3 hours. The bioavailability of valacyclovir

hydrochloride is 54%, compared to approximately 20% for oral acyclovir, and it is as effective as acyclovir in decreasing the duration of pain associated with posttherapeutic neuralgia and episodes of genital lesion healing.



The related analogue 6-deoxyacyclovir is a prodrug form of acyclovir that is activated through metabolism by xanthine oxidase. This drug, which has improved solubility characteristics compared to acyclovir, is used for the treatment of VZV infection.

Cidofovir



Mechanism of action

Cidofovir is a synthetic acyclic pyrimidine nucleotide analogue of cytosine (42). It is a phosphorylated nucleotide that is additionally phosphorylated by host cell enzymes to its active intracellular metabolite, cidofovir diphosphate. This reaction occurs without initial virus-dependent phosphorylation by viral nucleoside kinases. It has antiviral effects by interfering with DNA synthesis and inhibiting viral replication.

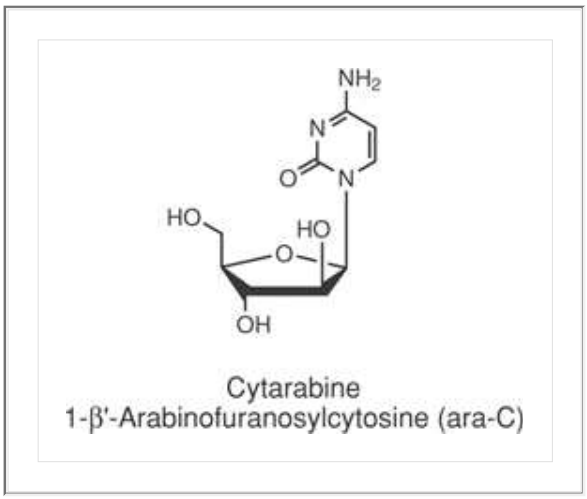
Pharmacokinetics

Topical cidofovir (0.2%) is as effective as trifluridine (1%) in reducing HSV-1 shedding and healing time in rabbits with dendritic keratitis. Cidofovir is administered IV, topically, and by ocular implant (Table 43.3). Peak plasma concentration of 3.1 to 23.6 mg/mL is achieved with doses of 1.0 to 10.0 mg/kg, respectively. The terminal plasma half-life is 2.6 hours, and 90% of the drug is excreted in the urine. It has a variable bioavailability (2–26%).

Clinical application

Cidofovir is active against herpesviruses, including HSV-1 and HSV-2, VZV, CMV, and EBV. It is effective against acyclovir-resistant strains of HSV and ganciclovir-resistant strains of CMV. Cidofovir is a long-acting drug for the treatment of CMV retinitis in patients with AIDS when given as an IV infusion or an intravitreal injection. It is not a curative drug, and its benefit over foscarnet or ganciclovir is yet to be determined. The major adverse effect is nephrotoxicity, which appears to result in renal tubular damage. Concomitant administration of cidofovir with probenecid is contraindicated because of increased risk of nephrotoxicity.

Cytarabine



Mechanism of Action

Cytarabine is a pyrimidine nucleoside related to idoxuridine (43). It is used primarily as an anticancer rather than an antiviral agent. Cytarabine acts by blocking the utilization of deoxycytidine, thereby inhibiting the replication of viral DNA. The drug is first converted to mono-, di-, and triphosphates, which interfere with DNA synthesis by inhibiting both DNA polymerase and the reductase that promotes the conversion of cytidine diphosphate into its deoxy derivatives.

Clinical application

Cytarabine is used to treat Burkitt's lymphoma and both myeloid and lymphatic leukemias. Its antiviral use is in the treatment of herpes zoster (shingles) infection (Table 43.3). It also is used to treat herpetic keratitis and viral infections resistant to idoxuridine. The drug generally is used topically, but it has been given by IV injection to individuals with serious herpesvirus infection (44). Cytarabine is deaminated rapidly in the body to an inactive compound, arabinosyluracil, which is excreted in

the urine. The half-life of the drug in plasma is 3 to 5 hours. The toxic effects of cytarabine are chiefly on bone marrow, the GI tract, and the kidney. The drug is not given during the early months of pregnancy because of its teratogenic and carcinogenic effects in animals.

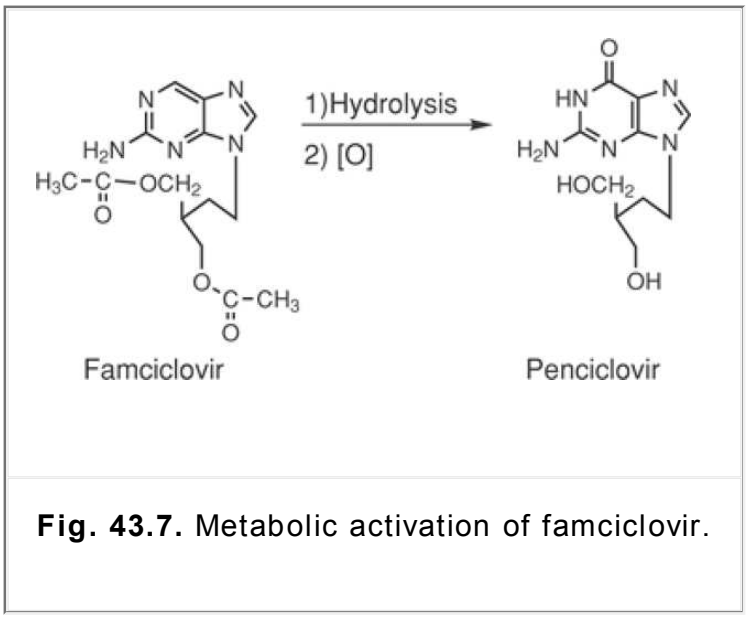


Fig. 43.7. Metabolic activation of famciclovir.

Famciclovir

Mechanism of action

Famciclovir (Fig. 43-7) is a synthetic purine nucleoside analogue related to guanine (45,46). It is the diacetyl 6-deoxy ester of penciclovir, which is structurally related to ganciclovir. Its pharmacological and microbiological activities are similar to those of acyclovir. Famciclovir is a prodrug of penciclovir, which is formed in vivo by hydrolysis of the acetyl groups and oxidation at the 6-position by mixed function oxidases. Penciclovir and its metabolite penciclovir triphosphate possess antiviral activity resulting from inhibition of viral DNA polymerase.

Clinical application

Famciclovir is active against recurrent HSV (genital herpes and cold sores), VZV, and EBV but is less active against CMV (Table 43.3). It is used in the treatment of recurrent localized herpes zoster and genital herpes in immunocompetent adults, and it also is promising for the treatment of chronic HBV reinfection after liver transplantation.

Pharmacokinetics

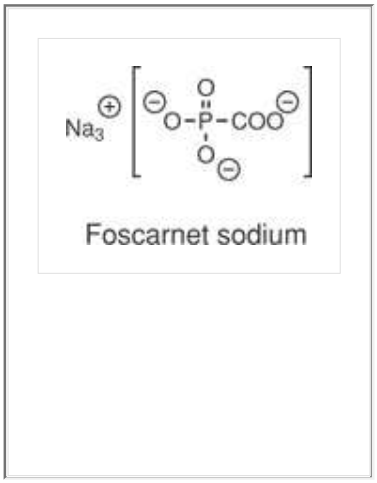
Famciclovir can be given with or without food. The most common adverse effects are headache and GI disturbances. Concomitant use of famciclovir with probenecid results in increased plasma concentrations of penciclovir. The recommended dose of famciclovir is 500 mg every 8 hours for 7 days. The absolute bioavailability of famciclovir is 77%, and the area under plasma concentration–time curve (AUC) is 86 μg/mL. Famciclovir with digoxin increased plasma concentration of digoxin to 19% as compared to digoxin given alone.

Fomivirsen

Fomivirsen sodium is used to treat CMV, which causes opportunistic retinitis in patients with AIDS. Such patients respond to fomivirsen but not to other treatment for CMV retinitis, which leads to blindness (47). Fomivirsen is the first antisense oligonucleotide agent that has been approved as an alternative medicine for patients with CMV retinitis for whom other agents did not work (see Chapter 8, Fomivirsen). It works by inhibiting the synthesis of proteins responsible for the regulation of viral gene expression that is involved in infection of CMV retinitis. Fomivirsen works only in the eye in which it is injected. It is not recommended if cidofovir is used within the last 2 to 4 weeks because of increased risk of eye inflammation. Fomivirsen is given in two induction doses, followed by monthly maintenance doses, each being 330 μg administered by intravitreal injection. It can cause increased pressure in the eye that

requires treatment by an ophthalmologist. Fomivirsen also is used in the treatment of Crohn's disease and certain cancers. It causes eye inflammation, abnormal vision, cataract, eye pain, and retinal problems. In addition, it causes several other side effects, such as stomach pain, headache, fever, infection, rash, vomiting, and liver dysfunction.

Foscarnet

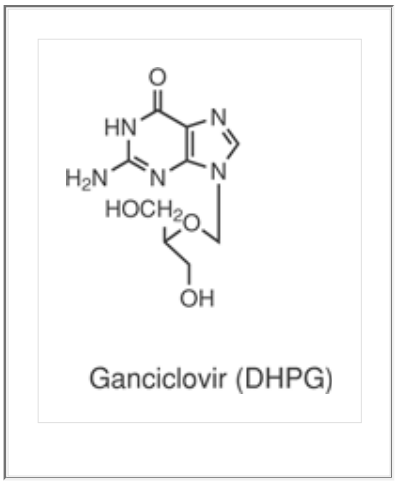


Foscarnet sodium is a trisodium phosphoformate hexahydrate that inhibits DNA polymerase of herpesviruses, including CMV and retroviral RT (48). It is not phosphorylated into an active form by viral host cell enzymes. Therefore, it has the advantage of not requiring an activation step before attacking the target viral enzyme.

Clinical application

Foscarnet sodium was approved by the U.S. FDA for the treatment of CMV retinitis in patients with AIDS. In combination with ganciclovir, the results have been promising, even in progressive disease with ganciclovir-resistant strains. Foscarnet sodium also is effective in the treatment of mucocutaneous diseases caused by acyclovir-resistant strains of HSV and VZV in patients with AIDS. Foscarnet sodium is administered IV at 60 mg/kg three times a day for initial therapy and at 90 to 120 mg/kg daily for maintenance therapy (Table 43.3). The plasma-half life is 3 to 6 hours. Foscarnet sodium penetrates into the CSF and the eye. The drug is neurotoxic, and common adverse effects include phlebitis, anemia, nausea, vomiting, and seizures. Foscarnet sodium carries the risk of severe hypocalcemia, especially with concurrent use of IV pentamidine. Foscarnet sodium used with zidovudine (ZDV) has an additive effect against CMV and acts synergistically against HIV.

Ganciclovir



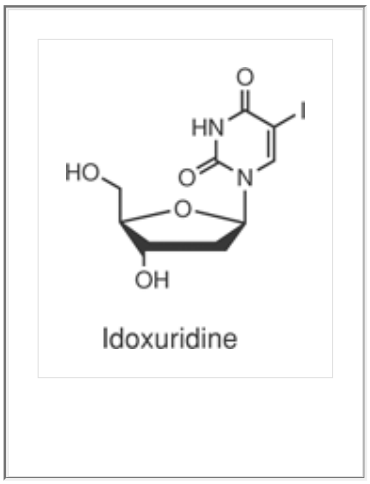
Mechanism of action

Ganciclovir sodium is an acyclic deoxyguanosine analogue of acyclovir (49). Ganciclovir inhibits DNA polymerase. Its active form is ganciclovir triphosphate, which is an inhibitor of viral rather than of cellular DNA polymerase. The phosphorylation of ganciclovir does not require a virus-specific thymidine kinase for its activity against CMV. The mechanism of action is similar to that of acyclovir; however, ganciclovir is more toxic than acyclovir to human cells.

Clinical significance

Ganciclovir has greater activity than acyclovir against CMV and EBV infection in immunocompromised patients. It also is active against HSV infection and in some mutants that are resistant to acyclovir. In patients with AIDS, ganciclovir stopped progressive hemorrhagic retinitis and symptomatic pneumonitis related to CMV infection. Ganciclovir is absorbed and phosphorylated by infection-induced kinases of HSV and VZV infections. Common side effects are leukopenia, neutropenia, and thrombocytopenia. Ganciclovir with ZDV causes severe hematologic toxicity. Ganciclovir is available only as an IV infusion, because its oral bioavailability is poor (Table 43.3). It is given in doses of 5 mg/kg twice daily for 14 to 21 days. When ganciclovir is given by IV administration, concentrations of the drug in the CSF and the brain vary from 25 to 70% of the plasma concentration. After minimal metabolism, ganciclovir is excreted in the urine. In adults with normal renal function, the serum half-life of the drug is approximately 3 hours. Ganciclovir has been approved by the U.S. FDA for the treatment of CMV retinitis in immunocompromised patients and in patients with AIDS.

Idoxuridine



Mechanism of action

Idoxuridine is a nucleoside containing a halogenated pyrimidine and is an analogue of thymidine (49). It acts as an antiviral agent against DNA viruses by interfering with their replication based on the similarity of structure between thymidine and idoxuridine. Idoxuridine is first phosphorylated by the host cell virus-encoded enzyme thymidine kinase to an active triphosphate form. The phosphorylated drug inhibits cellular DNA polymerase to a lesser extent than HSV DNA polymerase, which is necessary for the synthesis of viral DNA. The triphosphate form of the drug is then incorporated during viral nucleic acid synthesis by a false pairing system that replaces thymidine. When transcription occurs, faulty viral proteins are formed, resulting in defective viral particles (51).

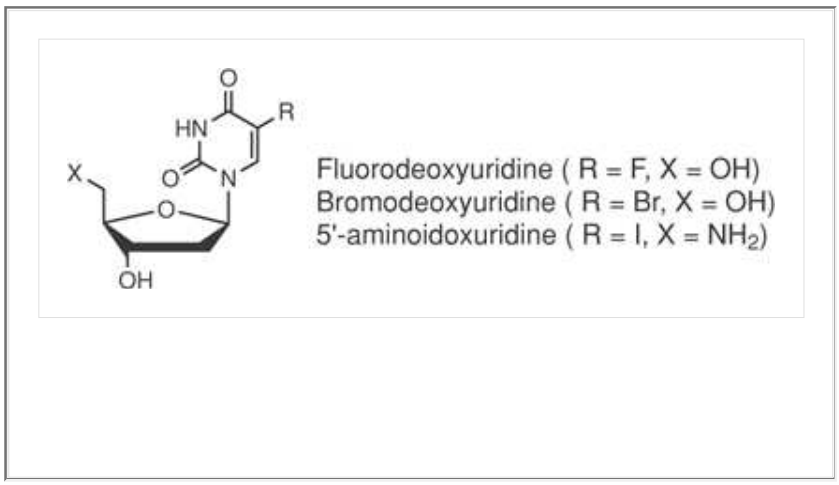
Clinical application

Idoxuridine is available as ophthalmic drops (0.1%) and ointment (0.5%) for the treatment of HSV keratoconjunctivitis, the leading cause of blindness in the United States (Table 43.3). Because of its

poor solubility, the drug is ineffective in the treatment of labial or genital HSV or of cutaneous herpes zoster infection. Idoxuridine in dimethyl sulfoxide (DMSO), however, has been used in mucocutaneous HSV infection of the mouth and nose. Because DMSO facilitates drug absorption and also has some therapeutic effect, a 40% solution of idoxuridine in DMSO is more effective than idoxuridine used without this vehicle. Therefore, the U.S. FDA approved idoxuridine only for topical treatment of herpes simplex keratitis, and it is more effective in epithelial than in stromal infections. It is less effective for recurrent herpes keratitis, probably because of the development of drug-resistant virus strains.

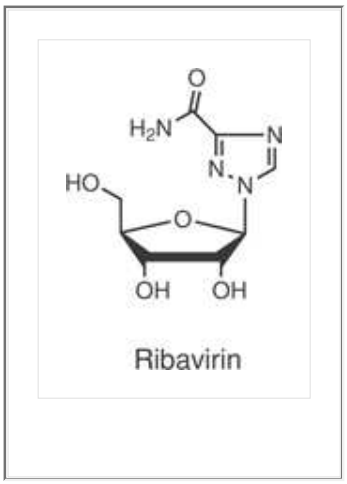
Adverse reactions of idoxuridine include such local reactions as pain, pruritus, edema, burning, and hypersensitivity. Systemic administration of idoxuridine by IV injection may be given in an emergency, but this leads to bone marrow toxicities, such as leukopenia, thrombocytopenia, and anemia. It also may induce stomatitis, nausea, vomiting, abnormalities of liver functions, and alopecia. Idoxuridine has a plasma half-life of 30 minutes and is rapidly metabolized in the blood to idoxuracil and uracil.

Additional Hydrogenated Uridines



Other halogenated uridine derivatives have been reported to exhibit antiviral activity. Fluorodeoxyuridine has in vitro antiviral activity but is not used in clinical practice. Bromodeoxyuridine is used in subacute sclerosing panencephalitis, a deadly, virus-induced CNS disease. This agent appears to interfere with DNA synthesis in the same way as idoxuridine. The 5′-amino analogue of idoxuridine (5-iodo-5′-amino-2′,5′-dideoxyuridine) is a better antiviral agent than idoxuridine, and it is less toxic. It is metabolized in herpesvirus-infected cells only by thymidine kinase to di- and triphosphoramidates. These metabolites inhibit HSV-specific late RNA transcription, causing reduction of less infective abnormal viral proteins. 5-Bromo-2′-deoxyuridine has an action similar to that of other iodinated compounds. None of these compounds are commercially available in the United States.

Ribavirin



Mechanism of action

Ribavirin, a guanosine analogue, has broad-spectrum antiviral activity against both DNA and RNA viruses (52,53). It is phosphorylated by adenosine kinase to the triphosphate, resulting in the inhibition of viral specific RNA polymerase, disrupting messenger RNA and nucleic acid synthesis.

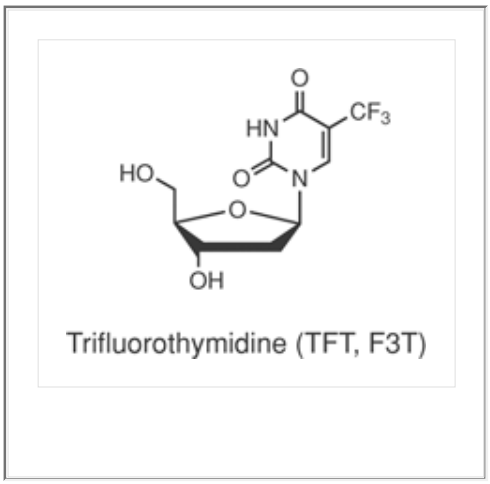
Clinical application

Ribavirin is highly active against influenza A and B viruses and the parainfluenza group of viruses, genital herpes, herpes zoster, measles, and acute hepatitis types A, B, and C. Aerosolized ribavirin has been approved by the U.S. FDA for the treatment of lower respiratory tract infections (bronchiolitis and pneumonia) and serious RSV infections, but it can cause cardiopulmonary and immunologic disorders in children (Table 43.3). Ribavirin inhibits in vitro replication of HIV-1. Clinically, ribavirin has been shown to delay the onset of full-blown AIDS in patients with early symptoms of HIV infection. Some viruses are less susceptible, such as poliovirus, herpesviruses excluding varicella, vaccinia, mumps, reovirus, and rotavirus. A randomized, double-blind study of aerosolized ribavirin treatment of infants with RSV infections indicated significant improvement in the severity of infection, with a decrease in viral shedding (54).

Pharmacokinetics

Oral or IV forms of ribavirin are useful in the prevention and treatment of Lassa fever. The oral bioavailability is approximately 45%, and the serum half-life is 9 hours. Peak plasma level after 1 hour is 1 to 3 mg/mL. Intravenous administration of the drug has higher peak plasma levels. Aerosol preparation delivery of drug (0.8 mg/kg/hour) produced drug levels in respiratory secretions of 50 to 200 mg/mL (Table 43.3). The clinical benefits of this agent are yet to be confirmed. Its few side effects generally are limited to GI disturbances, such as nausea, vomiting, and diarrhea. The drug is contraindicated in patients with asthma because of deterioration of pulmonary function. Viral strains susceptible to ribavirin have not been found to develop drug resistance, as is the case with other antiviral agents, such as acyclovir, idoxuridine, and bromovinyldeoxyuridine.

Trifluorothymidine



Trifluorothymidine (TFT, F3T)

Mechanism of action

Trifluorothymidine is a fluorinated pyridine nucleoside structurally related to idoxuridine (55). It has been approved by the U.S. FDA and is a potent, specific inhibitor of replication of HSV-1 in vitro. Its mechanism of action is similar to that of idoxuridine. Like other antiherpes drugs, it is first phos-phorylated by thymidine kinase to mono-, di-, and triphosphate forms, which are then incorporated into viral DNA in place of thymidine to stop the formation of late virus mRNA and subsequent synthesis of the virion proteins.

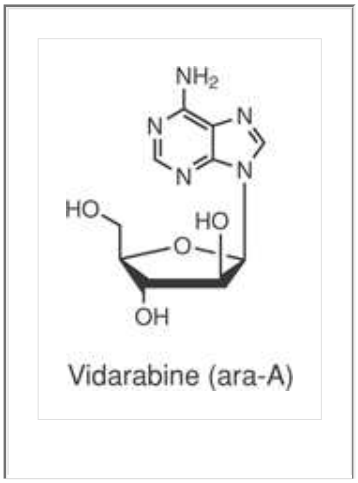
Clinical application

Trifluorothymidine, because of its greater solubility in water, is active against HSV-1 and HSV-2. It also is useful in treating infections caused by human CMV and VZV infections (Table 43.3). The advantage of use of this agent over idoxuridine is its high topical efficacy in the cure of primary keratoconjunctivitis and recurrent epithelial keratitis. It also is useful for difficult cases of herpetic iritis and established stromal keratitis.

Pharmacokinetics

Trifluorothymidine is available as a 1% ophthalmic solution, which is effective in dendritic ulcers. Generally, a 1% eye solution of trifluorothymidine is well tolerated. Cross-hypersensitivity and cross-toxicity between trifluorothymidine, idoxuridine, and vidarabine are rare. The most frequent side effects are temporary burning, stinging, localized edema, and bone marrow toxicity. It is less toxic but more expensive than idoxuridine. Trifluorothymidine, when given IV, shows a plasma half-life of 18 minutes and is excreted in the urine either unchanged or as the inactive metabolite 5-carboxyuracil.

Vidarabine



Vidarabine (ara-A)

Mechanism of action

Vidarabine is an adenosine nucleoside obtained from cultures of *Streptomyces antibioticus* (56). Cellular enzymes convert vidarabine to mono-, di-, and triphosphate derivatives that interfere with viral nucleic acid replication, specifically inhibiting the early steps in DNA synthesis. This agent was used originally as an antineoplastic drug. Its antiviral effect is, in some cases, superior to that of idoxuridine or cytarabine.

Clinical application

Vidarabine is used mainly in human HSV-1 and HSV-2 encephalitis, decreasing the mortality rate from 70 to 30%. Whitley et al. (57) reported that early vidarabine therapy is helpful in controlling complications of localized or disseminated herpes zoster in immunocompromised patients. Vidarabine also is useful in neonatal herpes labialis or genitalis, vaccinia virus, adenovirus, RNA viruses, papovavirus, CMV, and smallpox virus infections. Given the efficacy of vidarabine in certain viral infections, the U.S. FDA approved a 3% ointment for the treatment of herpes simplex keratoconjunctivitis and recurrent epithelial keratitis, and a 2% IV injection for the treatment of herpes simplex encephalitis and herpes zoster infections (Table 43.3). A topical ophthalmic preparation of vidarabine is useful in herpes simplex keratitis but shows little promise in herpes simplex labialis or genitalis. The monophosphate esters of vidarabine are more water-soluble and can be used in smaller volumes and even intramuscularly. These esters are under clinical investigation for the treatment of hepatitis B, systemic and cutaneous herpes simplex, and herpes zoster virus infections in immunocompromised patients.

Pharmacokinetics

Vidarabine is deaminated rapidly by adenosine deaminase, which is present in serum and red blood cells. The enzyme converts vidarabine to its principal metabolite, arabinosyl hypoxanthine (ara-HX), which has weak antiviral activity (Fig. 43.8) (58). The half-life of vidarabine is approximately 1 hour, whereas ara-HX has a half-life of 3.5 hours. The drug is detected mostly in the kidney, liver, and spleen, because 50% of it is recovered in the urine as ara-HX. Levels of vidarabine in CSF fluid are 50% of those in the plasma.

The most common side effects of vidarabine are GI disturbances, such as anorexia, nausea, vomiting, and diarrhea. The CNS side effects include tremors, dizziness, pain syndromes, and seizures. Bone marrow suppression is reported at higher doses. Because vidarabine is reported to be mutagenic, carcinogenic, and teratogenic in animal studies, its use in pregnant women is to be avoided. Allopurinol and theophylline may interfere with the metabolism of vidarabine at higher doses because of the xanthine oxidase metabolism of vidarabine. Therefore, this agent should be avoided or given with caution to patients receiving these medications concurrently. Also, adjustment of the dose is necessary in patients with renal insufficiency.

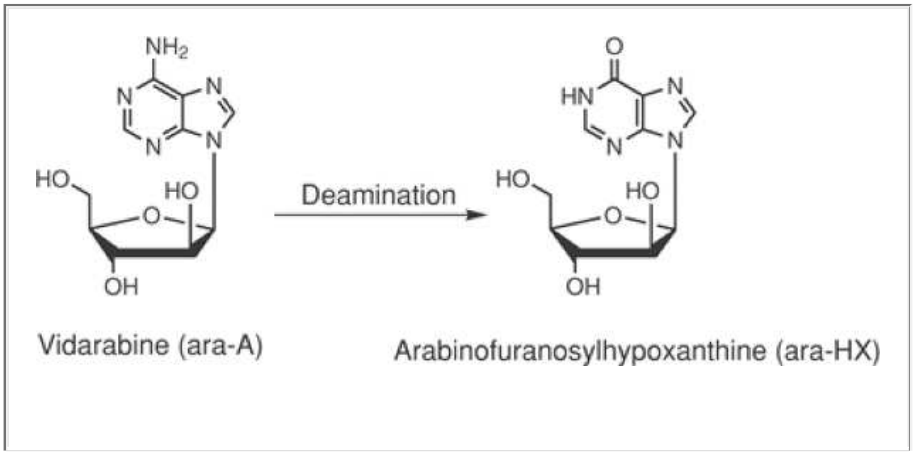


Fig. 43.8. Metabolism of vidarabine.

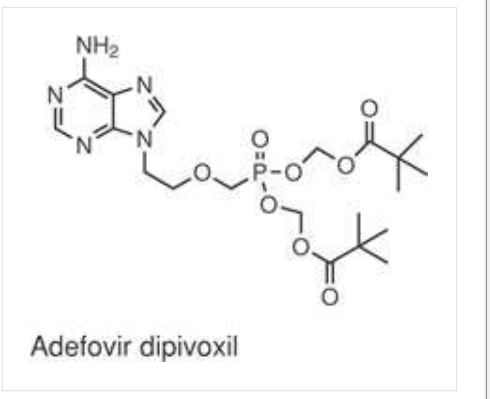
Adefovir Dipivoxil (59)



Mechanism of action

Adefovir dipivoxil is an orally active prodrug indicated for the treatment of chronic hepatitis B. The drug is hydrolyzed by extracellular esterases to produce adefovir, which in turn is phosphorylated by adenylate kinase to adefovir diphosphate, which inhibits HBV DNA polymerase. Incorporation of adefovir into viral DNA also leads to DNA chain termination. As shown in Figure 43.9, adefovir dipivoxyl is activated in two steps involving an esterase that exposes a free phosphate group (adefovir), followed by addition of a second phosphate by adenylate kinase to form adefovir diphosphate, the active form of the drug.

Pharmacokinetics

Adefovir is poorly absorbed orally, but the bioavailability of adefovir dipivoxil reaches approximately 59%. The drug is absorbed to an equal extent with or without the presence of food. Adefovir is excreted renally unchanged.

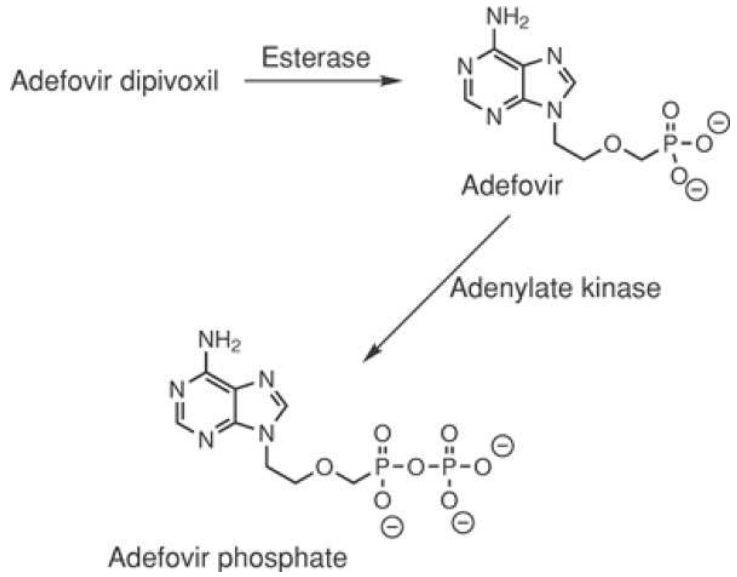


Fig. 43.9. Activation of the pro-drug adeflovir dipivoxyl by esterase and adenylate kinase.

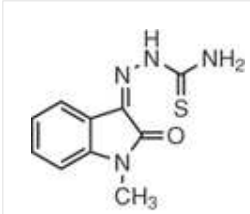
Methisazone: An Agent Affecting Translation of Ribosomes



Historically, methisazone was one of the first antiviral compounds used in clinical practice. Methisazone (60) acts by interfering with the translation of mRNA message at the ribosome, preventing protein synthesis. Ultimately, it produced a defect in protein incorporation into the virus. Although viral DNA increases and host cells are damaged, an infectious virus is not produced. Methisazone displayed activity against poxviruses, including variola and vaccinia (61). Some RNA viruses, such as rhinoviruses, echoviruses, reoviruses, influenza, parainfluenza, and polioviruses, also were inhibited. Methisazone is not available in the United States and appears to have minimal usefulness today.

Clinical application

Adefovir dipivoxil joins interferon and lamivudine in the treatment of chronic HBV. It can be used singly or

in combination with lamivudine. Early clinical studies indicate benefit of the use of adefovir dipivoxil to treat lamivudine-resistant HBV with a low level of resistant virus developing to monotherapy with adefovir dipivoxil.

Antiretroviral (Anti-HIV) Agents Including Protease Inhibitors (62,63)

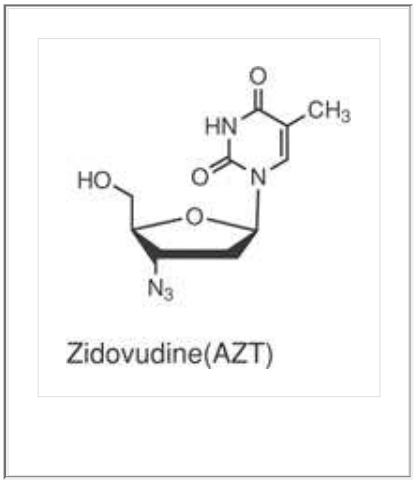
There can be no permanent cure of AIDS without the prevention or elimination of HIV infection, but patients with AIDS can prolong their life if the disease is diagnosed early and treatment is promptly initiated. Initial HIV treatment requires specific drugs that inhibit RT and HIV protease (i.e., protease inhibitors [PIs]). In advanced HIV infection, AIDS is complicated by other organisms that proliferate in immunocompromised hosts, known as opportunistic infections. Such patients are treated symptomatically with a variety of drugs depending on the opportunistic infections (64,65,66). Anti-HIV agents have side effects, but patients can be managed by a careful monitoring of the drugs. Opportunistic diseases include infections by parasites, bacteria, fungi, and viruses. Neoplasms, including Kaposi's sarcoma and Burkitt's lymphoma, also commonly occur.

Anti-HIV agents are classified according to the mode of action. The drugs inhibiting RT interfere with replication of HIV and stop synthesis of infective viral particles. They are further classified into nucleoside and nonnucleoside RT inhibitors. The drugs inhibiting HIV protease inactivate RT activity and block release of viral particles from the infected cells. The chemistry, pharmacokinetics, side effects, toxicity, and drug interactions of RT inhibitors and PIs are discussed below.

Nucleoside Reverse Transcriptase Inhibitors (67,68,69)

The synthesis of viral DNA under the direction of RT requires the availability of purines and pyrimidine nucleosides and nucleotides. Therefore, it is not surprising that a variety of chemical modifications of natural nucleosides have been investigated. Two such modifications have resulted in active drugs. Removal of the 3′-hydroxyl group of the deoxynucleosides has given rise to dideoxyadenosine (didanosine is the prodrug for this derivative) (70,71), dideoxycytodine (72,73,74), and didehydrodideoxythymidine (75). Replacement of the 3′-deoxy with an azido group has given 3′-azidothymidine (76,77,78,79) and 3′-azidouridine (no longer used as a drug) (80). All of these drugs have similar mechanisms of action in that their incorporation into the viral DNA will ultimately lead to chain-terminating blockade because of the lack of a 3′-hydroxyl needed for the DNA propagation.

Zidovudine



Mechanism of Action

Zidovudine (AZT, ZDV) is an analogue of thymidine in which the azido group is substituted at the 3-carbon atom of the dideoxyribose moiety. It is active against RNA tumor viruses (retroviruses) that are the causative agents of AIDS and T-cell leukemia. Retroviruses, by virtue of RT, direct the synthesis of a provirus (DNA copy of a viral RNA genome). Proviral DNA integrates into the normal cell DNA, leading to

the HIV infection. Zidovudine is converted to 5′-mono-, di-, and triphosphates by the cellular thymidine kinase. These phosphates are then incorporated into proviral DNA, because RT uses ZDV-triphosphate as a substrate. This process prevents normal 5′,3′-phosphodiester bonding, resulting in termination of DNA chain elongation because of the presence of an azido group in ZDV. The multiplication of HIV is halted by selective inhibition of RT and, thus, viral DNA polymerase by ZDV-triphosphate at the required dose concentration. Zidovudine is a potent inhibitor of HIV-1, but it also inhibits HIV-2 and EBV.

Clinical Application

Zidovudine is used in AIDS and AIDS-related complex (ARC) to control opportunistic infections by raising absolute CD4 lymphocyte counts. It was first synthesized in 1964 (81), and its biological activity was reported in 1974 (82). In 1986, Yarchoan et al. (83) demonstrated application of ZDV in clinical trials of AIDS and related diseases. Zidovudine is recommended in the control of the disease in asymptomatic patients in whom absolute CD4 lymphocyte counts are less than 200/mm^3. It prolongs the life of patients affected with

Pneumocystis carinii pneumonia and improves the condition of patients with advanced ARC by reducing the severity and frequency of opportunistic infections. Substantial benefits are obtained when the drug is given after the CD4 cell counts fall to less than 500/mm^3. Therefore, ZDV is used in early and advanced symptomatic treatment of patients with AIDS or ARC. Use with other RT inhibitors or in combination with PIs is more beneficial when resistance to ZDV occurs.

Human immunodeficiency virus attacks susceptible cells and interacts mainly with CD4 cell surface proteins of helper T cells. As discussed above, the viral glycoprotein gp120 forms a complex with CD4 receptor on host cells and enters the cells by endocytosis. The sequence of events is shown in Figure 43.2. Ultimately, the immune system of the host is altered, and symptoms of AIDS appear. Patients with AIDS have symptoms such as high fever, weight loss, lymphadenopathy, chronic diarrhea, myalgias, fatigue, and night sweats. Zidovudine is given in such conditions; however, the drug is toxic to the bone marrow and causes macrocytic anemia, neutropenia, and granulocytopenia. Other adverse reactions include headache, insomnia, nausea, vomiting, seizures, myalgias, and confusion.

Pharmacokinetics

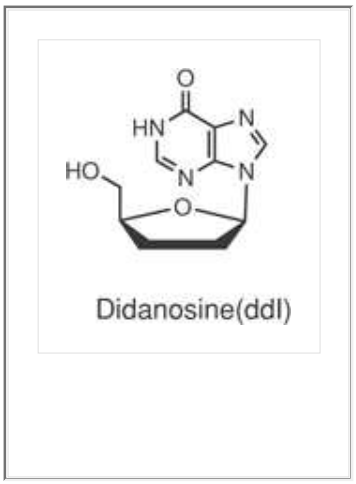
Zidovudine is available in various dosage forms for oral or IV administration (Table 43.4). For asymptomatic adults, the initial recommended dosage is 1,200 mg daily (200 mg every 4 hours), which is reduced to 600 mg daily (100 mg every 4 hours) for patients with advanced disease. The maintenance dose is 600 mg daily in symptomatic patients. Zidovudine is sensitive to heat and light because of its azide group and should be stored in colored bottles at 15 to 25°C. It is well absorbed through the GI tract, and it concentrates in the body tissues and fluids, including the CSF. The bioavailability of the drug was found to be approximately 65%. Its half-life is approximately 1 hour. Intravenous doses of 2.5 mg/kg or oral doses of 5 mg/kg yielded peak plasma concentrations of 5 mmol/L. Plasma protein binding was approximately 30%. Most of the drug is converted to its inactive glucuronide metabolite and is excreted unchanged through urine. Additionally, ZDV crosses the blood-brain barrier. Pentamidine, dapsone, amphotericin B, flucytosine, and doxorubicin may increase the toxic effects of ZDV. Probencid prolongs the plasma half-life of the drug.

Table 43.4. HIV Reverse Transcriptase Inhibitors

Generic Name	Common Name	Trade Name	Dosage Form
Nucleoside Reverse Transcriptase Inhibitors			
Zidovudine	AZT	Retrovir	Tablet (300 mg), Capsule

	ZDV		(100 mg), syrup (50 mg/5 mL), injectable (10 mg/mL)
Didanosine	ddI	Videx	Tablet (25, 50, 100, 150, and 200 mg)
Dideoxyadenosine	ddA		Powder for oral solution (100, 167, and 250 mg)
Zalcitabine	ddC	Hivid	Tablet (0.375 mg)
Stavudine	D4T	Zerit	Capsule (15, 20, 30, and 40 mg), powder for oral solution (1 mg/mL)
Lamivudine	3TC	Epivir	Tablet (150 mg), solution (10 mg/mL)
		Epivir HBV	Tablet (100 mg), solution (5 mg/mL)
Abacavir	ABC	Ziagen	Tablet (300 mg), solution (20 mg/mL)
Tenofovir disoproxil		Viread	Tablet (300 mg)
Emtricitabine		Emtriva	Caplet (200 mg)
Nonnucleoside Reverse Transcriptase Inhibitors			
Nevirapine		Viramune	Tablet (200 mg)
Delavirdine	DLV	Rescriptor	Tablet (100 mg)
Efavirenz		Sustiva	Capsule (50, 100, and 200 mg)

Didanosine



Mechanism of Action

Didanosine (ddI) is a purine dideoxynucleoside, which is an analogue of inosine. Chemically, it is 2′,3′-dideoxyinosine, and it differs from inosine by having hydrogen atoms in place of the 2′- and 3′-hydroxyl groups on the ribose ring. Didanosine is a pro-drug that is bioactivated by metabolism to dideoxyadenosine triphosphate, which is a competitive inhibitor of viral RT and is incorporated into the developing viral DNA in place of deoxyladenosine triphosphate. As such, this agent causes chain termination because of the absence of a 3′-hydroxyl group. Didanosine inhibits HIV RT and exerts a virustatic effect on the retroviruses. Combined with ZDV, antiretroviral activity of ddI is increased.

Pharmacokinetics

Didanosine has a plasma half-life of 1.5 hours and is given in a 200 mg dose twice daily. Oral bioavailability of the drug is approximately 25% at doses of 7 mg/kg or less. Didanosine significantly decreased p24 antigen levels and increased CD4 cell counts. Viral resistance to ddI occurred after treatment for 1 year. Didanosine is less toxic than ZDV. The CSF fluid/plasma

ratio of ddI is 0.2. Didanosine is ultimately converted to hypoxanthine, xanthine, and uric acid through the usual metabolic pathway for purines (Fig. 43.10). The latter is a nontoxic metabolic product.

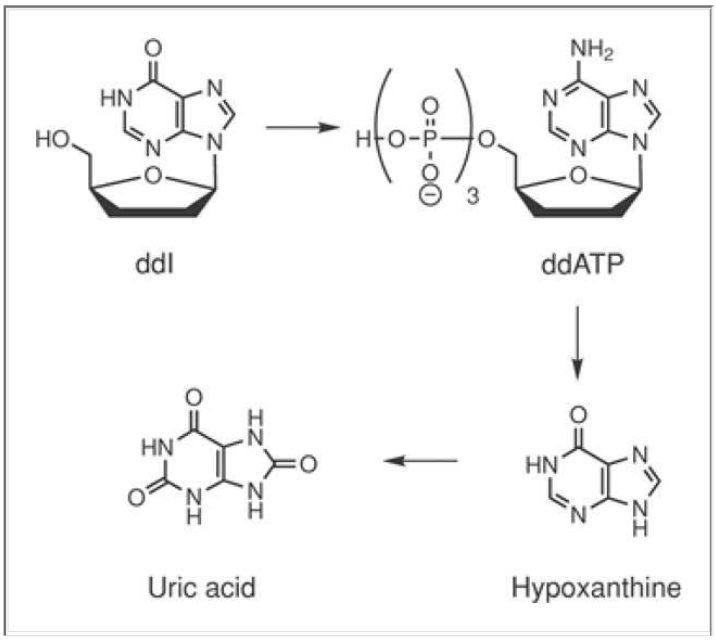


Fig. 43.10. Metabolism of didanosine.

Didanosine is given in advanced HIV infection, ZDV intolerance, or significant clinical/immunologic deterioration. The major side effects of ddI are painful peripheral neuropathy and pancreatitis. Some of the minor side effects include abdominal pain, nausea, and vomiting. The use of products, such as pentamidine, sulfonamides, and cimetidine, should be avoided with ddI. The combination of ddI with ZDV is beneficial, however, because these drugs have different toxicity profile.

Zalcitabine, lamivudine, and emtricitabine

These three synthetic pyrimidine nucleoside analogues are quite similar in structure and in mechanism of action (Fig. 43.11). The three compounds differ from 2′-deoxycytidine in that the 3′-hydroxymethylene group of 2′-deoxyriboribose moiety is replaced with either a methylene or a sulfur atom. Additionally, in the case of emtricitabine, the C_5 hydrogen is replaced with a fluoro atom. In all three cases, these drugs act as pro-drugs and must first be phosphorylated to the respective 5′-triphosphates derivatives, which are the active forms. The resulting triphosphates compete with the normal substrate (deoxycytidine-5′-triphosphate) for incorporation into the viral DNA by inhibiting HIV RT, which ultimately leads to termination of viral DNA elongation.

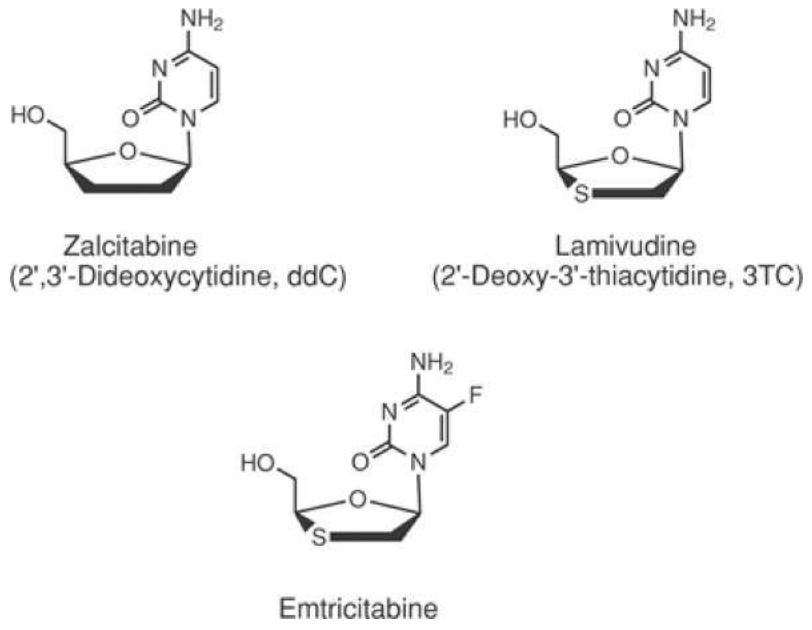

Fig. 43.11. Deoxycytidine analogues as nucleoside reverse transcriptase inhibitors.

Zalcitabine

Zalcitabine (ddC) (Table 43.4) is a useful alternate drug to ZDV and is given in combination with ZDV when CD4 cell counts fall to less than 300 cells/mm^3. Monotherapy with ddC is more active than ZDV. Its oral bioavailability is 87%, and its plasma half-life is approximately 1 hour. It has side effects, such as stomatitis, rash, fever, malaise, arthritis, and arthralgia. In low doses (0.005 mg/kg every 4 hours), ddC produces sustained decrease in p24 antigen level and increase in CD4 cell counts. The CSF fluid/plasma ratio of ddC is 0.2.

Following oral administration, bioavailability of ddC is less than 80%, which is further reduced when

taken with food. The mean maximum plasma concentration of the drug also is reduced from 25.2 to 15.5 ng/mL when the drug was taken with food. Dideoxyuridine is the major metabolite in urine and feces. The drug penetrates the blood-brain barrier. The major toxicity of ddC is peripheral neuropathy, in which case it should be discontinued. In some cases, pancreatitis occurs when given alone or in combination with ZDV.

Lamivudine (84)

Lamivudine (3TC) (Fig. 43.11) usually is given with other antiretroviral agents, such as ZDV or D4T. 3TC at a dose of 600 mg/day reduced HIV cells by 75%, and in combination with ZDV, the reduction in viral load was 94%. 3TC is rapidly absorbed through the GI tract. Its bioavailability is approximately 86% after oral administration of 2 mg/kg twice daily; peak serum 3TC concentration is approximately 2 mg/mL. 3TC binding to human plasma is approximately 36%. In vivo, it is converted to the *trans* sulfoxide metabolite, although a majority of the drug is eliminated unchanged in urine.

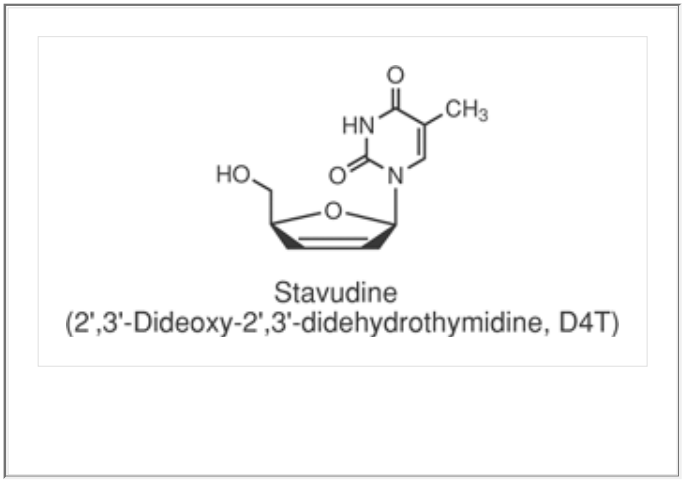
The U.S. FDA approved 3TC in combination with ZDV for the treatment of disease progression caused by HIV infection. The combinations of 3TC with ddI, ddC, or D4T also are used for advanced HIV infection. Such combinations have the ability to delay resistance to ZDV and restore ZDV sensitivity in patients with AIDS. Recently, oral therapy with lower doses of 3TC (Table 43.4) has been approved by the U.S. FDA for the treatment of chronic hepatitis B. Peripheral neuropathy and GI disturbances are the major side effects of 3TC. The minor side effects are nausea, vomiting, and diarrhea.

Emtricitabine (85)

Emtricitabine (Fig. 43.11) is an orally active nucleoside RT inhibitor that is administered once daily. The (–)-enantiomer is the most active form of the drug, although the (+)-isomer also is active. The drug is not bound to plasma protein, and approximately 86% is excreted unchanged in the urine. The only

metabolites identified consist of the 3′-sulfoxide and the 2′-O-glucuronide. Emtricitabine is reported to be more active than lamivudine, with a low level of resistance developing when used in combination therapy with efavirenz and didanosine.

Stavudine

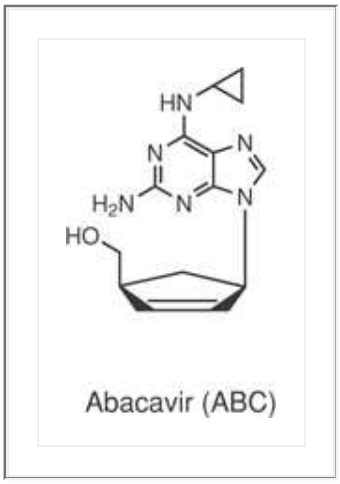


Stavudine (D4T) is a pyrimidine nucleoside analogue that has significant activity against HIV-1 after intracellular conversion of the drug to a D4T-triphosphate. It differs in structure from thymidine by the replacement of the 3′-hydroxyl group with a hydrogen atom and a double bond in the 2′,3′-positions on the deoxyribose ring. It decreases p24 antigen and raised CD4 cell counts. D4T is beneficial for patients where CD4 cell counts do not decrease to less than 300 cells/mm^3 with ZDV and ddI. It is more effective than ZDV or ddC in treating patients by delaying the progression of HIV infection. It is recommended for patients with advanced HIV infection.

Pharmacokinetics

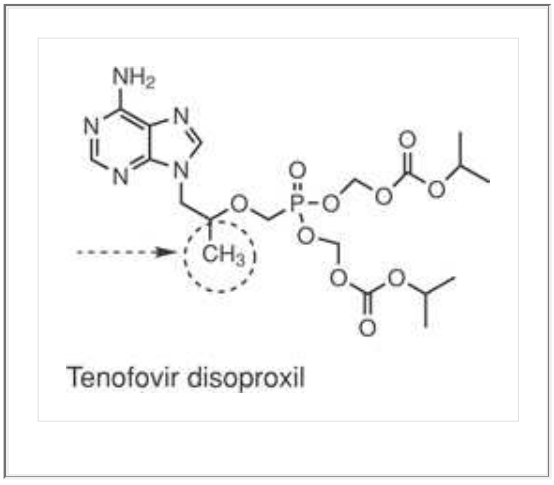
D4T is rapidly absorbed, and absolute bioavailability in adults is 85% at an oral dose of 4 mg/kg (Table 43.4). A peak plasma concentration occurs in dose-dependent manner within 1 hour. It can be taken with food. The apparent volume distribution after oral dose is 66 L. The plasma half-life of D4T is approximately 1.5 hours, and the intracellular half-life of D4T-triphosphate is 3.5 hours. It is less toxic to bone marrow but causes peripheral neuropathic toxicity. The side effects include pain, tingling, and numbness in the hands and feet.

Abacavir



Abacavir sulfate (ABC) was approved in 1998 as a nucleoside RT inhibitor to be used in combination with other drugs for the treatment of HIV and AIDS. The drug is extensively metabolized via stepwise phosphorylation to 5′-mono-, di-, and triphosphate. Abacavir is well absorbed (>75%) and penetrates the CNS. The drug can be taken without regard to meals. The drug does not show any clinically significant drug–drug interactions. Abacavir has been reported to produce life-threatening hypersensitivity reactions. The major use of abacavir appears to be in combination with other nucleoside RT inhibitors. A fixed-combination product has recently been approved by the U.S. FDA consisting of 300 mg of ABC, 150 mg of 3TC, and 300 mg of ZDV (Trizivar). The combination has been shown to be superior to other combinations in reducing viral load as well as to show improvement in CD4 cell count. The most common adverse effects reported with abacavir include headache, nausea, vomiting, malaise, and diarrhea.

Tenofovir disoproxil (86)



Tenofovir disoproxil is a prodrug in a manner similar to that of adefovir dipivoxil. In both cases, the phosphate esters are removed through the action of plasma esterase, leading in this case to tenofovir,

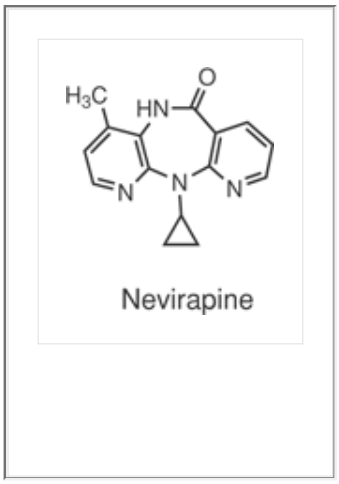
which differs from adefovir by the presence of the indicated methyl group (Fig. 43.9). Tenofovir disoproxil exhibits good bioavailability (25%), which is improved in the presence of food (35%). The drug is approved for the treatment of HIV infections in adult patients. Tenofovir diphosphate is an HIV RT inhibitor. The active form of tenofovir is the tenofovir diphosphate, which competes with dATP for incorporation into viral DNA, and when incorporated, tenofovir diphosphate results in premature termination of DNA growth and inhibition of DNA polymerase. Tenofovir disoproxil is indicated for treatment-experienced patients with HIV-1. The drug also appears to be effective in treatment-naive patients, but initial approval is for treatment-experienced patients. The drug is administered as one tablet taken once daily (Table 43.4). It is recommended that the drug be combined with other RT inhibitors or HIV PIs, which results in additive or synergistic activity.

Nonnucleoside RT Inhibitors

The U.S. FDA recently approved several nonnucleosides that inhibit RT activity. They are used with nucleoside drugs to obtain synergistic activity in decreasing the viral load and increasing the CD4 cell count. These drugs are primarily designed and synthesized by protein structure–based drug design methodologies. Their use as monotherapy may be limited because of rapid onset of resistance and hypersensitivity reactions. Interaction of nonnucleoside drugs, however, with other PIs, such as saquinavir, indinavir, and ritonavir, is being investigated. Also, interaction of these

drugs with clarithromycin, ketoconazole, rifabutin, and rifampin are currently being studied. Nonnucleosides that inhibit RT activity are discussed below.

Nevirapine



Nevirapine and its analogues exhibit antiretroviral effect against azothymidine-resistant HIV strains (87). Nevirapine in combination with ZDV and ddI produced approximately 18% higher CD4 cell counts and a decrease in viral load compared with patients who took ZDV and ddI. Nevirapine is recommended with nucleosides for patients infected with HIV-1 who have experienced clinical or immunologic deterioration. The significant side effects of nevirapine are liver dysfunction and skin rashes.

Mechanism of Action

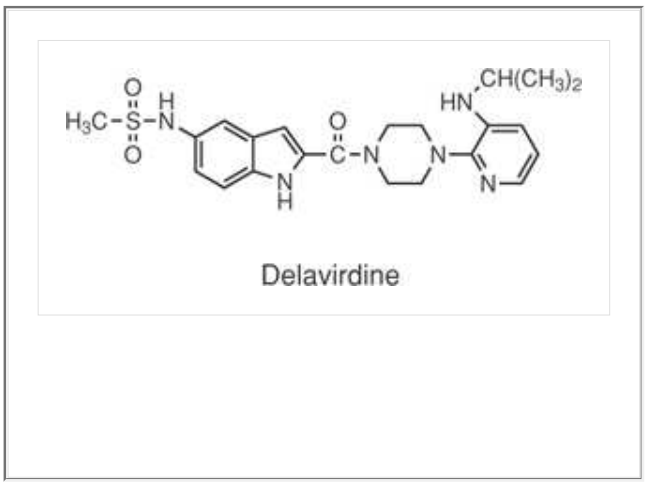
Nevirapine is a dipyridodiazepinone derivative that binds directly to RT. Thus, it blocks RNA- and DNA-dependent polymerase activities by causing a disruption of the enzyme's catalytic site. The activity of nevirapine does not compete with template or nucleoside triphosphate. The HIV-2 RT and human DNA polymerases are not inhibited by nevirapine. The 50% inhibitory concentration ranged within 10 to 100 nM against HIV-1.

Pharmacokinetics

Nevirapine is rapidly absorbed after oral administration, and its bioavailability is approximately 95%.

Peak plasma nevirapine concentrations of 2 ± 0.4 mg/mL (7.5 mM) are obtained in 4 hours following a single 200 mg dose (Table 43.4). Following multiple doses, nevirapine concentrations appear to increase linearly in the dose range of 200 to 400 mg/day. Nevirapine is approximately 60% bound to plasma proteins in the plasma concentration range of 1 to 10 mg/mL. It readily crosses the placenta and is found in breast milk. Nevirapine is metabolized as glucuronide conjugates of hydroxylated metabolites, which are excreted in urine. In vivo, ketoconazole did not produce any significant inhibitory effect on nevirapine metabolism. The plasma concentrations of nevirapine were elevated or reduced in patients receiving cimetidine or rifabutin, respectively.

Delavirdine



Delavirdine, a bisheteroarylpiperazine derivative, is a potent nonnucleoside RT inhibitor of activity specific for HIV-1 (88). The U.S. FDA has approved this drug for use in combination with other anti-HIV agents (Table 43.4). In Phase I/II study trials, it demonstrated sustained improvements in CD4 cell counts, p24 antigen levels, and RNA viral load. Promising results were obtained when the drug was used in two- or three-drug combinations with nucleoside drugs. Combination of delavirdine with ddI, ddC, or ZDV demonstrated additive or synergistic effects. Delavirdine with ZDV, however, was more beneficial in early HIV infection. Combinations of nevirapine and delavirdine had an antagonistic effect on HIV-1 RT inhibition.

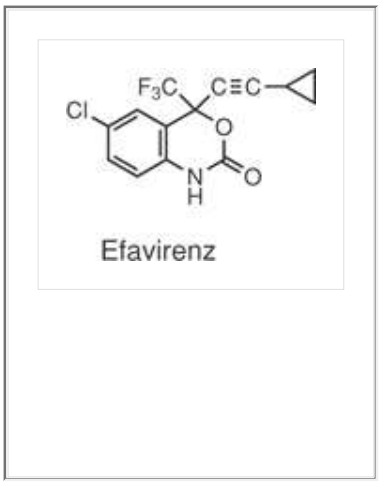
Mechanism of Action

Delavirdine directly inhibits RT and DNA-directed DNA polymerase activities of HIV-1 after the formation of the enzyme–substrate complexes, thereby causing chain-termination effects.

Pharmacokinetics

Delaviradine is rapidly absorbed by oral administration and peak plasma concentration was obtained in 1 hour. Administration of delaviridine at 400 mg three times daily resulted in peak plasma concentration of 45 mM. The single dose bioavailability of delaviridine tablets relative to oral solution was approximate 85%. The 50% inhibitory concentration for delavirdine against RT activity was 6.0 nM. Delaviridine is extensively bound to plasma protein (~98%). It is metabolized to its N-desisopropyl metabolite in liver, and the pharmacokinetics is nonlinear. Clarithromycin, rifabutin, or ergot alkaloid derivatives are predicted to increase plasma concentration of delaviridine. Skin rashes are the major side effect of delavirdine therapy. Cross-resistance between delavidine and PIs, such as indinavir, nelfinavir, ritonavir, and saquinavir, is unlikely because of action on different enzyme targets.

Efavirenz



Efavirenz is a nonnucleoside RT inhibitor that is a potent inhibitor of wild-type as well as resistant mutant HIV-1 (89). Inhibition of up to 95% is reported for efavirenz at concentrations of 1.5 mM. In combination with indinavir, a mean reduction in HIV RNA of 1.68 log and an increase in CD4 cell counts of 96 cells/mm^3 have been reported. Coadministration of efavirenz with indinavir reduced the indinavir concentration (AUC) by approximately 35%.

Efavirenz is administered once a day and can be used as a substitute for indinavir in combination therapy with standard drugs, such as ZDV and 3TC. Because it is given once a day, it cuts down the number of pills that a patient with AIDS must swallow. In the current cocktail therapy used for patients with AIDS, efavirenz is a good option to reduce the many side effects of cocktail therapy. It is administered to both adults and children and may be less expensive than indinavir.

The side effects of efavirenz include dizziness, insomnia, impaired concentration, abnormal dreams, and drowsiness. The most common adverse effect is a skin rash. Other side effects are diarrhea, headache, and dizziness. Efavirenz is recommended to be taken at bedtime with or without food. Patients on efavirenz should avoid driving or operating machinery and the intake of high fat meals. It should always be taken in combination with at least one other anti-HIV agent. Efavirenz is contraindicated with midazolam, triazolam, or ergot derivatives.

HIV Protease Inhibitors (Table 43.5) (90)

The HIV protease is an enzyme that is essential for viral growth and that mediates the posttranslational modification of core proteins into structural proteins. The structural proteins p7, p9, p17, and p24, which play important roles in infectivity of HIV, are products of a *pol* gene. The HIV genome contains various regions designated as genes, such as the *gag* and *gag-pol* genes, that are translated as polyproteins and form immature viral particles. These precursor protein molecules are cleaved by a viral *pol*-encoded *aspartic proteinase to form the desired structural proteins of the mature viral particle. The HIV protease also activates RT and plays an important role in the release of infectious viral particles. Thus, an area of considerable interest has been the development of drugs that act as inhibitors of protease and pol gene. Such inhibitors act on HIV protease and prevent posttranslational processing and budding of immature viral particles from the infected cells. This group of drugs represents a major breakthrough in the treatment of HIV when used in combination with RT inhibitors, and their development is one of the most significant advances in medicinal chemistry.*

Mechanism of action

The HIV protease exists as a dimer in which each monomer contains one of two conserved aspartate residues at the active site. Drugs that inhibit HIV protease are designed as transition-state mimetics that align at the active site of HIV-1 protease, as defined by three-dimensional crystallographic analysis of the protein structure. A number of oligopeptide-like analogues have been synthesized that differentially inhibit viral and mammalian aspartic proteases, and the most useful of these are selective for the viral

enzyme HIV-1 protease. Structurally, these agents are either peptidomimetic and nonpeptide compounds. Their effectiveness is related to their ability to inhibit the *gag-pol* gene, which processes p24, p55, and p160. Consequently, the infectivity of HIV-1 is diminished.

Table 43.5. HIV Protease Inhibitors

Generic Name	Common Name	Trade Name	Dosage Form(mg/unit)
Saquinavir		Invirase	Capsule (200 mg)
		Fortovase	Capsule (200 mg)
Ritonavir	RTV	Norvir	Capsule (200 mg)
Indinavir	IDV	Crixivan	Capsule (200 and 400 mg)
Nelfinavir	NFV	Viracept	Tablet (250 mg), powder (50 mg/g)
Amprenavir	APV	Agenerase	Capsule (50 and 150 mg), solution (15 mg/mL)
Lopinavir/ritonavir	LPV/r	Kaletra	Capsule (133.3/33.3 mg), solution (80/20 mg/mL)
Atazanavir	ATZ	Reyataz	Capsule (150 and 200 mg)
Fosamprenavir	Fos-APV	Lexiva	Tablet (700 mg)
Tipranavir	TPV	Aptivus	Capsule (250 mg)

Although some compounds exhibit both in vitro and in vivo antiviral activities, optimization of their pharmacokinetic and pharmacodynamic properties has presented major problems. In view of the great demand for successful anti-AIDS drugs, the U.S. FDA has approved nine drugs as PIs under the accelerated approval process.

Metabolism

The PIs have a high potential for drug interactions, stemming from the fact that they are substrates for and inhibitors of the CYP3A4 enzyme system. As a result, concurrent use of PIs with other drugs metabolized by CYP3A4 may be contraindicated, and in some cases, the drug interactions can be life-threatening. The most potent cytochrome P450 (CYP450) inhibitor in this class is ritonavir (used to

advantage in combination with lopinavir); followed by indinavir, nelfinavir, and amprenavir as moderate inhibitors; and by saquinavir as the least potent inhibitor. Drug interactions have been reported with bepridil, dihydroergotamine, and a number of benzodiazepines. Marked increase in activity of amiodarone, lidocaine (systemic), quinidine, the tricyclic antidepressants, and warfarin might be expected. Other interactions have been reported to include rifampin, rifabutin phenobarbital, phenytoin, dexamethasone, or carbazepine. Because the PIs are themselves metabolized by CYP450, their action may be altered by other agents that induce or inhibit this system. In the case of rifabutin, which inhibits CYP3A4 in the gut, relative bioavailability of the PIs is increased, and the dose of the PIs may need to be decreased.

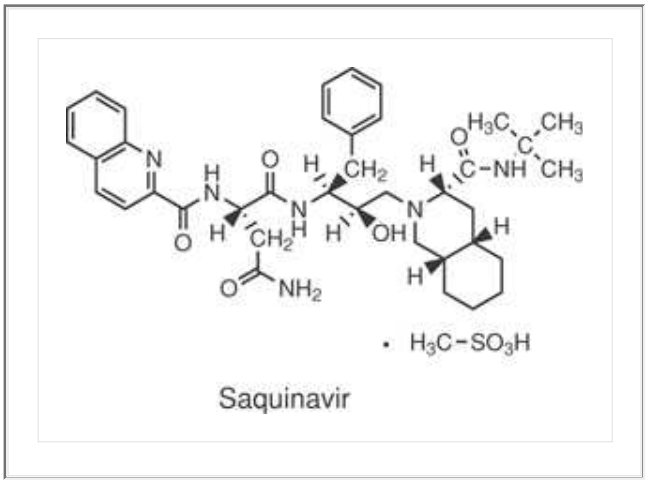
Resistance

Resistance to the transition-state peptidomimetic PIs has already become problematic. Resistance is associated with point mutations among various amino acids within the peptide chain of the HIV protease. Single-amino-acid mutations reduce the activity of

the PIs, but total resistance appears to require multiple mutations. The most susceptible mutations consist of Leu^{33} to Ile, Val, or Phe; Val^{82} to Ala, Phe, Leu, or Thr; Ile^{84} to Val; and Leu^{90} to Met. These changes are referred to a PI resistance–associated mutations. The presence of one or two such mutations leads to reduced susceptibility, whereas five or more mutations can lead to resistance.

Specific drugs

Saquinavir



Saquinavir mesylate was the first PI approved by the U.S. FDA in December 1995 (91,92). It is a carboxamide derivative that is specifically designed to inhibit HIV protease, thus preventing posttranslational formation of viral proteins. It contains a hydroxyethylamine moiety rather than the Phe-Pro scissile bond present in the normal substrate for HIV protease.

Clinical Application

Saquinavir is used in the treatment of advanced HIV infection in selected patients. Saquinavir is used concomitantly with either ZDV in untreated patients or ddC in patients previously treated with prolonged ZDV therapy. Although combined therapy did not slow progression of disease, CD4 cell counts were increased in patients infected with HIV in the United States and European countries. Triple therapy with saquinavir, ZDV, and ddC has been more effective than double therapy with saquinavir plus ZDV or ddC. Thus, combination therapy slowed disease progression and mortality.

The IC50 concentration of saquinavir in both acutely and chronically infected cells was 1 to 30 nM. In combination with ZDV, ddC, or ddI, the activity of saquinavir was increased without increased cytotoxicity. The resistance of HIV isolates to saquinavir was observed as a result of substitution

mutations in the HIV protease at amino acid positions 48 (glycine to valine) and 90 (leucine to methionine).

Pharmacokinetics

The bioavailability of saquinavir in a single, 600 mg dose following a high-fat meal was shown to be approximately 4%. Approximately 30% of a 600 mg dose of saquinavir reached the liver, where it showed first-pass metabolism. The poor bioavailability is associated with intestinal metabolism catalyzed by CYP3A4 and, possibly, CYP3A5. Additionally, P-glycoprotein found in intestinal epithelial cells acts as an efflux pump interfering with saquinavir absorption. The metabolites, mono- and dihydroxylated compounds (Fig. 43.12), are not active (93). Approximately 88 and 19% of a 600 mg oral dose was found in the feces and urine, respectively. The volume distribution following IV administration of a 12 mg dose of saquinavir was 700 L. The drug is 98% bound to plasma proteins, and a very low concentration of saquinavir was found in the CSF. As compared to multiple dosing, the steady-state AUC was 2.5-fold higher than that observed after a single dose of 600 mg in HIV-infected patients after a meal. Saquinavir has a plasma half-life of approximately 1.8 hours. Although the saquinavir hard-gel capsule used in combination with other antiretroviral drugs reduces the risk of disease progression or death, it has limited bioavailability. To overcome this limitation, the U.S. FDA has approved saquinavir soft-gel capsules. Saquinavir is well tolerated in combination with ZDV and/or ddC, and it has few side effects. Gastrointestinal disturbances, however, have been common adverse effects. Saquinavir also has a few mild side effects, such as headache, rhinitis, nausea, and diarrhea.

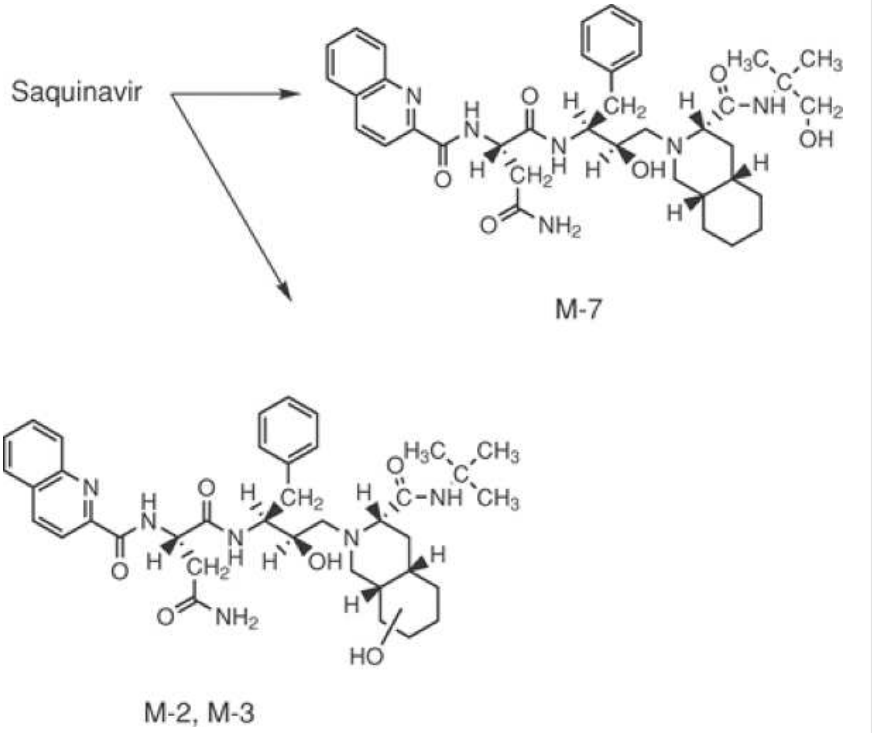


Fig. 43.12. Major metabolic products from saquinavir.

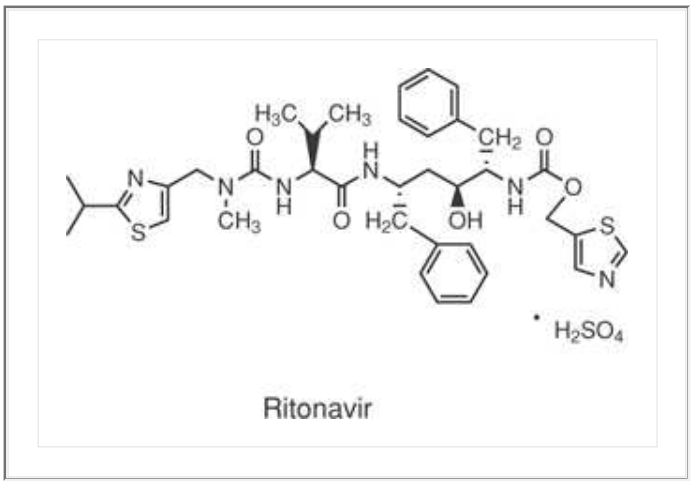
Ritonavir



Ritonavir is another HIV PI and was approved by the U.S. FDA in March 1996 (94). Ritonavir is a peptidomimetic inhibitor of both the HIV-1 and HIV-2 proteases. A 50% reduction in viral replication was obtained at 3.8 to 153 nM of ritonavir.

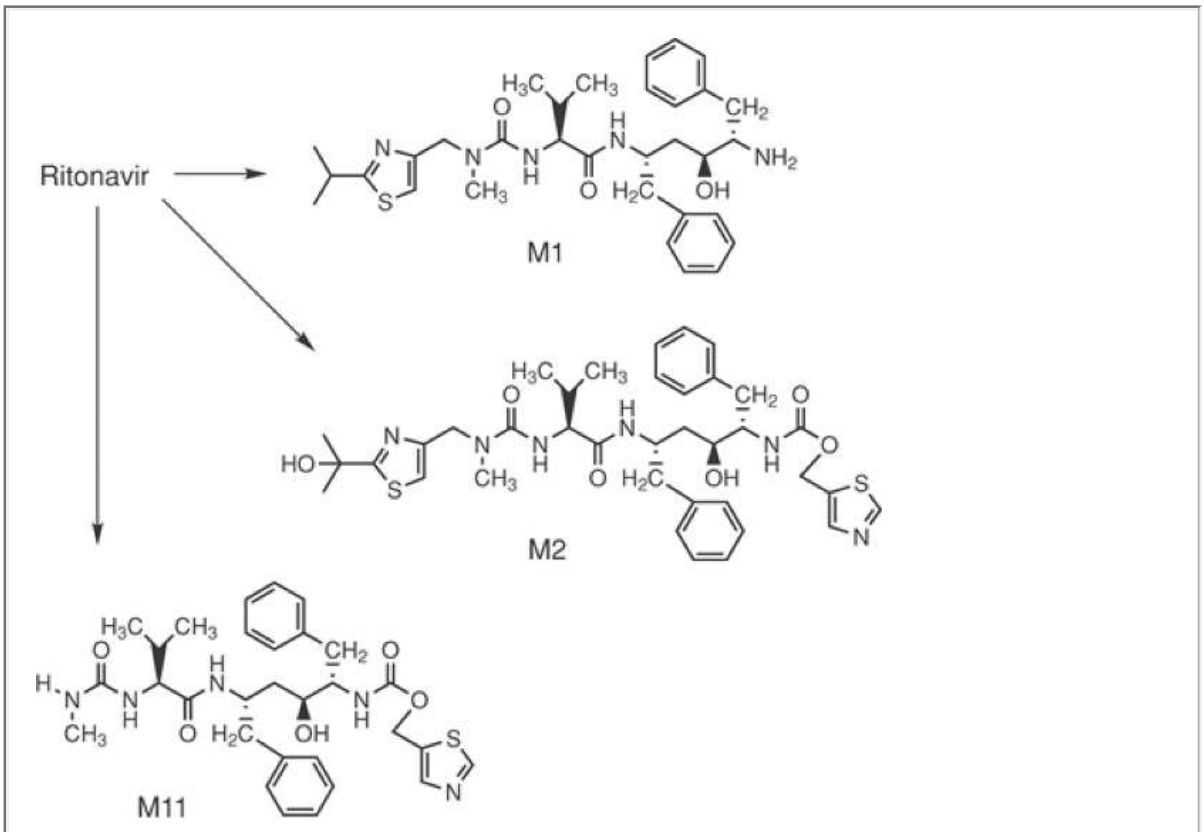


Fig. 43.13. Major metabolic products from CYP3A4 metabolism of ritonavir.

Pharmacokinetics

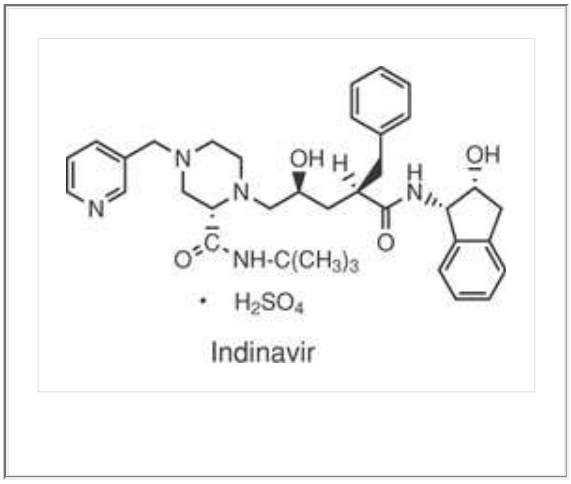
After a 600 mg dose of an oral solution, peak concentrations of ritonavir were obtained in approximately 2 or 4 hours under fasting or nonfasting conditions, respectively. Under nonfasting conditions, peak ritonavir concentrations decreased 23%, and the extent of absorption decreased 7% relative to fasting conditions. In two separate studies, the capsule and oral solution indicated AUC values of 129.5 ± 47.1

and 129.0 ± 39.3 mg/h/mL, respectively, when a 600 mg dose was given under nonfasting conditions. Five ritonavir metabolites have been isolated from human urine and feces, the most significant of which are shown in Figure 43.13 (95). The isopropylthiazole oxidation product was the major active metabolite (M2).

As with saquinavir, ritonavir is metabolized by CYP3A4 and is an inhibitor of the CYP450 system. Ritonavir is contraindicated with various compounds, such as astemizole, cisapride, clarithromycin, desipramine, ethinyl estradiol, rifabutin, several of the statins, sulfamethoxazole, and trimethoprim, because of increased concentrations of these drugs in the plasma as a result of inhibited oxidative metabolism as well as the fact that several of these drugs are CYP450 inducers. Ritonavir is the most potent PI in its ability to inhibit CYP450 and the efflux pump P-glycoprotein; as a result, the potential for severe drug interactions is quite great. Ritonavir alone or in combination with 3TC, ZDV, saquinavir, or ddC increased CD4 cell counts and decreased HIV RNA particle levels. Cross-resistance between ritonavir and RT inhibitors is unlikely because of the different mode of action and enzyme involved. Common adverse reactions, such as nausea, diarrhea, vomiting, anorexia, abdominal pain, and neurologic disturbances, have been reported with the use of ritonavir alone or in combination with other nucleoside analogues. Ritonavir is used for the treatment of advanced HIV infection, including opportunistic infections. In combination with nucleoside drugs, ritonavir has reduced the risk of mortality and clinical progression.

Because of the strong CYP450-inhibiting effects of ritonavir, the drug has found value when used in fixed-dosage combinations with other PIs to block their metabolism and act as a booster for these drugs (lopinavir/ritonavir and tipranavir/ritonavir). In these cases, ritonavir is used in a subtherapeutic dose but boosts the effectiveness of the coadministered drug. The utilization of ritonavir in a therapeutic dose for treating HIV infections appears to be decreasing, but its utilization as a booster drug is finding favor.

Indinavir



Indinavir sulfate, a pentanoic acid amide derivative, was approved by the U.S. FDA in March 1996 (96). The 95% inhibitory concentration against laboratory-adapted HIV variants, primary clinical isolates and clinically resistant virus to indinavir analogues, is 25 to 100 nM in drug combination studies with ZDV and ddI. In some patients, however, HIV has shown resistance to ritonavir. This resistance is caused by mutation of the virus that is correlated with the expression of amino acid substitutions in the viral protease. Cross-resistance to indinavir is observed with other PIs but not with the RT inhibitor. For this reason, indinavir is beneficial with ZDV and other nucleoside drugs.

Pharmacokinetics

Indinavir is rapidly absorbed in fasting patients, and plasma peak concentration is observed in approximately 1 hour. At a dose of 800 mg every 8 hours, peak plasma concentration is approximately 300 nM. The drug is approximately 60% bound to human plasma proteins. Indinavir is metabolized via oxidation and glucuronide conjugation (M1 in Fig. 43.14). At least seven metabolites have been

identified, with the conjugate being the major metabolite (97). These metabolites were recovered in feces and urine, with approximately 20% of the drug excreted in the urine. The half-life of indinavir is approximately 1.8 hours.

Because of indinavir's metabolism, a number of drug interactions are possible. Indinavir interacts with rifabutin or ketoconazole, leading to increased or decreased indinavir concentration, respectively, in the blood plasma. Administration of drug combinations of indinavir with antiviral nucleoside analogues, cimetidine, quinidine, trimethoprim/sulfamethoxazole, fluconazole, or isoniazid resulted in an increased activity of indinavir. Indinavir is

contraindicated in patients taking triazolam or midazolam, because the inhibition of metabolism of these drugs may result in prolonged sedation, nephrolithiasis, asymptomatic hyperbilirubinemia and GI problems (anorexia, constipation, dyspepsia, and gastritis). The usual oral dose for indinavir alone or in combination with other antiviral agents is one 800 mg capsule every 8 hours. The drug is well absorbed if given on an empty stomach or 1 hour before or 2 hours after a light meal with water. The dose is reduced to 600 mg every 8 hours if given concurrently with ketoconazole. Indinavir activity is increased when combined with RT inhibitors.

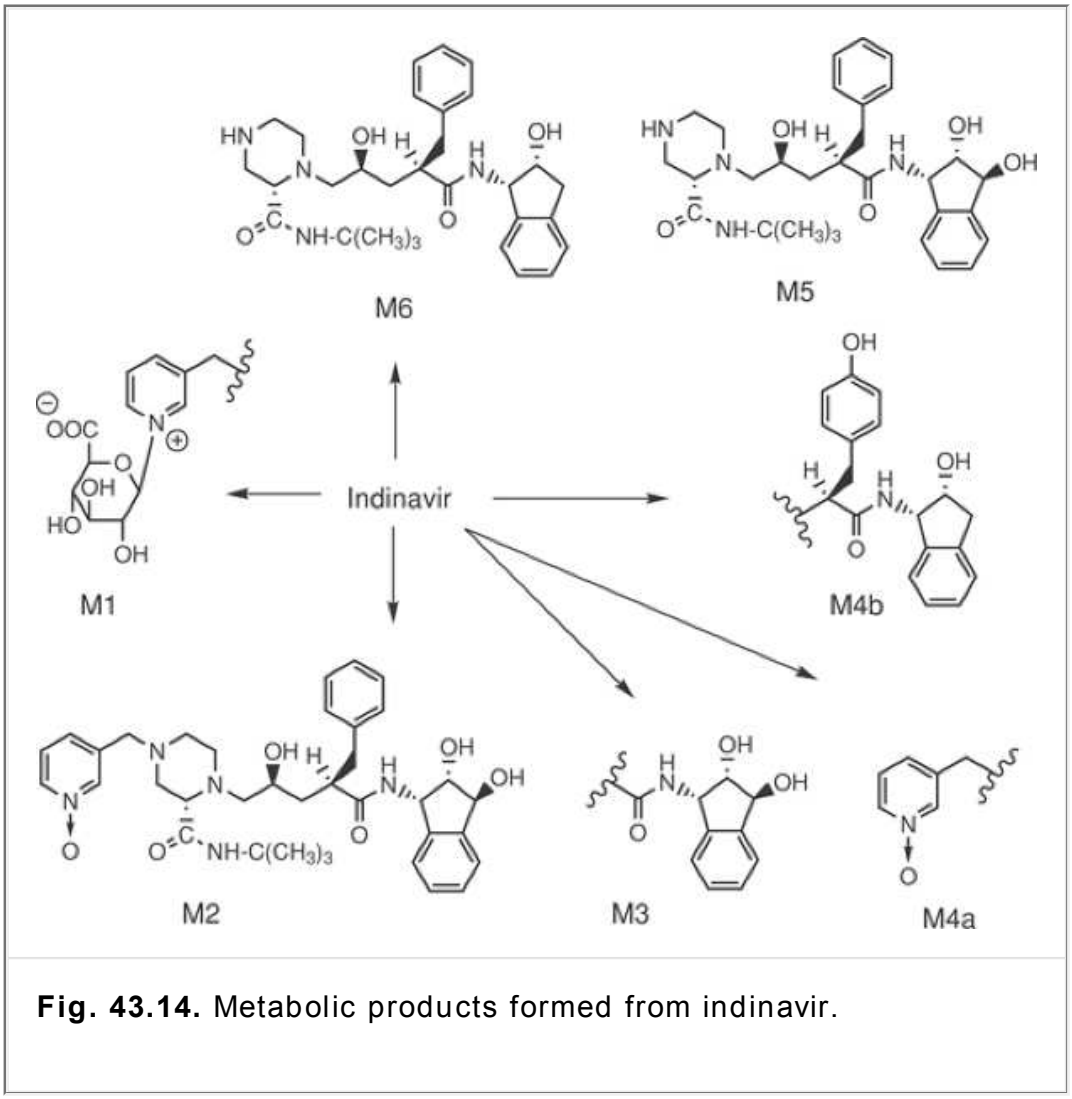


Fig. 43.14. Metabolic products formed from indinavir.

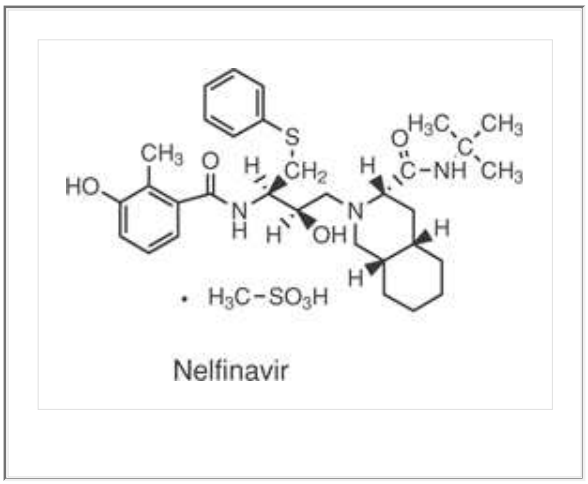
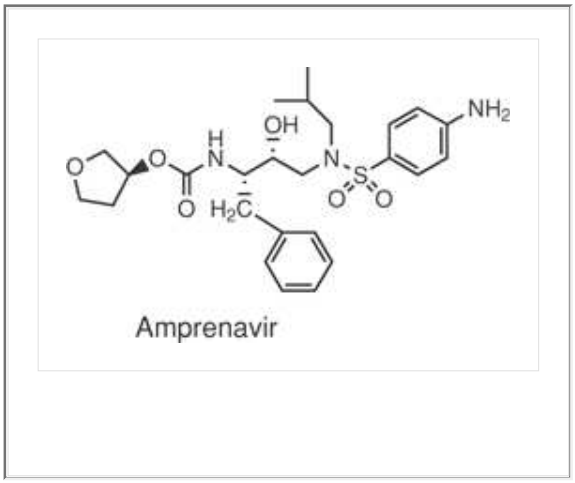
Nelfinavir



Nelfinavir mesylate is a peptidomimetic drug that is effective in HIV-1 and HIV-2 wild-type and ZDV-resistant strains, with median effective dose concentrations ranging from 9 to 60 nM (95% effective dose, 0.04 mg/mL) (98). After IV administration, the elimination half-life of nelfinavir was approximately 1 hour. In combination with D4T, nelfinavir reduced HIV viral load by approximately 98% after 4 weeks. It is well tolerated when used with azole antifungals (ketoconazole, fluconazole, or itraconazole) or macrolide antibiotics (erythromycin, clarithromycin, or azithromycin); however, it causes diarrhea and other side effects common to nonnucleoside drugs. Following oral administration, nelfinavir peak levels in plasma ranged from 0.34 mg/mL (10 mg/kg in the dog) to 1.7 mg/mL (50 mg/kg in the rat). In the dog, nelfinavir was slowly absorbed, and bioavailability was 47%. The drug appeared to be metabolized in the liver, and the major excretory route was in feces.

Amprenavir

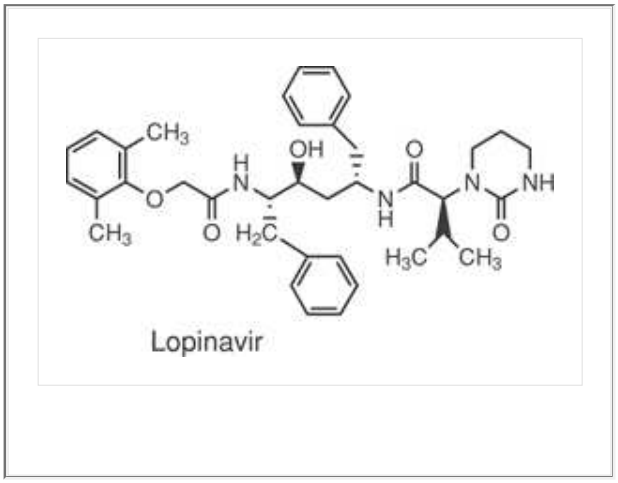


Amprenavir is the fifth in a series of PIs to be approved for marketing in the United States. Although it is structurally unique from the previous agents, its pharmacological profile does not appear to differ significantly from those of the previously marketed agents. Early studies suggest that a different resistance profile may exist and that the drug may be effective against some resistant strains of HIV. Side effects appear to be more common than with other PIs and include nausea, vomiting, paresthesia, depression, and rash. Because amprenavir is a sulfonamide, there is some concern regarding cross-sensitivity with antibacterial sulfonamides. This has not been reported, but care should be taken if sensitivity to trimethoprim/sulfamethoxazole, used in *Pneumocystis carinii* pneumonia, is reported.

Amprenavir is rapidly absorbed following oral administration and may be taken with or without food. High-fat meals decrease the absorption of the drug and, therefore, should be avoided. The product is available in capsule and liquid form. The recommended adult and adolescent dose of 1,200 mg twice

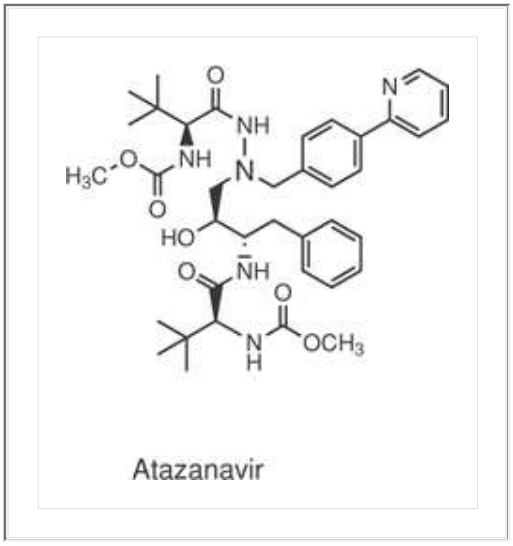
daily requires the patient to take eight capsules (150 mg each) twice daily. The liquid preparation is recommended for children between 4 and 12 years of age or for patients 13 to 16 years of age who weigh less than 50 kg. The dose is 22.5 mg/kg twice daily or 17 mg/kg three times a day. Because this preparation contains the excipient propylene glycol, it is not recommended for children less than 4 years of age and certain other individuals who are unable to metabolize this alcohol.

Lopinavir/Ritonavir



Recently, the U.S. FDA has approved the release of lopinavir/ritonavir combination in patients who have not responded to other regimens for treatment of HIV. The product is available in a soft-gelatin capsule containing 133.3 mg of lopinavir and 33.3 mg of ritonavir as well as in oral solutions containing 80 mg/mL of lopinavir and 20 mg/mL of ritonavir. The small amount of ritonavir is not expected to have antiretroviral activity; rather, the ritonavir is meant to increase the plasma concentrations of lopinavir by inhibiting lopinavir's metabolism by CYP3A4 (ritonavir acts as a booster). These drugs, in combination with other antiretroviral agents, have been approved for use in adults as well as in patients between the ages of 6 months and 12 years. This is the first PI to be indicated for the very young.

Atazanavir (99)

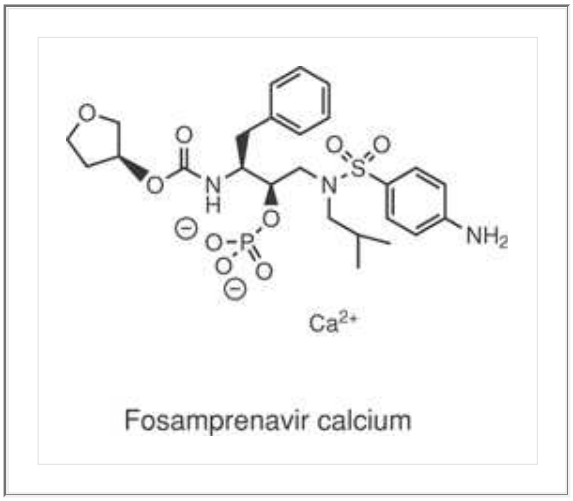


Atazanavir is an antiretroviral agent approved for use in combination with other antiretroviral agents for the treatment of HIV infections. Atazanavir is a peptidomimetic transition-state inhibitor that targets HIV-1 protease and reduces the viral replication and, thus, the virulence of HIV-1. Similar to saquinavir, ritonavir, indinavir, nelfinavir, amprenavir, and lopinavir, the drug is used in combination with RT inhibitors to produce excellent efficacy in patients with AIDS.

Pharmacokinetics

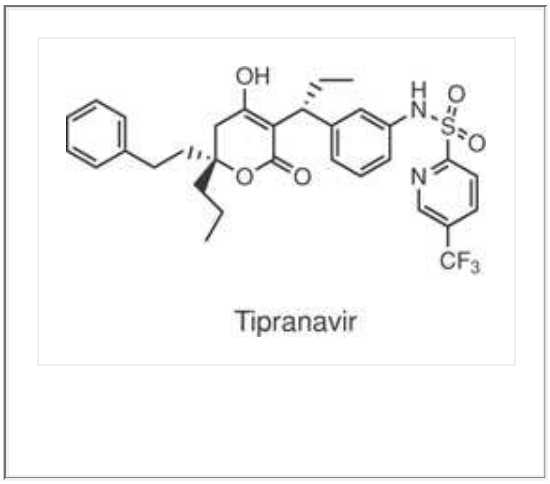
Atazanavir is dosed orally once daily, thus reducing "pill burden," and it appears to have minimal impact on lipid parameters but does increase total bilirubin. The drug is well absorbed when administered orally with food (bioavailability, ~68%). The drug is highly bound to plasma protein (86%) and is metabolized by CYP3A isoenzyme. Atazanavir is a moderate inhibitor of CYP3A, and potential drug–drug interactions are possible with CYP3A inhibitors and inducers.

Fosamprenavir (100)



Fosamprenavir calcium has been approved for the treatment of HIV in adults when used in combination with other anti-HIV drugs. It is a prodrug that, on hydrolysis by serum phosphatases, gives rise to amprenavir, which is a peptidomimetic transition-state inhibitor that targets HIV-1 protease and reduces the viral replication and, thus, the infectiousness of HIV-1. It is commonly administered in combination with RT inhibitors to produce excellent efficacy in patients with AIDS. The drug is administered as two 700 mg tablets twice daily or, in combination with ritonavir, can be given as two 700 mg tables once daily or one 700 mg tablet twice daily. As a result, formaprenavir lowers the "pill burden" in patients with AIDS.

Tipranavir (101,102,103,104)



Tipranavir was released as a nonpeptide PI in June 2005 for the treatment of HIV in adults. The drug was derived through a structure-based design and differs significantly from the design of the previously discussed transition-state peptidomimetics. Tipranavir appears to be bound to the same active site of HIV-1 protease as the peptidomimetics

are, but because of its different chemical structure, cross-resistance is significantly less than that seen between the peptidomimetics. The drug suppresses viral replication in various strains of HIV-1 in vitro, and when combined with azothymidine or delaviridine, synergistic activity is noted in vitro. Tipranavir has an advantage over the other PIs in that it is not as strongly bound to plasma protein as the earlier PIs are, a property that reduces the 90% inhibition concentration.

Tipranavir is administered with a booster dose of ritonavir. The tipranavir/ritonavir must be taken with other anti-HIV drugs. Normal dosing consists of 500 mg of tipranavir and 200 mg of ritonavir twice daily. Whereas tipranavir is a substrate for CYP3A4, in the presence of ritonavir very little metabolism of tipranavir occurs, although the combination leads to induction of P-glycoprotein, which may increase the bioavailability of tipranavir. By itself, tipranavir exhibits increased absorption in the presence of food. Initially, tipranavir was available as the disodium salt, but it was demonstrated that the free acid, in the form of a self-emulsifying drug delivery system (soft-gel capsules), showed improved bioavailability.

Drug interactions occur between tipranavir and fluconazole and between tipranavir and clarithromycin, increasing the AUC over a 12 hour period for tipranavir by 56 and 59%, respectively. Care should be taken when administering tipranavir with CYP450 inhibitors and inducers, because clinically significant interactions are possible. Coadministration of tipranavir with antacids decreases the tripranavir AUC by up to 33%.

The most common side effects reported for tipranavir consist of diarrhea and nausea. These adverse events may be significant enough to lead to drug discontinuance.

Combination Drug Therapy (105,106)

Combination drug therapy for viral infections is another approach currently under investigation. The synergistic antiviral effects of rimantadine with ribavirin and tiazofurin against influenza B virus and of ganciclovir (DHPG) with foscarnet against HSV-1 and HSV-2 are noteworthy. The synergistic action of either trifluorothymidine or acyclovir with leukocyte interferon has been used in the topical treatment of human herpetic keratitis. During the past decade, research into combination antiretroviral therapy for patients with AIDS has made remarkable progress. The first approved drug for HIV-infected patients, ZDV, produced bone marrow toxicity. To overcome toxic effects, combinations of ZDV with foscarnet, ddC, or ddI have been used. Such combination therapy indicated improved efficacy and decreased side effects as compared to either drug when used alone. The combination of ZDV with interferon-α has been used to treat patients with AIDS-related Kaposi's sarcoma. This combination drug therapy delayed emergence of ZDV-resistant HIV strains.

A combination of granulocyte-macrophage colony-stimulating factor with ZDV and interferon-α has been successful in managing treatment-related cytopenia in HIV-infected patients. The advantages of combination therapy include therapeutic antiviral effect, decreased toxicity, and low incidence of drug-resistant infection. In recent years, emergence of drug resistance has been demonstrated in patients receiving single antiviral agent therapy. Resistance to amantadine, acyclovir, ribavirin, ganciclovir, ZDV and other antiviral agents is noteworthy.

Combined antiretroviral drug therapy serves different purposes. It prolongs the life of patients with AIDS; removes drug resistance, and/or reduces the toxicity of drugs. With these objectives, successful combinations of ZDV have been reported with ddC, ddI, 3TC, or D4T. Recently, combination of nucleosides drugs (ZDV, ddC, ddI, and 3TC) are used with PIs (saquinavir, indinavir, and ritonavir) for delaying HIV infection. Combined nucleoside drugs are known to delay progression of HIV infection.

Antiretroviral therapy includes nucleosides or nonnucleoside RT inhibitors and PIs. These drugs inhibit HIV replication at different stages of viral infection. Nucleoside and nonnucleoside drugs inhibit RT by preventing RNA formation or viral protein synthesis. Nonnucleoside drugs inhibit RT by inactivating the catalytic site of the enzyme. The PIs act after HIV provirus has integrated into the human genome. These drug inhibit protease, which is an enzyme responsible for cleaving viral precursor polypeptides into effective virions. Thus, PIs combined with RT inhibitors act by a synergistic mechanism to interrupt HIV replication.

Two-drug combinations, such as ZDV plus ddI or ddC, 3TC and ZDV, and D4T plus ddI, have been

successful in raising CD4 cell counts and decreasing HIV RNA viral load. Triple-drug therapy consisting of ZDV, 3TC, and one PI (indinavir, ritonavir, or nelfinavir) has been more effective than double-drug therapy consisting of two nonnucleoside analogue combinations. Also, fewer opportunistic infections were noted when patients took the three-drug combination. Additionally, ZDV can be combined with immunomodulators to increase immunologic response in patients with AIDS. Zidovudine has been combined with interferon-α to obtain synergistic activity of the drug. An ideal approach of combined antiretroviral drug therapy would be drugs acting at different stages of HIV cell replication.

Investigational Antiviral Agents: Short Interfering RNA (107)

The field of directed RNA interference (RNAi) has rapidly developed into a highly promising approach for specifically interrupting gene function to alleviate disease pathology. RNAi is a mechanism for silencing gene expression that has been conserved through evolution in eukaryotes ranging from plants to humans. In this process, double-stranded duplexes of 21 to 25

nucleotides in length are created from a parent double-stranded RNA molecule. These short interfering RNAs (siRNAs) direct the cell to cleave target mRNAs that share sequence identity with the siRNAs. Many research groups are attempting to develop RNAi therapies that induce the degradation of target mRNA involved in inherited or acquired disorders. This technology is especially well-suited to treating viral infections, and numerous examples now illustrate that a wide range of viruses can be inhibited with RNAi, both in vitro and in vivo. Antiviral RNAi therapies can be tailored to the biochemical characteristics of each pathogen and can be made more specific through choice of delivery vehicle, route of administration, selection of gene targets, and regulation of RNAi induction. As has been mentioned above, successful antiviral therapeutics possess the ability to discriminate virus from host. Because viruses rely extensively on host cell machinery for many functions and activities involved in viral replication, however, they offer a very limited number of therapeutic targets. Because RNAi specifically targets a short stretch of viral nucleic acids rather than a viral protein, even a small viral genome can provide a large number of potential targets.

Case Study

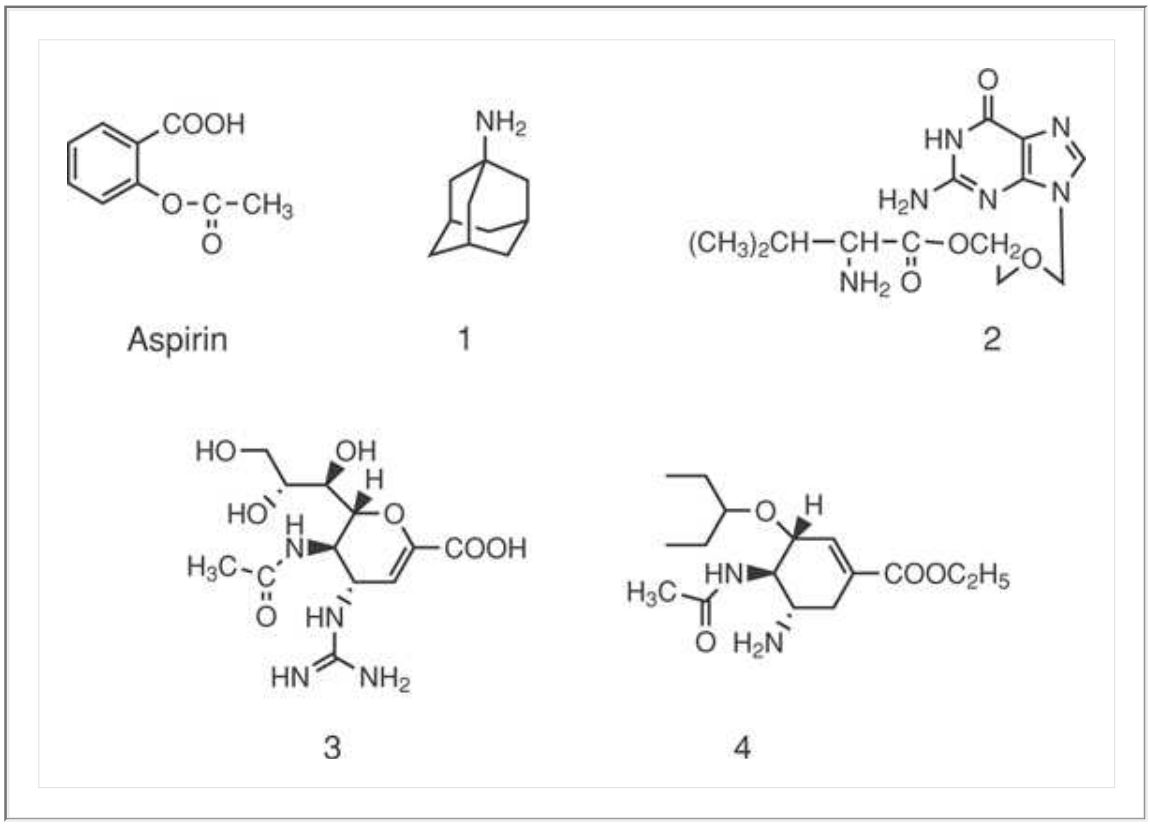
Victoria F. Roche

S. William Zito

You are an Oregon pharmacist mentoring the American Pharmacist Association Academy of Student Pharmacists chapter of a local pharmacy school in its service outreach program with an area shelter for abused women. This shelter serves about 50 women and their children, assisting the women with work placements when needed and providing day care services and transportation to area schools for the kids. All residents have breakfast together at 6:30 AM, and dinner is offered at 6:00 PM. with about three-quarters of the families partaking on any given evening. Various community groups make sure the pantry is well stocked, and one has provided supplies of aspirin and other over-the-counter products for as-needed use by the shelter's clients. The corporate headquarters of Sea Mist, a company that markets products made from locally grown cranberries, has selected this shelter as the primary beneficiary of its community service commitment, and it provides the residents with essentially limitless quantities of its products, including cranberry juice (enjoyed often by most of those living at the shelter).

A recent outbreak of influenza A has struck your community, and although only a few residents of the shelter have become ill, you and the MD who also donates her services to the facility realize that all the residents (including the children) are at risk. Because of a nationwide shortage of vaccine, vaccination of the residents is not possible, but together, you are trying to secure sufficient quantities of an orally active, antiviral agent to treat and/or protect these patients. The Sea Mist employees have volunteered to cover the cost of any medication not donated by the manufacturer.

Taking advantage of a “teachable moment” in clinical practice, you ask your ASP students who are currently taking medicinal chemistry to identify the best agent of the four structural choices shown below to meet the needs of this diverse population.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patients.

Chapter 44

Asthma and Chronic Obstructive Pulmonary Disease

S. William Zito

Drugs covered in this chapter:

β_2-Adrenergic Agonists

- Albuterol
- Bitolterol mesylate
- Epinephrine (Adrenalin)
- Fenoterol hydrobromide
- Formoterol fumarate
- Isoetharine hydrochloride
- Metaproterenol sulfate
- Salmeterol xinafoate
- Terbutaline sulfate

Antimuscarinics

- Ipratropium hydrobromide
- Tiotropium bromide

Methylxanthines

- Dyphylline
- Theophylline

Adrenocorticoids

- Beclomethasone dipropionate
- Budesonide
- Flunisolide
- Fluticasone propionate
- Hydrocortisone
- Methylprednisolone
- Mometasone furoate
- Prednisolone
- Triamcinolone acetonide

Mast cell degranulation inhibitors

- Cromolyn sodium
- Nedocromil sodium

Leukotriene modifers

- Montelukast
- Zafirlukast
- Zileutin

Monoclonal anti-IgE antibody

- Omalizumab

Asthma

Epidemiology

Asthma is a Greek word that is derived from the verb “aasein,” meaning to pant or exhale with open mouth. The earliest use of the term as a medical condition dates back to Ancient Greece, in Hippocrates' *Corpus Hippocraticum* (1). The incidence of asthma is greatest in the developed world, and there has been an increase in asthma over the last two decades in the United States (2). According to 2002 U.S. population data gathered by the National Center for Health Statistics, the number of people who were ever diagnosed with asthma by a health professional (lifetime prevalence) is 30.8 million (111 per 1,000). Of that number, it is estimated that 20 million people are currently under treatment and that as many as 12 million had an asthma attack in the 12 months before the survey. Children aged 0 to 17 years have the highest rate of asthma (83 per 1,000), but the rate decreases significantly in adults, indicating that many children “outgrow” the disease. Race and gender seem to play a role in the prevalence of asthma. Puerto Ricans, blacks, and Native Americans have an asthma prevalence much higher than in Caucasians. The high Puerto Rican incidence is masked when they are included among all Hispanics. Boys have a higher incidence of asthma than girls; however, this reverses in adulthood, when females show a 30% higher prevalence compared to males. Asthma causes a significant loss of schooldays and workdays and results in nearly 2 million visits to the emergency department each year. If asthma is not controlled, it can result in death: almost 5,000 people died from asthma in 2002. Blacks had an asthma death rate more than 200% higher than that in Caucausians, and women had a death rate 40% higher than males. These data reinforce the influence of race and gender on the morbidity and mortality of asthma and point out the fact that asthma is a significant public health burden in the United States (3).

Etiology, Signs, and Symptoms

Asthma is a complex disorder involving biochemical, autonomic, immunologic, infectious, environmental, and psychological factors to varying degrees in different individuals. Patients with asthma demonstrate recurrent episodes of paroxysmal dyspnea, wheezing, and cough. Most asthmatic attacks are short-lived, with the patient being free from symptoms between exacerbations. Some patients may have persistent difficulty breathing that does not respond to any treatment and that is believed to be the result of airway remodeling (4). The National Institutes of Health (NIH) Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma (EPR-2) simply defines asthma as a chronic inflammatory response of the airways (5).

The most common form of asthma is allergic asthma (atopic or extrinsic asthma), and it is associated with environmental allergens, such as plant pollens, house dust mites (*Dermatophagoides farinae*), domestic pet dander, molds, and foods. The less common form, intrinsic asthma, has no known allergic cause and usually occurs in adults older than 35 years. Intrinsic asthma may result from an autonomic dysfunction characterized by excess cholinergic

and/or tachykinin activity, but this hypothesis has never been proven (6). Aside from environmental allergens, an asthmatic attack may be precipitated by

respiratory infection, exercise, polyps, drugs (e.g., aspirin and β-adrenergic antagonists), and environmental pollutants (e.g., sulfur dioxide, cigarette smoke, and occupational chemicals). In predisposed individuals, emotional stress and drugs or foods that contain tartrazine, sulfites, and preservatives also can precipitate an asthmatic onset (7).

Clinical Significance

The therapeutic approach to the management of asthma and chronic obstructive pulmonary disease (COPD) has changed dramatically over the past several decades. Treatment guidelines have evolved based on a better understanding of these disease states as well as on the development of newer and more efficacious treatment modalities through the application of structure–activity relationships (SARs) of chemical lead compounds. Although both disease states are characterized by pulmonary obstruction and chronic inflammation, the nature of such pulmonary abnormalities differ between the two conditions. Traditional therapy had focused on the symptomatic relief of airflow obstruction through the use of bronchodilators, such as adrenergic agonists and anticholinergics. Today, however, greater emphasis is placed on managing the underlying inflammation and minimizing disease progression.

The current therapeutic approach to managing these diseases includes the use of rapidly acting drugs to relieve acute symptoms as well as maintenance medications to minimize inflammation and control long-term symptoms. Short-acting adrenergic agonists are the agents most commonly used to manage acute exacerbations of these disease states. Although effective, older agents, such as epinephrine and isoproterenol, were limited in their pharmacokinetic profile as well as in their lack of pulmonary selectivity. Modifying the chemical structure of these compounds, however, has resulted in the development of agents with significant clinical advantages in terms of duration of action and adverse effect profiles. Similarly, the application of SAR principles to the development of anti-inflammatory agents, such as corticosteroids, leukotriene antagonists, and mast-cell stabilizers, has lead to the availability of superior long-term controlling agents in terms of potency, pharmacokinetic profile, and safety.

In treating patients with asthma and COPD clinicians should be mindful of the SARs of those agents being employed. The application of these principles should be used to determine the most appropriate drug therapy in light of patient-specific needs and desired therapeutic outcomes. Additionally, clinicians can look forward to the availability of newer and more clinically appropriate agents for the management of asthma and COPD as research in medicinal chemistry results in the development of increasingly selective drug entities and improved receptor targeting modalities.

Joseph V. Etzel Pharm.D.

Assistant Dean of Student Affairs, Associate Clinical Professor of Pharmacy, College of Pharmacy & Allied Health Professions, St. John's University, Jamaica, New York

Why has there been a marked increase in asthma in affluent industrialized countries? To answer this question, recent thought has focused on the “hygiene hypothesis,” which implicates an imbalance of TH_1 and TH_2 lymphocytes as a major cause of the increased prevalence of asthma

(8). The TH_1 lymphocytes are the type of CD4+ T lymphocyte associated with defense against bacterial infection, whereas the TH_2 type predominates in allergic inflammation. The hypothesis claims that because bacterial infections have significantly decreased in industrialized nations, there is an imbalance, in susceptible children, in favor of the TH_2-type lymphocytes, and this imbalance therefore favors allergic asthma (9).

Asthma frequently occurs in families, and studies have shown that this results, at least in part, from mutually shared genes (10,11). Asthma is a complex disorder and lacks a mendelian genetic pattern, so it is difficult to study. To date, however, genetic research indicates that what is inherited is the susceptibility to develop asthma. It is clear that genes alone are not responsible for the development of asthma, because environmental factors also play a major role. Numerous genes on various chromosomes have been linked to asthma. Table 44.1 shows several gene products that may influence the development of asthma (10,11,12,13,14,15). In reality, however, there is little correlation between gene expression and clinical symptoms. The one exception to this is the low-expression allele of macrophage migration inhibitory factor (MIF), which has been shown to have a strong association with patients that have mild asthma (16). Drug development of MIF inhibitors might lead to future treatments for asthma.

Table 44.1. Putative Asthma Associated Gene Products

Gene Products
β_2-Adrenergic receptor
Interleukin-4, -5, -9, and -13
Interleukin-4 receptor α (Il-4Rα)
β Chain of the high-affinity IgE receptor (FcεRIβ)
Tumor necrosis factor α (TNFα)
Major histochemical complex (MHC)
T-cell receptor α/δ complex
ADAM33 (a disintegrin and metalloproteinase)
Dipeptidyl peptidase 10
PHD finger protein 11
Prostanoid DP1 receptor
Macrophage migration inhibitory factor (MIF)

Pathogenesis of Asthma

For a long time, asthmatic symptoms were thought to be the result of airway smooth muscle abnormalities, resulting in episodic bronchoconstriction. Today, however, it is clear that the constriction of bronchial smooth muscle is only one of many effects of chronic airway inflammation. Evidence of inflammation appears very soon after the onset of symptoms; therefore, treatment algorithms for asthma now emphasize quick relief of the bronchoconstriction and the amelioration of the underlying inflammation (17).

Inflammation in asthma is characterized by mucous plugging, epithelial shedding, basement membrane thickening, inflammatory cell infiltration, and smooth muscle hypertrophy and hyperplasia (Fig. 44.1). An acute extrinsic asthmatic attack begins when mast cells become activated. Activation of mast cells occurs when an antigen cross-links with immunoglobulin (Ig) Es on their surface. This IgE complex triggers mast cell degranulation, leading to the rapid release of inflammatory mediators, such as histamine, prostaglandins, leukotrienes, and cytokines

(including tumor necrosis factor α and interleukins). The initial attack generally resolves within an hour; however, a second phase begins 4 to 6 hours after exposure and can last up to 24 hours. This late phase is a result of recruitment of additional inflammatory cells, primarily eosinophils, by the release of cytokines from macrophages and TH_2-type lymphocytes in the lower lung (18).

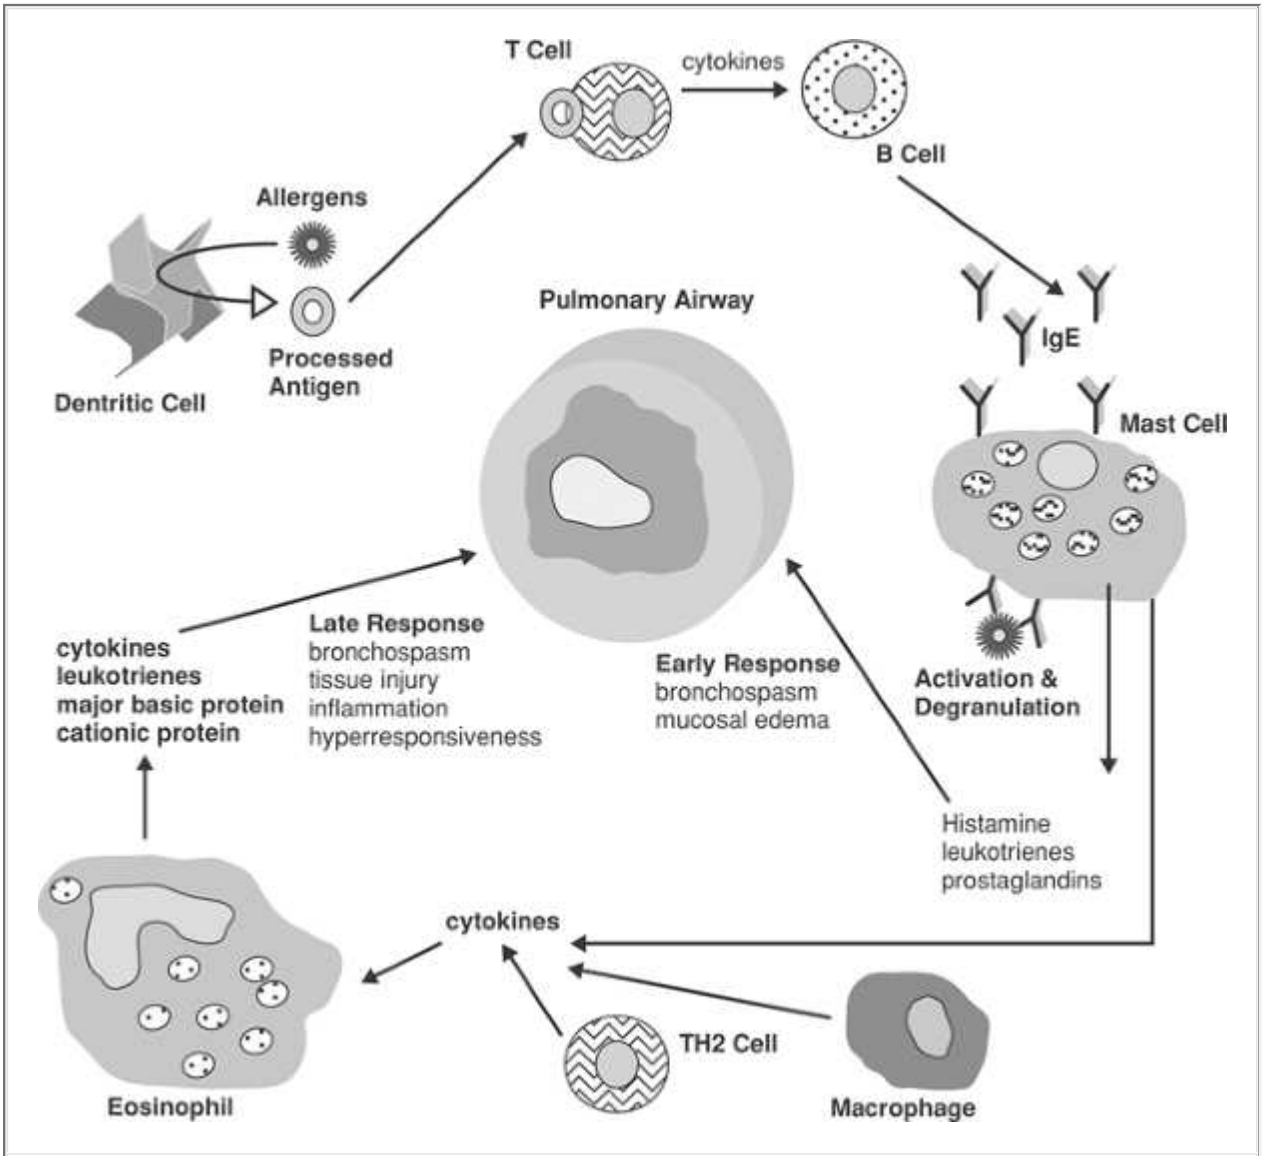

Fig. 44.1. Pictorial summary of asthma pathogenesis.

Clinical Evaluation

Most patients with asthma are asymptomatic between acute exacerbations. The onset of symptoms can be sudden or gradual and frequently can occur during the night or early in the morning. Acute symptoms include shortness of breath, wheezing or whistling at the end of exhalation, cough, and chest tightness. Patients with chronic and poorly controlled asthma develop barrel chest and diminished diaphragm movement, both of which are evidence of chronic pulmonary hyperinflation.

Acute asthmatic attacks may be mild, moderate, or severe depending on the degree of airway

obstruction. The determination of the degree of airflow obstruction is accomplished by pulmonary function testing. The most common pulmonary function test utilizes spirometry, which measures the rate at which the lung changes volume during forced breathing maneuvers. The most important spirometric measure is the forced vital capacity (FVC). This requires the patient to exhale as rapidly and as completely as possible after a maximal inhalation. Normal lungs generally can empty their volume in 6 seconds or less. When airflow is obstructed, however, the expiratory time may increase by as much as fivefold. In practice, the forced expiratory volume in the first second of expiration (FEV_1) is measured and compared to the FVC and then recorded as the ratio of FEV_1 to FVC (FEV_1/FVC) (Fig. 44.2) (measurement is done by means

of a spirometer). Healthy persons normally can expel at least 75% of their FVC in the first second. Deceases in the FEV_1/FVC ratio indicate obstruction, and a decrease below 40% indicates severe asthma (17,18).

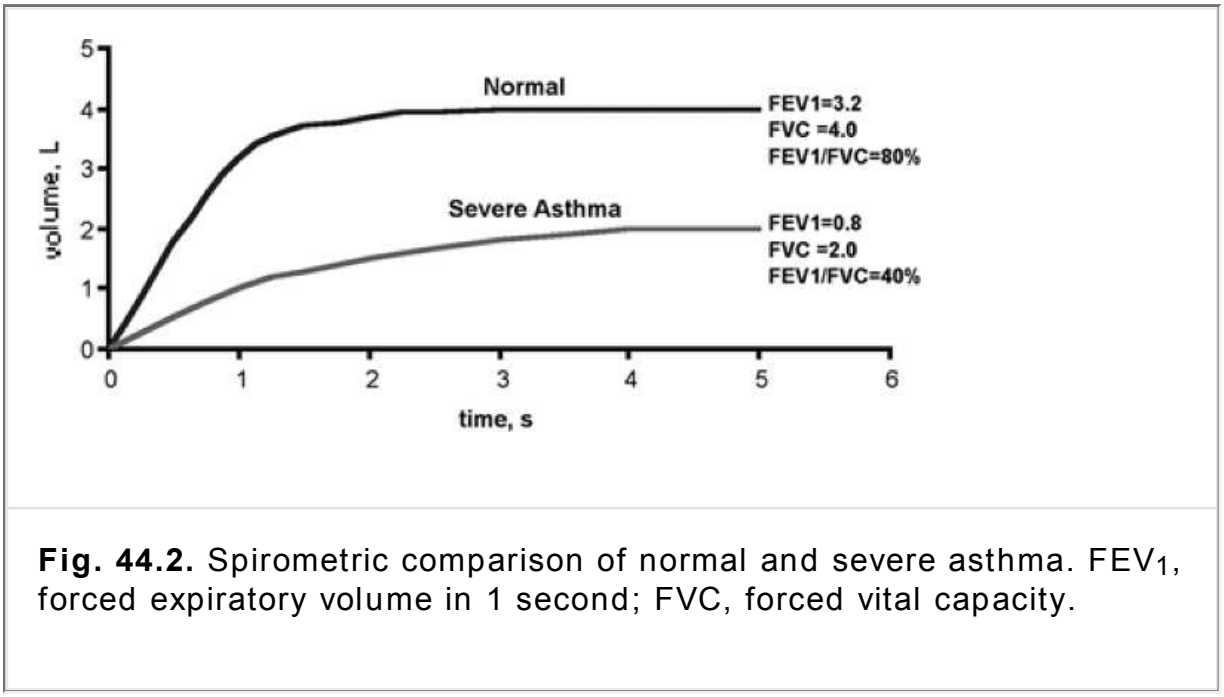

Fig. 44.2. Spirometric comparison of normal and severe asthma. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

A more convenient way to measure airway obstruction is to determine the peak expiratory flow (PEF) rate. The PEF rate correlates well with the FEV_1; can be determined using inexpensive, handheld, peak flow meters; and is easily and simply measured at home. The PEF rate is the maximal rate of flow that is produced through forced expiration. Peak flow meters come with a chart that lists predicted PEF rates based on the patient's age, gender, and height. The patient or clinician can then compare the determined PEF rate with the predicted PEF rate and make an evaluation regarding the severity of an asthmatic attack. The PEF rate or the FEV_1, along with the frequency of daytime and nighttime symptoms, forms the basis for the classification of the severity of an asthmatic attack. Table 44.2 shows the severity classification of asthma established by the NIH Expert Panel Report 2: Guidelines for the Diagnosis and Management of Asthma (EPR-2) (5).

General Therapeutic Approaches to The Treatment and Management of Asthma

Asthma symptoms are caused by bronchoconstriction and inflammation, and approaches to treatment are directed at both these physiological problems. Therefore, drugs that affect adrenergic/cholinergic bronchial smooth muscle tone and drugs that inhibit the inflammatory process are used to treat and control asthma symptoms. In the normal lung, bronchiole smooth

muscle tone results from the balance between the bronchoconstrictive effects of the cholinergic system and the bronchodilating effects of the adrenergic system on the smooth muscles of the bronchioles. Pharmacological treatment of asthmatic bronchoconstriction consists of either increasing adrenergic tone with an adrenergic agonist or inhibiting cholinergic tone with an anticholinergic agent.

Table 44.2. Classification of Asthma Severity (5)

	Step 1 (Mild Intermittent)	Step 2 (Mild Persistent)	Step 3 (Moderate Persistent)	Step 4 (Severe Persistent)
Frequency of symptoms				
Days	≤2/week	3–6/week	Daily	Continual
Nights	≤2/month	3–4/month	≥5/month	Frequent
PEF or FEV_1	≥80%	≥80%	>60% <80%	≤60%
PEF or FEV_1 variability	<20%	20–30%	>30%	>30%

FEV_1, forced expiratory volume in 1 second; PEF, peak expiratory flow.

The inflammatory effects seen in asthma result from the release of physiologically active chemicals from a variety of inflammatory cells. Pharmacological treatment, therefore, uses anti-inflammatory drugs (corticosteroids), mast cell stabilizers, leukotriene modifiers, and IgE monoclonal antibodies. Figure 44.3 depicts the overall approach to the pharmacological treatment of asthma.

Therapeutic management of asthma requires the use of quickly acting drugs to relieve an acute attack as well as drugs that control symptoms over the long-term. The current approach to asthma management utilizes a stepwise approach (5). The quick-reliever medication is almost always an inhaled short-acting β_2-adrenergic agonist, whereas controller drugs are inhaled corticosteroids, long-acting β_2-agonists, leukotriene modifiers, cromolyn sodium, and/or methylxanthines. The dose, route of administration, and number of controller drugs depends on the severity of the patient's disease. Table 44.3 shows the stepwise approach to asthma management based on disease severity.

Therapeutic Classes of Drugs Used to Treat Asthma and Chronic Obstructive Pulmonary Disease

β_2-Adrenergic Agonists

Introduction

What structural features make a drug an adrenergic agonist? What features make it a selective β_2-agonist? The answers to these questions lie in the structural relationship

of a drug to that of norepinephrine (NE), the physiological neurotransmitter of the sympathetic branch of the autonomic nervous system. Drugs that act on postsynaptic sympathetic receptors in the same way as NE are called sympathomimetics or, more commonly, adrenergic agonists. The related natural agonist epinephrine (EPI; adrenalin) is the predominant adrenergic hormone produced in the chromaffin cells of the adrenal medulla. Epinephrine interacts just like NE at all adrenergic receptors.

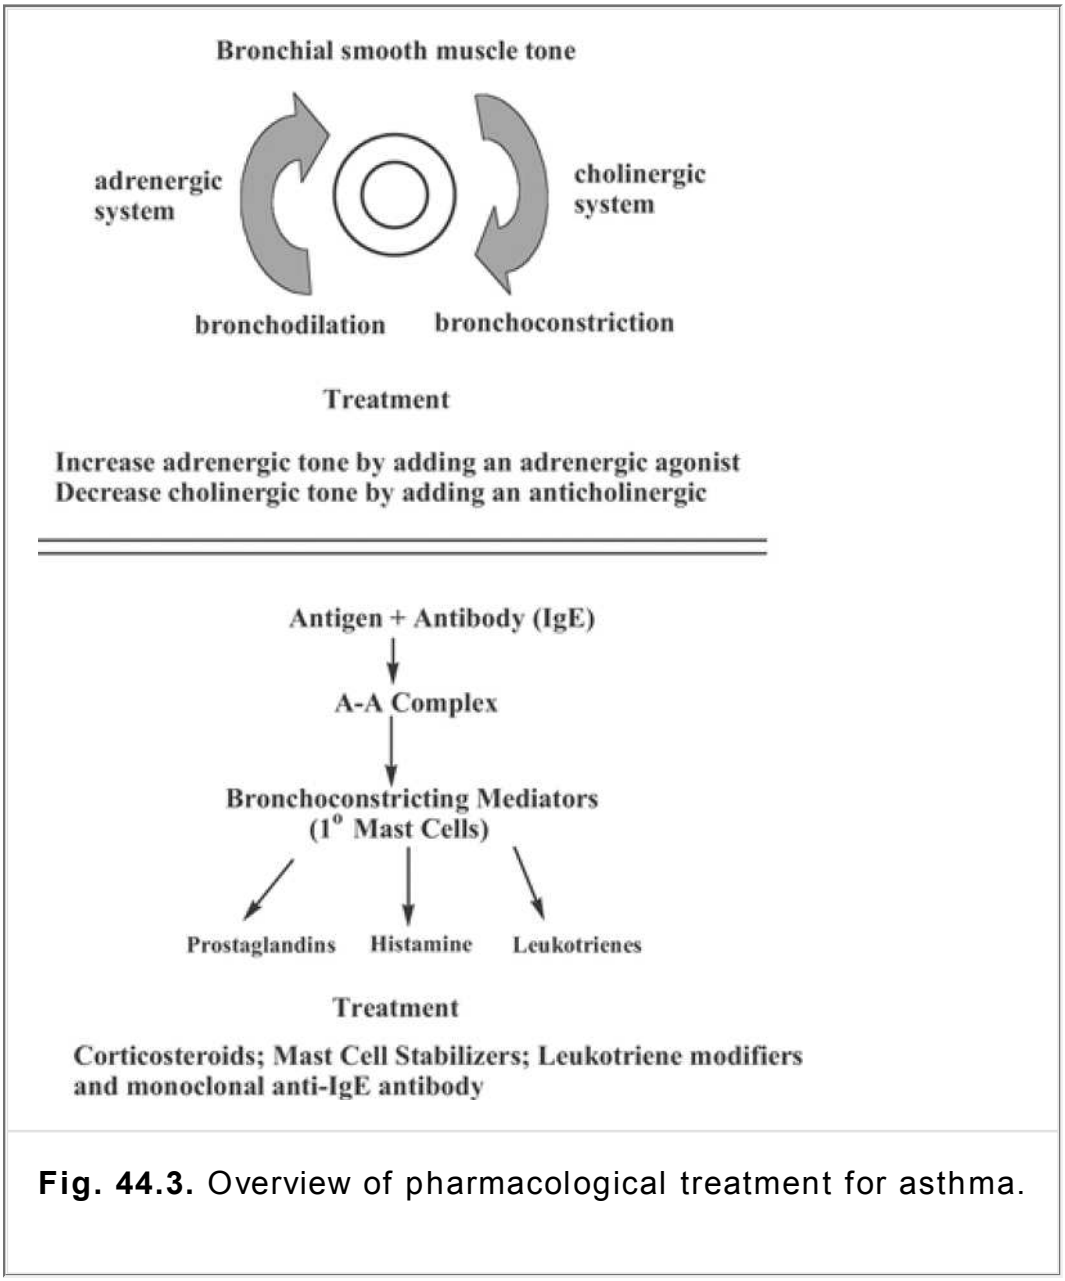

Fig. 44.3. Overview of pharmacological treatment for asthma.

Chemistry and Biochemistry of Norepinephrine and Epinephrine

Chemically, NE is classified as a catecholamine. A catechol is a 1,2-dihydroxybenzene, and NE is a β-hydroxyethylaminodihydroxybenzene. Epinephrine is the N-methyl derivative of NE, and they both have acidic and basic functional groups. Physiologically, however, they behave as a base, being more than 90% protonated at pH 7.4 (pK_a = 9.6) and functioning as an ionized acid.

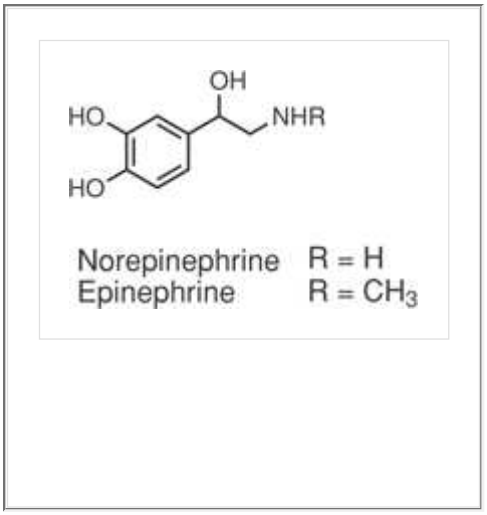

Table 44.3. Stepwise Medication Management of Asthma

All Patients: Short-Acting Inhaled β_2-Agonist as Needed for Acute Episodes	Severity Classification	Long-Term Control
Mild Intermittent	No daily medication needed	
(Step 1)	A course of systemic steroid may be necessary to treat a severe episode	
Mild Persistent	Low-dose inhaled steroid	
(Step 2)	Other treatment options: Cromolyn/nedocromil OR Leukotriene modifier OR Sustained-release theophylline	
Moderate	Low- to medium-dose inhaled steroid	

Persistent	PLUS an inhaled long-acting β_2-agonist
(Step 3)	Other treatment options: Medium-dose inhaled steroid PLUS cromolyn/nedocromil OR Medium-dose inhaled steroid PLUS leukotriene modifier OR Medium-dose inhaled steroid PLUS sustained-release theophylline
Severe Persistent (Step 4)	High-dose inhaled steroid PLUS a long-acting bronchodilator PLUS one or more of the following: Oral long-acting β_2-agonist Sustained-release theophylline Oral steroid Leukotriene modifier

Norepinephrine is biosynthesized in the neurons of both the central nervous system and the autonomic nervous system, whereas EPI is formed in the chromaffin cells of the adrenal medulla. Both NE and EPI are derived from L-tyrosine by a series of enzyme-catalyzed reactions (Fig. 44.4 depicts the overall pathway). L-Tyrosine hydroxylase hydroxylates the meta position of L-tyrosine, producing L-dihydroxyphenylalanine (L-DOPA) and is the rate-limiting step. The L-DOPA is then decarboxylated by L-aromatic amino acid decarboxylase to form dopamine, which is converted to NE by the action of dopamine β-hydroxylase. Dopamine β-hydroxylase occurs in storage vesicles of the nerve ending, and the NE formed is stored there until it is released into the synaptic cleft. In the chromaffin cells, the formed NE is converted to EPI by N-methylation catalyzed by phenylethanolamine N-methyltransferase.

Termination of Neurotransmission

Stimulated adrenergic neurons release NE into the synaptic cleft, which then binds reversibly with receptors to produce a characteristic adrenergic response. Termination of the adrenergic response occurs primarily by reuptake (uptake-1) into the presynaptic neuron; however, diffusion away from the receptors and extracellular metabolism also occurs to a limited extent. The NE that is taken back up into the presynaptic neuron is

either used again as a neurotransmitter or is metabolized by mitochondrial monoamine oxidase (MAO). The extraneuronal NE that diffuses away from the neurons is either metabolized by

catechol O-methyl transferase (COMT) in situ or reaches the circulatory system and is metabolized by COMT and MAO in various tissues, most importantly the liver, gastrointestinal (GI) tract, and the lungs. Figure 44.5 depicts the possible metabolic pathways for both NE and EPI. It is important to note that agonists that are resistant to MAO and/or COMT have greater oral availability and longer duration of action.

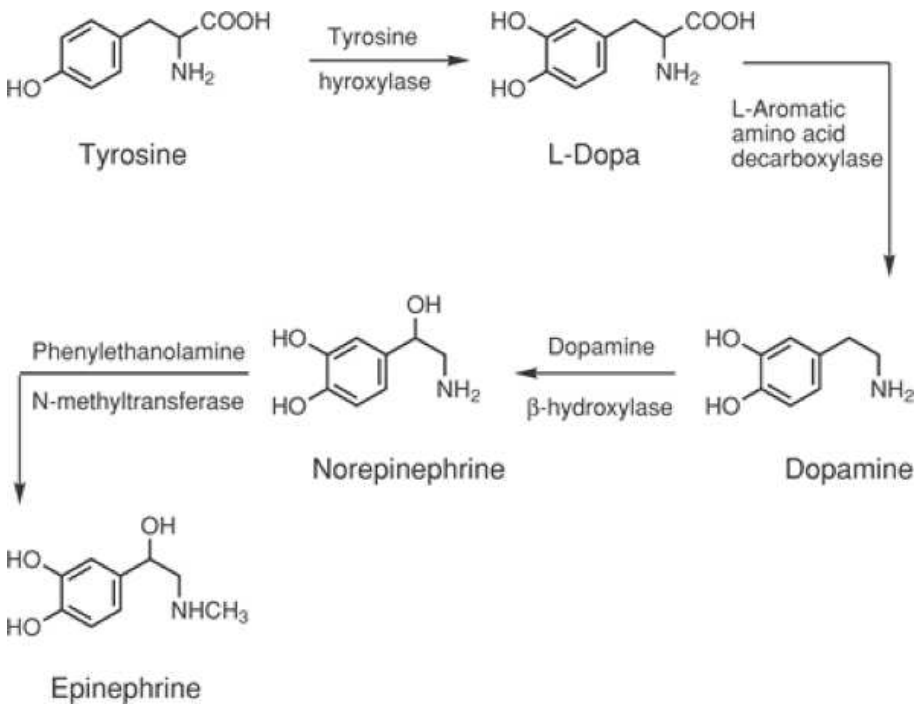

Fig. 44.4. The biosynthesis of norepinephrine and epinephrine from tyrosine.

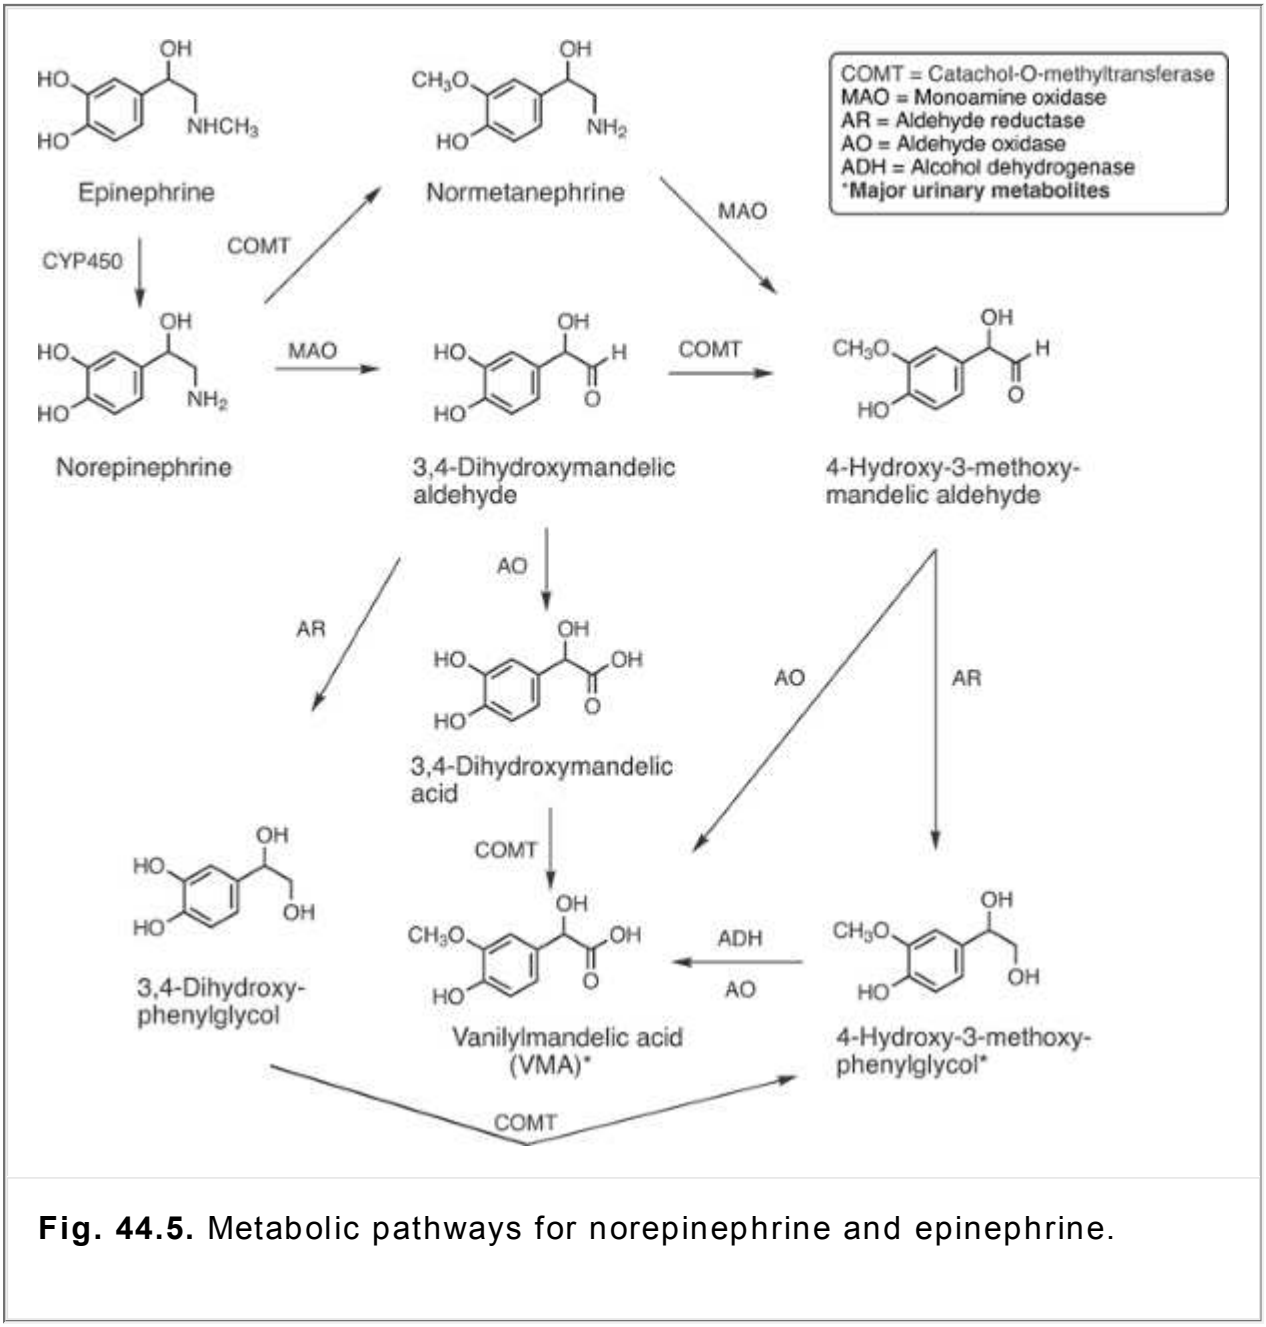

Fig. 44.5. Metabolic pathways for norepinephrine and epinephrine.

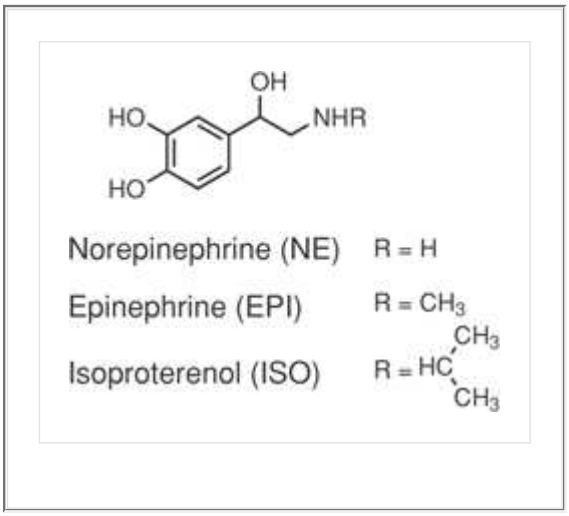
Adrenergic Receptors

The adrenergic receptors have long been pharmacologically classified as α or β based on their interaction with NE, EPI, and the adrenergic prototype, isoproterenol (19).



As mentioned above, NE and EPI are nonselective and interact with all adrenergic receptors, but isoproterenol selectively interacts only with the β-receptors. The adrenergic receptors have been further divided into three groups, α_1, α_2 and β, each of which has been further divided into three receptor subtypes based on their organ distribution and physiologic activities (20). Therefore, there are now a total of nine adrenergic receptor subtypes, but the most important in relation to the treatment of asthma and chronic obstructive pulmonary disease (COPD) are the β_1 and β_2 subtypes that are found primarily in the heart and the lung, respectively. As may be deduced from Table 44.4, adrenergic agonists that are selective for the β_2 subtype will cause bronchial dilation and might be expected to relieve the bronchospasm of an asthmatic attack. Nonselective β-agonists, however, will have stimulatory cardiac effects and, therefore, would have limited use in cardiac patients with asthma.

Adrenergic Receptor Structure and Agonist Interactions

The adrenergic receptors are a member of the guanine nucleotide binding regulatory protein–coupled receptor family more commonly referred to as G protein–coupled receptors. They affect biological activity by releasing secondary messenger molecules inside the cell after they bind an extracellular agonist. This process usually is referred to as signal transduction and is common to hormone and neurotransmitter receptors found in the muscarinic, serotonergic, dopaminergic, and adrenergic systems. All the G protein–coupled receptors are structurally similar, being comprised of seven transmembrane α-helix bundles. The helices are connected by short stretches of hydrophilic residues, which form multiple loops in the intracellular and extracellular domains. The G proteins generally are bound to the third intracellular loop and imbedded in the inner membrane (Fig. 44.6).

Table 44.4. Physiological Response in Relationship to β-receptor Subtype and Organ Site

Receptor Subtype	Organ Location	Response
β_1	Heart	Increased rate and force Increased conduction velocity

β_2	Bronchiole smooth muscle	Dilation
	Intestine	Decreased motility
	Liver	Increased gluconeogenesis Increased glycogenolysis
	Uterus	Contraction
	Lungs	Bronchial dilation

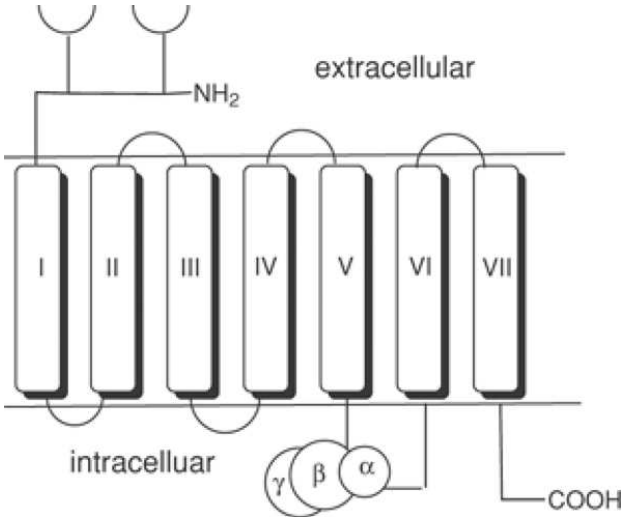


Fig. 44.6. Representation of the G protein–coupled receptor.

All the β-adrenergic receptors are coupled to adenylate cyclase via specific G stimulatory proteins (Gs). When agonist binds to the β-adrenergic receptors, the α-subunit migrates through the membrane and stimulates adenylate cyclase to form cyclic adenosine monophosphate (cAMP) from adenosine triphosphate. Once formed in the cell, cAMP activates protein kinase A, which catalyzes the phosphorylation of numerous proteins, thereby regulating their activity and leading to characteristic cellular responses. The intracellular enzyme phosphodiesterase (PDE) hydrolyzes cAMP to form AMP and terminates its action (Fig. 44.7).

A great deal of research has been done to identify the binding residues of the adrenergic receptors. Molecular modeling methods have been used to construct three-dimensional models for agonist complexes with the β-adrenergic receptors. The picture that has emerged is that NE binds ionically via its protonated amine to Asp-113 in helix 3 and hydrogen bonds to both

hydroxyls of the catechol ring with Ser-204 and Ser-207 in helix 5. That binding limits configurational and rotational freedoms, which allows reinforcing van der Waals interactions between the aromatic ring with residues Phe-290 in helix 6 and Val-114 in helix 3. The N-alkyl substituents are believed to fit into a

pocket formed between aliphatic residues in helix 6 and helix 7. Stereochemistry also plays an important role in receptor binding. The β-carbon in NE/EPI is chiral and can be either *R* or *S* in configuration. Endogenous NE/EPI exists in the *R* configuration so that the β-hydroxyl oriented toward the receptor Asn-293. (Fig. 44.8) (21,22).

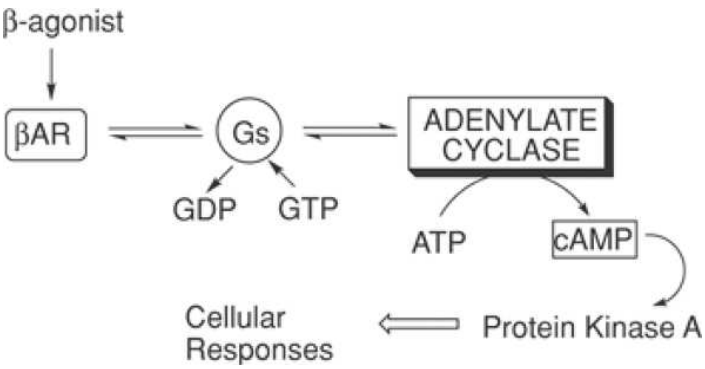

Fig. 44.7. β-Adrenergic receptor G protein coupling to adenylate cyclase.

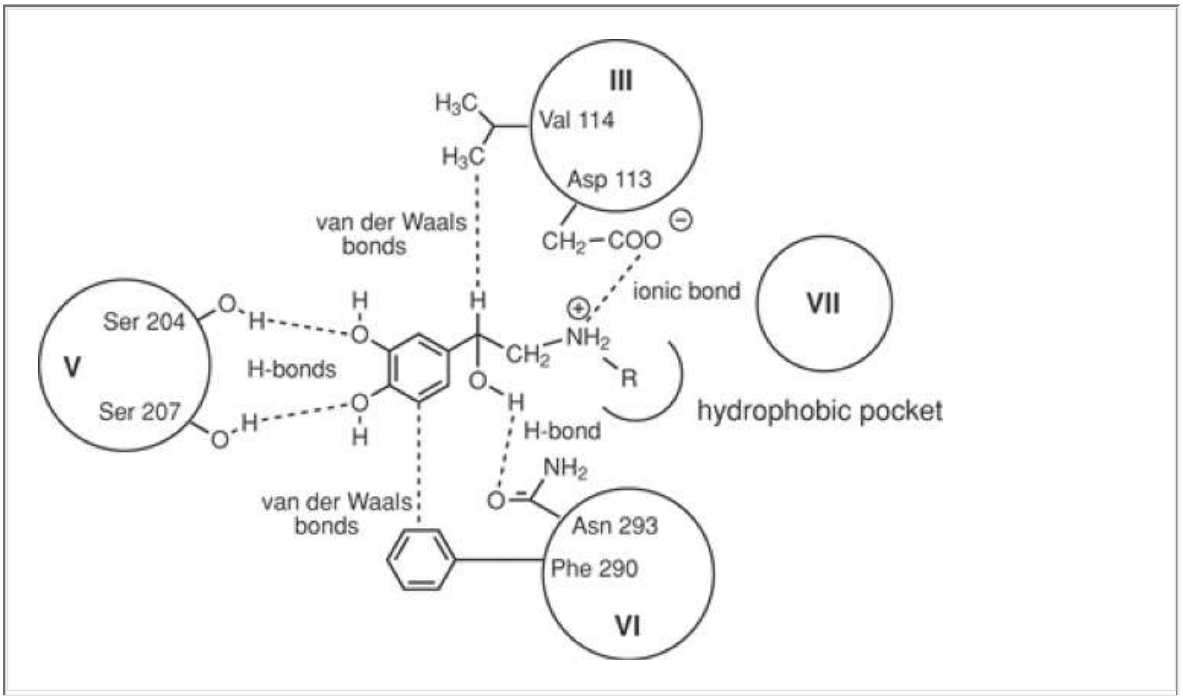

Fig. 44.8. Ligand binding to key residues in the adrenergic receptor.

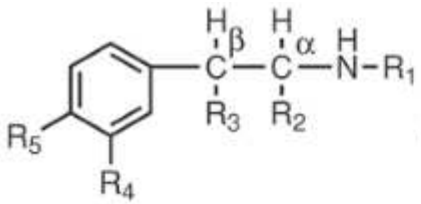
Adrenergic Agonist Structure–Activity Relationships

The fundamental pharmacophore for all adrenergic agonists is a substituted β-phenylethylamine (Table 44.5). The nature and number of substituents on the pharmacophore influences whether an analogue will be direct-acting or indirect-acting or have a mixture of direct and indirect action. In addition, the nature and number of substituents also influences the specificity for the β-receptor subtypes. Direct-acting adrenergic agonists bind the β-adrenergic receptors just like NE/EPI, producing a sympathetic response. Indirect-acting agonists cause their effect by a number of mechanisms. They can stimulate the release of NE from the presynaptic terminal, inhibit the reuptake of released NE, or inhibit the metabolic degradation of NE by neuronal MAO (i.e., MAO inhibitors). Mixed-acting agonists work as their name implies (i.e., they have both direct and indirect abilities). Table 44.5 shows the relationship between substituents and the mechanisms of action by adrenergic agonists.



Adrenergic agonist pharmacophore

Action	R_3	R_4	R_5
Direct[1]	OH	OH	OH
or	OH	OH	H
Indirect[2]	H	H	H
or	H	H	OH
Mixed[3]	H	OH	OH
or	OH	H	OH

[1] β-OH (R_3) necessary for direct action, optimal if in the R-configuration; *m*-OH (R_4) also necessary for direct action; *p*-OH (R_5) can be an H or OH, however catechol optimal.
[2] Without the catechol OH's (R_4 & R_5) or β-OH (R_3) there is little affinity for the β-receptor; *p*-OH doesn't contribute to β-receptor binding affinity.
[3] β-OH (R_3) or *m*-OH (R_4) contribute to direct action.

Table 44.5. Relationship of Substituents to Adrenergic Agonist Mechanism of Action

Relationship of Structure to α- or β-Receptor Selectivity

The substituents on the amino group (R_1) determines α- or β-receptor selectivity. As was noted above, when the N-substituent was changed from hydrogen (NE) to methyl (EPI) to isopropyl, the receptor affinity went from nonselective for NE/EPI to β-selective for isopropyl. Therefore, one can say that the larger the bulk of the N-substituent, the greater the selectivity for the β-receptor. As a matter of fact, if R_1 is *t*-butyl or aralkyl, there is complete loss of α-receptor affinity, and the β-receptor affinity shows preference for the β_2-receptor. It must be said that receptor selectivity is dose related, and when the dose is high enough, all selectivity can be lost.

Substituents on the α-carbon (R_2) other than hydrogen will show an increased duration of action, because they make the compound resistant to metabolism by MAO. In addition, if the substituent is ethyl, there is a selectivity for the β_2-receptor, which is enhanced by a bulky N-substituent. Interestingly, α-methyl substitution shows a slight β-receptor enhancement and only for the *S*-configuration.

For an adrenergic agonist to demonstrate significant β_2-receptor selectivity, there needs to be in addition to the bulky N-substituent an appropriately substituted phenyl ring. The currently

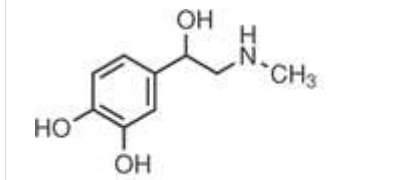
marketed adrenergic agonists contain a resorcinol ring, a salicyl alcohol moiety, or a m-formamide group (Fig. 44.9). In addition, these ring configurations are resistant to COMT metabolism and will increase the duration of action.

Specific Adrenergic Drugs Used to Treat Asthma

For a more detailed discussion of the chemistry of adrenergic agents, see Chapter 13.

Fig. 44.9. Ring configurations that contribute to β_2-receptor selectivity.

Epinephrine (Adrenalin)



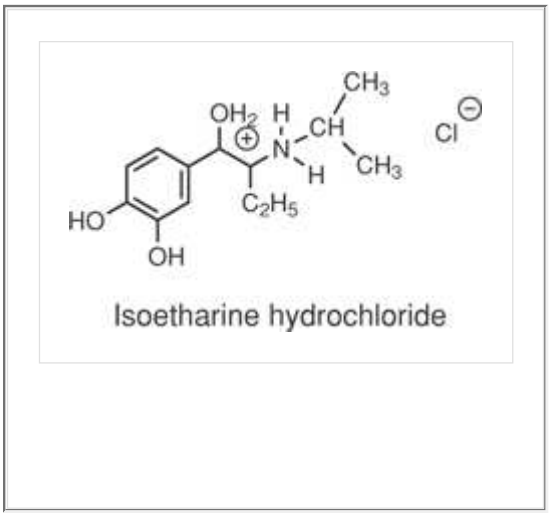
The combination of the catechol nucleus, the β-hydroxyl group, and the N-methyl give EPI a direct action and a strong affinity for all adrenergic receptors. Epinephrine and all other catechols are chemically susceptible to oxygen and other oxidizing agents, especially in the presence of bases and light, quickly decomposing to inactive quinones. Therefore, all catechol drugs are stabilized with antioxidants and dispensed in air-tight amber containers.

Epinephrine is ultimately metabolized by COMT and MAO to 3-methoxy-4-hydroxy-mandelic acid (vanillylmandelic acid), which is excreted as the sulfate or glucuronide in the urine (Fig. 44.5).

Only a very small amount is excreted unchanged.

Epinephrine usually is administered slowly by intravenous (IV) injection to relieve acute asthmatic attacks not controlled by other treatments. Intravenous injection produces an immediate response. Use of EPI with drugs that enhance cardiac arrhythmias (digitalis or quinidine) is not recommended. Tricyclic antidepressants and MAO inhibitors will potentiate the effects of EPI on the heart. Epinephrine should be used with caution in individuals suffering from hyperthyroidism, cardiovascular disease, hypertension, or diabetes. Adverse effects include palpitations, tachycardia, sweating, nausea and vomiting, respiratory difficulty, dizziness, tremor, apprehension, and anxiety.

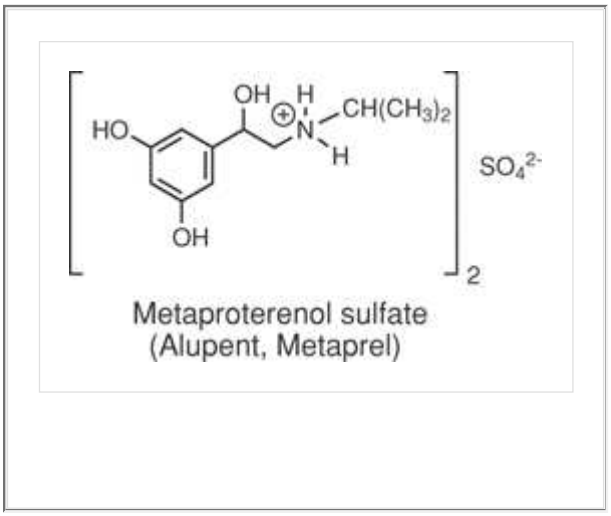
Isoetharine Hydrochloride



The α-ethyl group confers β_2-selectivity, and the β-hydroxyl group and catechol nucleus makes this a direct-acting drug. It is susceptible to COMT metabolism; however, the α-ethyl group inhibits MAO. Therefore, one would expect some oral activity.

Isoetharine is dispensed as a solution only for inhalation administration to treat reversible bronchospasm of asthma. It has fallen into relative disuse, because with high doses, there is a significant incidence of cardiovascular (β_1-receptor) adverse effects and it has a low β_2-receptor potency compared to newer β_2-selective agonists. It has a 2- to 4-minute onset of action when inhaled and a duration of action of 3 hours. Isoetharine has adverse effects similar to those of EPI, including palpitations, tachycardia, nausea and vomiting, dizziness, tremor, and headache. Isoetharine may cause decreased levels of theophylline when coadministered. Cardiovascular effects are a concern when isoetharine is taken with other asthma drugs.

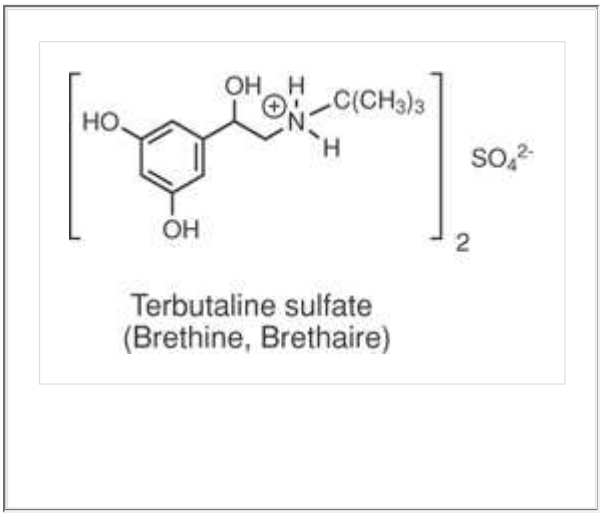
Metaproterenol Sulfate



Metaproterenol sulfate
(Alupent, Metaprel)

Metaproterenol is a direct-acting resorcinol analogue of isoproterenol. The N-isopropyl is β-directing, and the combination with the resorcinol ring system enhances the selectivity for the β_2-receptors. It is the least potent of the β_2-selective agonists, however, most likely because of the poor β_2-selectivity of the isopropyl group. It has good oral bioavailability being resistant to COMT and only slowly metabolized by MAO. When administered orally, it has an onset of approximately 30 minutes with a 4-hour duration. Inhaled metaproterenol can have an onset as quick as 5 minutes; however, it can be as long as 30 minutes in susceptible individuals. Metaproterenol is available in tablet, syrup, and inhalation dosage forms and is recommended for bronchial asthma attacks and treatment of acute asthmatic attacks in children 6 years of age and older (5% solution for inhalation only). Metaproterenol has the same adverse effect profile as other adrenergic agonists, but with a decreased incidence of arrhythmias.

Terbutaline Sulfate



Terbutaline sulfate
(Brethine, Brethaire)

Terbutaline is the N-*t*-butyl analogue of metaproterenol and, as such, would be expected to have a more potent β_2-selectivity. When compared to metaproterenol, terbutaline has a threefold greater potency at the β_2-receptor. Like metaproterenol, it is resistant to COMT and slowly metabolized by MAO, therefore having good oral bioavailability with similar onset and duration. Terbutaline is available as tablets and solutions for injection and inhalation. Adverse effects are similar to other

direct-acting β_2-selective agonists, however, with a greater incidence of palpitations.

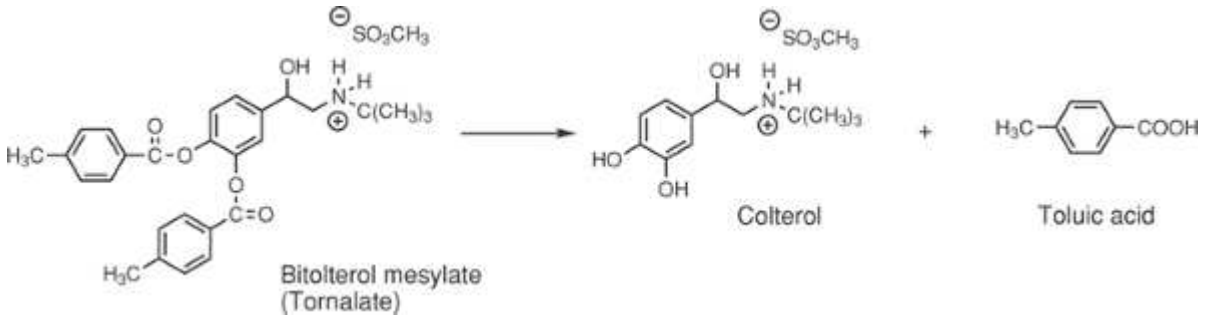


Fig. 44.10. Esterase hydrolysis of bitolterol.

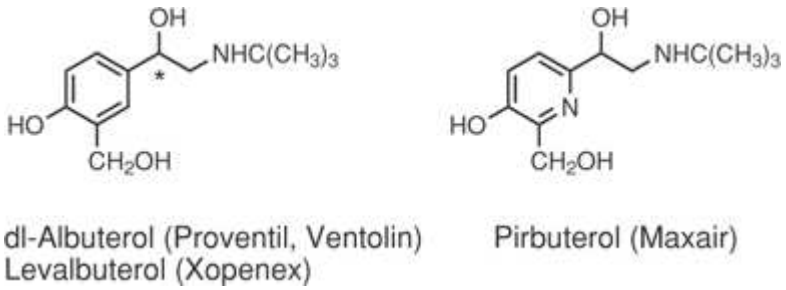
Bitolterol Mesylate

Bitolterol is a prodrug that releases colterol on activation by esterases in the lung (Fig. 44.10). Colterol is a direct-acting agonist, and the N-*t*-butyl group makes it β_2-selective with a binding potency equivalent to that of isoetharine and terbutaline. The ester form is lipophilic, which helps to keep it local in the lung and resistant to COMT, which tends to increase its duration of action. Onset begins 2 to 4 minutes after administration, and the effect can last as long as 8 hours. It has a adverse effect profile similar to that of other β_2-selective agonists, with less drowsiness and restlessness compared to other direct-acting agonists.

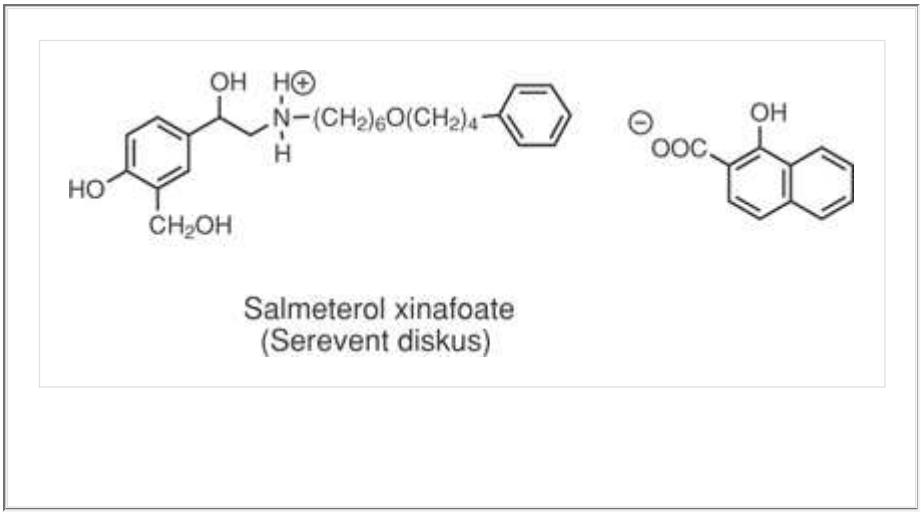
Albuterol



Albuterol has the N-*t*-butyl and a salicyl alcohol phenyl ring, which gives it optimal β_2-selectivity. It is resistant to COMT and slowly metabolized by MAO, giving it good oral bioavailability. Its onset by inhalation is within 5 minutes, with a duration of action between 4 and 8 hours. It currently is the drug of choice for relief of the acute bronchospasm of an asthmatic attack. Levalbuterol is the *R*-(–)-isomer of albuterol and is available only in solution to be administered via nebulizer. Because it is the active isomer, the dose is fourfold less than that of albuterol.

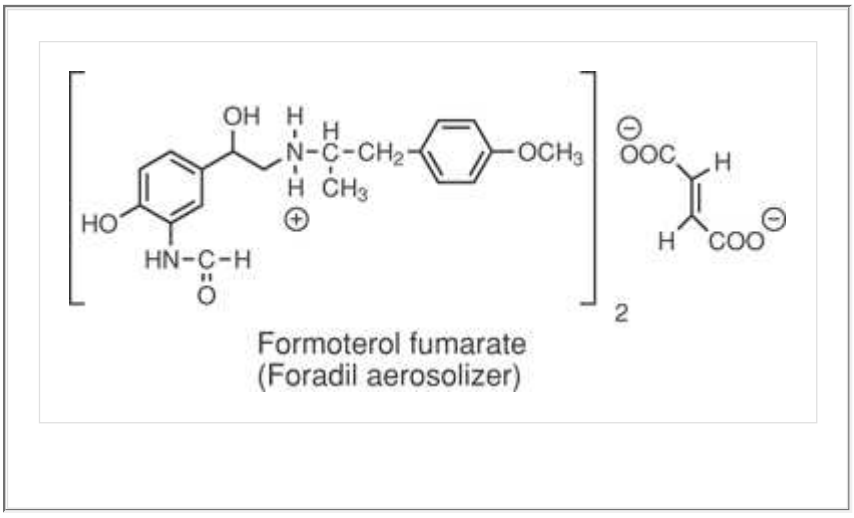
Pirbuterol is the pyridine isostere of albuterol. It has pharmacokinetics similar to albuterol but is half as potent at the β_2-receptor. Pirbuterol is only available as an inhaler, whereas albuterol comes in tablet, syrup, solution, and aerosol formulations. Adverse effects of pirbuterol are nervousness, tremor, and headache, which is less than the profile for albuterol, which adds nausea, vomiting, dizziness, hypertension, insomnia, tachycardia, and palpitations.

Salmeterol Xinafoate



Salmeterol has an N-phenylbutoxyhexyl substituent in combination with a β-hydroxyl group and a salicyl phenyl ring for optimal direct-acting β_2-receptor selectivity and potency. Salmeterol has the greatest receptor affinity of all the adrenergic agonists. It is resistant to both MAO and COMT and that, together with its increased lipophilicity, gives salmeterol a long duration of action. It is postulated that the phenylbutoxyhexyl N-substituent binds outside of the receptor site and keeps the active pharmacophore moiety in position for prolonged stimulations. It is available only as a powder for inhalation, with a 20-minute onset of action, which lasts for 12 hours. It is used as a controller for the long-term treatment of asthma and is not recommended for quick relief of an acute attack. It also is available in combination with the steroid fluticasone proprionate (Advair Diskus). There was a small but significant increase in asthma-related deaths among patients receiving salmeterol during a large clinical trial. Subgroup analyses suggested that the risk may be greater in black patients compared with Caucasian patients (23).

Formoterol Fumarate

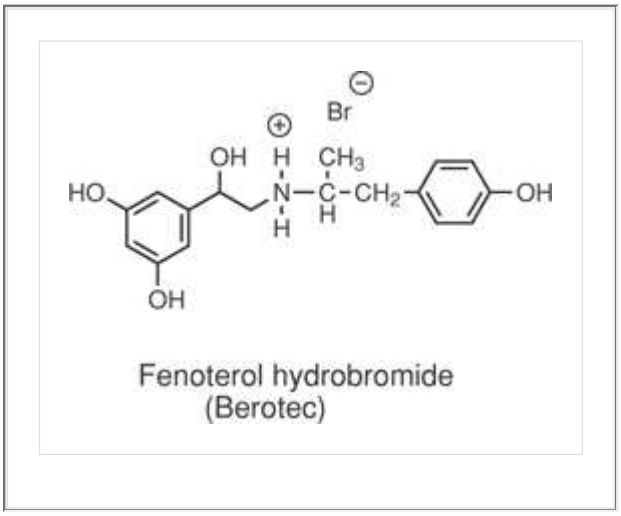


Formoterol has a β-directing N-isopropyl-*p*-methoxyphenyl group and a unique *m*-formamide and *p*-hydroxyphenyl

ring, which provides selectivity for β_2-receptors. It is resistant to MAO and COMT, making it a long-acting agonist. Formoterol has a more rapid onset as compared to salmeterol while maintaining the same long duration of action.

This is believed to result from formoterol's greater water solubility, allowing it to get to the receptor sites faster, whereas its moderate lipophilicity keeps it in the lungs longer. It is indicated for the long-term maintenance treatment of asthma and for patients with symptoms of nocturnal asthma who require regular treatment with inhaled, short-acting, β_2-agonists. It is not indicated for patients whose asthma can be managed by occasional use of inhaled, short-acting, β_2-agonists. Formoterol is available only as a powder in a capsule for administration via the aerosolizer. Patients should be cautioned not to take the capsules orally and to keep them in a safe place to avoid accidental oral administration.

Fenoterol Hydrobromide



Fenoterol is an investigational drug in the United States that has been in use in Europe since 1970. It is the *p*-hydroxyphenyl derivative of metaproteronol, and the combination of the resorcinol ring and the bulky *p*-hydroxyphenyl isopropyl group on the nitrogen gives fenoterol significant β_2-receptor selectivity. It has approximately half the affinity for the β_2-receptor as compared to albuterol. The resorcinol ring is resistant to COMT metabolism, and the bulky nitrogen substituent greatly retards MOA metabolism as well giving fenoterol a reasonable oral bioavailability with pharmacokinetics similar to albuterol (i.e., rapid onset and a 4- to 6-hour duration of action after oral inhalation).

Antimuscarinics

Introduction

Acetylcholine is the endogenous neurotransmitter of the parasympathetic nervous system. The parasympathetic nerve fibers are found in both the autonomic and central nervous systems. These fibers are classified into those that are stimulated by muscarine and those that are stimulated by nicotine. Nicotine, an alkaloid from *Nicotiana tabacum*, stimulates preganglionic fibers in both the parasympathetic and sympathetic systems as well as the somatic motor fibers of the skeletal system. Muscarine, an alkaloid from the poisonous mushroom *Amanita muscaria*, stimulates postganglionic parasympathetic fibers with receptors found on autonomic effector

cells. The central nervous system has fibers that contain both nicotinic and muscarinic receptors. In this chapter, we are most interested in the drugs that block the muscarinic fibers (antimuscarinics), because blocking them results in cardiovascular, mydriatic, antispasmodic, antisecretory, and bronchodilatory effects.

Biochemistry and Metabolism of Acetylcholine

Acetylcholine is the ester formed between acetylcoenzyme A and choline by the action of choline acetyltransferase in the presynaptic cholinergic neurons. Most of the choline used to biosynthesize acetylcholine comes via uptake from the synaptic space, where it is produced from the hydrolysis of acetylcholine by acetylcholinesterase, a serine hydroxylase. Additionally, some choline is biosynthesized in the presynaptic neurons from serine (Fig. 44.11). Once formed, acetylcholine is stored in vesicles from which it is released on stimulation.

The duration of action of acetylcholine is very short, because it is rapidly hydrolyzed by the acetylcholinesterase present in the synaptic space. This hydrolysis is a straightforward splitting of the acetylcholine into acetic acid and choline; however, the way this happens is very interesting and begins by the proper binding of acetylcholine in the catalytic pocket. Binding of the cationic N-end to tyrosine, glutamate, and tryptophan via a combination of π-cation and electrostatic forces places the acyl head of acetylcholine in the correct position for attack by the serine hydroxyl group (Fig. 44.12).

Once properly bound, the hydrolysis actually involves two hydrolytic steps. The first step is the hydrolysis of acetylcholine by nucleophilic attack at the carbonyl carbon by the serine hydroxyl group, which liberates choline and leaves the enzyme acetylated. A triad formed between glutamine, histidine, and the serine at the catalytic site activates the serine for the nucleophilic attack. The second step is the hydrolysis of the acetylated enzyme by water to regenerate the free enzyme. The water is activated by hydrogen-bonding to the histidine residue, which increases the nucleophilic character of

the oxygen of water. The activated water attacks the electrophilic carbonyl carbon of the acetyl group to generate acetate and regenerate the free hydroxyl group of serine (Fig. 44.13) (24).

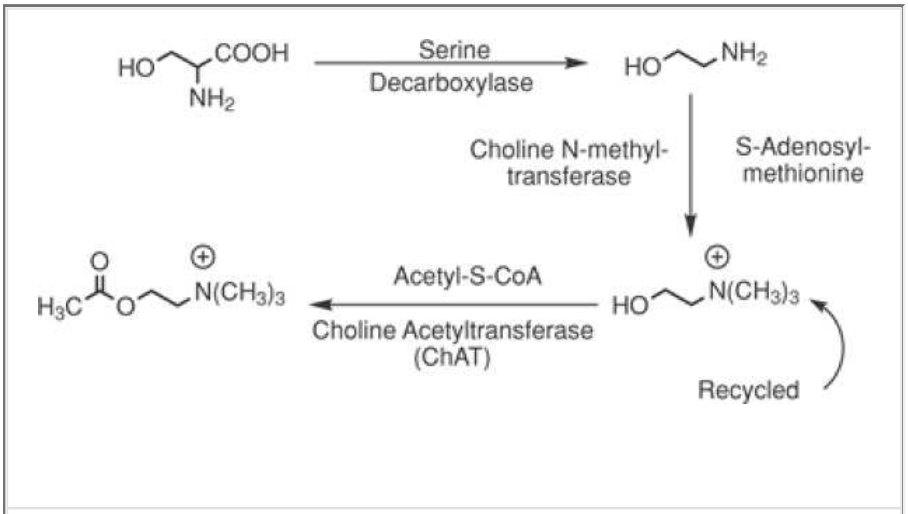


Fig. 44.11. Biosynthesis of acetylcholine.

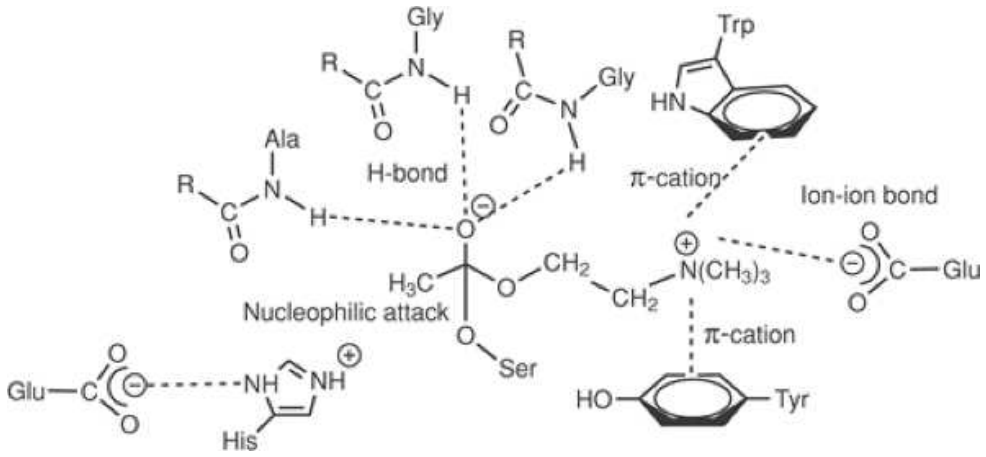

Fig. 44.12. Binding of acetylcholine in the catalytic site of acetylcholinesterase.

Muscarinic Receptor Structure and Agonist/Antagonist Interactions

The muscarinic receptors are considered to be part of the superfamily of G protein–coupled receptors. They consist of seven transmembrane helices and are linked to their G protein through interaction with the second and third intracellular loops (25). There are five subtypes of receptor, designated M_{1-5}, and the odd-numbered receptors (M_1, M_3, and M_5) are coupled to the G_q/G_{11} class. This class of receptors activate intracellular phospholipase C to hydrolyze phosphatidylinositol 4,5-diphosphate to diacylglycerol and inositol triphosphate as intracellular messengers. The even-numbered receptors (M_2 and M_4) are coupled to the G_i/G_o class, which mediates the inhibition of adenylate cyclase (Fig. 44.14).

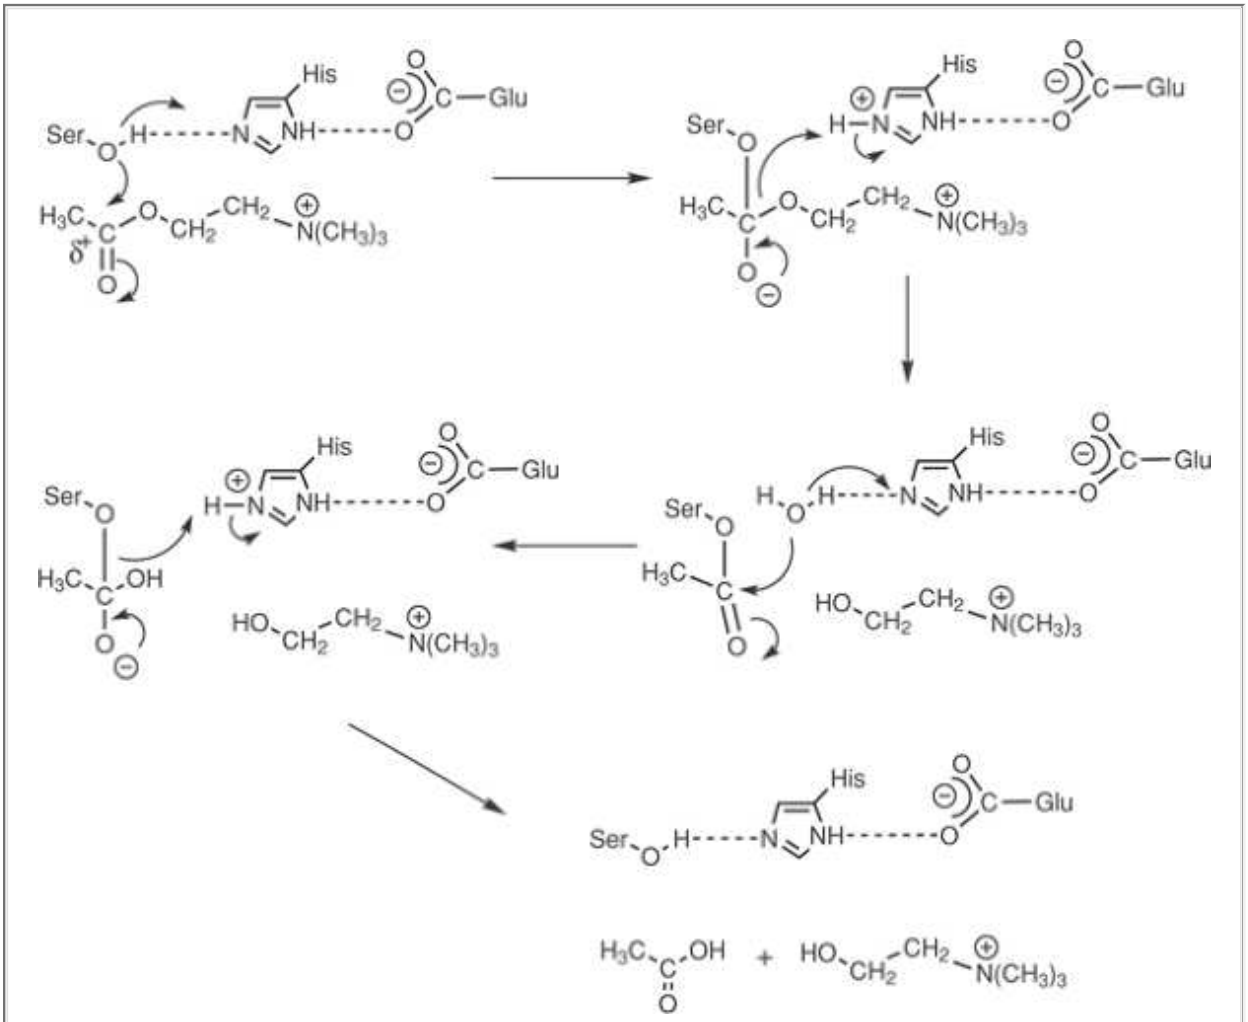

Fig. 44.13. The role of the triad formed between glutamine, histidine, and serine in the hydrolysis of acetylcholine by acetylcholinesterase.

Table 44.6 lists the physiologic action of the M_3 receptors. Because the M_3 receptors cause bronchiole constriction, they counterbalance the bronchiole dilation of the β_2-adrenergic receptors in the lung, resulting in maintenance of bronchiole tone. This forms the basis for the therapeutic use of inhaled antimuscarinics, because they block cholinergic bronchiole constriction and allow

adrenergic bronchiole dilation to help overcome the pulmonary constriction associated with an asthmatic attack.

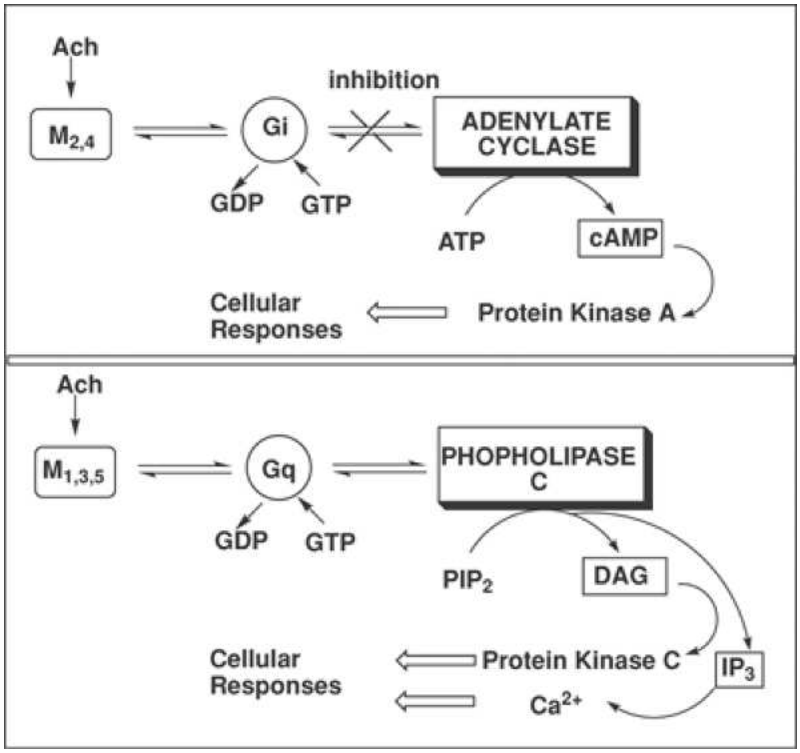

Fig. 44.14. Comparison of the role of G protein in odd- and even-numbered muscarinic receptors.

Affinity labeling and mutagenic studies have established that acetylcholine binds to its receptor in a narrow region of the circular arrangement of the seven transmembrane helices approximately 10 to 15 angstroms away from the membrane surface. The cationic nitrogen of acetylcholine binds to the anionic carboxylate of an Asp located in helix 3 (26). As depicted in Figure 44.15, the ionic interaction is stabilized by hydrogen-bonding with a Tyr in helix 5 and a Thr in helix 5. It is postulated that muscarinic antagonists (see Structure–Activity Relationships of Antimuscarinic Agents below) bind to the Asp and contain hydrophobic substituents that bind to a hydrophobic pocket in the receptor, which does not allow the change in conformation needed to transfer the agonist signal to the coupled G protein (27).

Table 44.6. Physiological Action Associated with the M_3 Muscarinic Receptors

Organ	M_3-Receptor Effect
Eye	
Iris circular muscle	Contracts
Ciliary muscle	Contracts

Heart	
Sinoatrial node	Decelerates
Atrial contractility	Decelerates
Bronchiole smooth muscle	Contracts
Gastrointestinal tract	
Smooth muscle	Contracts

receptor.

Structure–Activity Relationships of Antimuscarinic Agents

The structural pharmacophore for all antimuscarinic drugs is an acetylcholine analogue in which the acetyl methyl group is substituted with at least one phenyl ring. This pharmacophore generally is classified as an amino alcohol ester. The ester function can be replaced with different moieties to produce different classes of antimuscarinic drugs. When the ester function is replaced by an ether function, the amino alcohol ether class is produced. When the ester function is replaced by a saturated carbon, the amino alcohols are obtained when R_1 is a hydroxyl group, and the amino amides are obtained when R_1 is an amido group (Fig. 44.16).

The classic chemical prototype for the antimuscarinics is atropine, an alkaloid from *Atropa belladonna*. Buried within its structure is the amino alcohol ester pharmacophore, where R_1 is a hydroxymethyl group, R_2 is a hydrogen, and the nitrogen is part of a bicyclic ring system called tropine (Fig. 44.17).

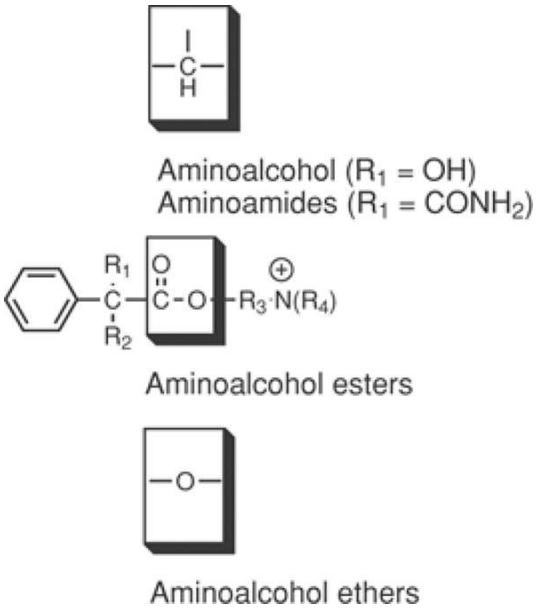

Fig. 44.16. The pharmacophore for all classes of antimuscarinic agents.

P.1243

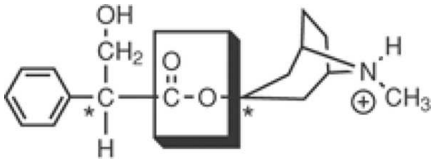

Fig. 44.17. Atropine is an example of the amino alcohol ester class of antimuscarinic agents.

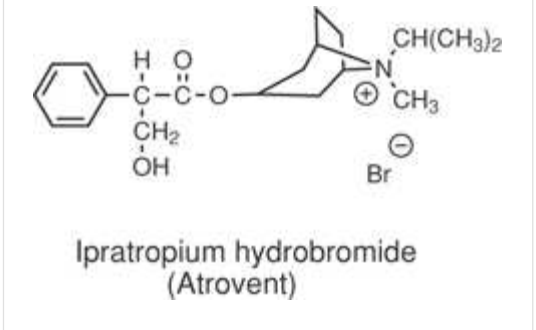
Although atropine does not have a quaternary nitrogen, the nitrogen is protonated at physiologic pH; therefore, it can bind to the anionic Asp residue in the muscarinic receptor. The nitrogen is not absolutely necessary for activity and can be replaced with a carbon atom. This leads to a substantial lose of binding affinity, however, and there are no marketed drugs with this configuration. The nitrogen can be substituted with alkyl groups, and methyl is the optimal size. When the nitrogen is made quaternary, the molecule loses its oral availability but leads to compounds that can be administered effectively by inhalation. The asterisks in atropine (Fig. 49.17) refer to chiral carbons. When stereochemistry is present in the amino alcohol moiety (tropine), there is little difference between the activities of the *R*- and *S*-configurations. When stereochemistry is found in the acid moiety, however, the *R* configuration is approximately 100-fold more active than the *S*-isomer. This indicates the importance of the binding role for the phenyl ring in causing the uncoupling of the G protein, which leads to receptor inhibition (28).

Specific Antimuscarinic Drugs Used to Treat Asthma

For a more detailed discussion of the chemistry of cholinergic agents, see Chapter 12.

Ipratropium Hydrobromide

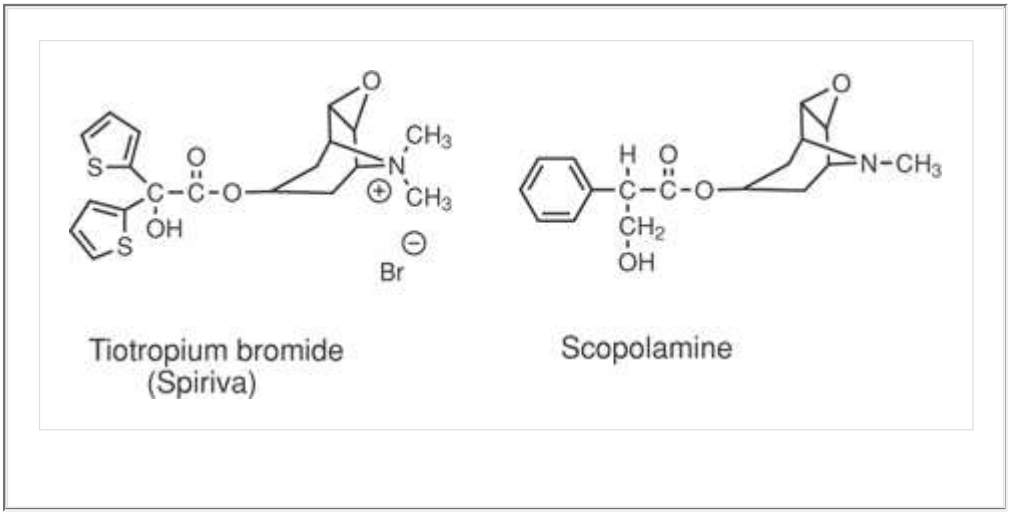


Ipratropium hydrobromide
(Atrovent)

Ipratropium is the N-isopropyl analogue of atropine. Its quaternary cationic nature makes it highly hydrophilic and poorly absorbed from the lungs after inhalation via solution or aerosol. Much of an inhaled dose is swallowed. There is no significant absorption, however, and the bronchodilation effect can be considered to be a local, site-specific effect. Ipratropium is indicated primarily for the relief of bronchospasms associated with COPD (chronic obstructive pulmonary disease) and has seen little application for the treatment of asthma. It also is administered by nasal spray for the relief of rhinorrhea associated with the common cold and

perennial rhinitis. Inhaled ipratropium has a 15-minute onset of action and a rather short duration of action (<4 hours); therefore, it is dosed four times a day. Other drugs, including adrenergic agonists, methylxanthines, steroids, and cromolyn sodium, can be coadministered with ipratropium without adverse drug reactions. The little ipratropium that reaches the circulation is minimally protein bound and is partially metabolized to inactive esterase products. Most adverse effects from ipratropium are common to antimuscarinics and include blurred vision, dry mouth, tachycardia, urinary difficulty, and headache. Patients should be careful not to spray ipratropium into their eyes, because its dilation effects can precipitate or exacerbate narrow-angle glaucoma.

Tiotropium Bromide



Tiotropium is the dithienyl derivative of N-methyl scopolamine, a quaternary analogue of naturally occurring scopolamine in *Atropa belladonna*. It is indicated primarily for the relief of bronchospasms associated with COPD and can be considered to be a site-specific, local medication to the lung. Tiotropium is administered as a dry powder via inhalation using a HandiHaler, in which is placed the drug, contained in a green capsule. Patients should be cautioned not to be confused and take the medication orally. Systemic distribution following oral inhalation is minimal, essentially because of its hydrophilic character. If swallowed, only approximately 14% of the dose is eliminated in the urine, with the remainder being found in the feces. Inhaled tiotropium has a 30-minute onset of action but a much longer duration of action than ipratropium (24 versus <4 hours, respectively). Tiotropium is metabolized by both CYP3A4 and CYP2D6, followed by glutathione conjugation to a variety of metabolites. Only a very small amount is nonenzymatically hydrolyzed to inactive products. Tiotropium has an adverse reaction profile similar to that of ipratropium, with dry mouth being the most common adverse effect; however, blurred vision, tachycardia, urinary difficulty, headache precipitation, and exacerbation of narrow-angle glaucoma have been reported.

Methylxanthines

Introduction

The methylxanthines naturally occur in coffee (*Coffea arabica*), cacao (*Theobroma cacao*), and tea (*Camellia sinensis*) (29). The major methylxanthines are caffeine, theophylline, and theobromine, and they differ by the

position and number of methyl groups on their xanthine ring system (Fig. 44.18).

	R_1	R_2	R_3
Caffeine	CH_3	CH_3	CH_3
Theophylline	CH_3	CH_3	H
Theobromine	H	CH_3	CH_3

Fig. 44.18. Structural differences between the methylxanthines.

The most common source of these xanthines is in the beverages coffee, tea, and cocoa, which are universally consumed mainly for their stimulant properties. A cup of coffee or tea contains between 60 and 85 mg of caffeine, and a cup of cocoa can have as much as 250 mg of theobromine. Caffeine frequently is added to cola drinks as well as to over-the-counter analgesics and stimulants. Theophylline is used for its bronchodilating effects in the treatment of asthma. Its importance has declined greatly since the development of the inhaled β_2-adrenergic agonists and inhaled steroids and because its narrow therapeutic window requires close patient monitoring and periodic blood level determination to avoid serious side effects.

Theophylline

In spite of a great deal of investigation, just how theophylline causes bronchodilation is not clearly understood. Inhibition of the enzyme PDE, which is responsible for the hydrolysis of cAMP and cyclic guanosine monophosphate (cGMP), generally is put forth as the mechanism of action; however, theophylline also is an adenosine antagonist and has been implicated in stimulation of the release of catecholamines. It has been clearly shown that theophylline does inhibit PDEs in vitro, and x-ray crystallographic studies have identified the binding residues that interact with the methylxanthines (Fig. 44.19).

Theophylline binds to a subpocket of the active site and appears to be sandwiched between a phenylalanine and a valine via hydrophobic bonds. Its binding affinity is reinforced by hydrogen-bonding between a tyrosine and N-7 and a glutamine and O-6 of the xanthine ring system. There are more than 11 families of PDEs, and studies have shown that theophylline binds in a similar manner to both the PDE4 and PDE5 family isoforms (30). (For a more detailed description of PDE subtypes and their inhibitors, see Chapter 17.)

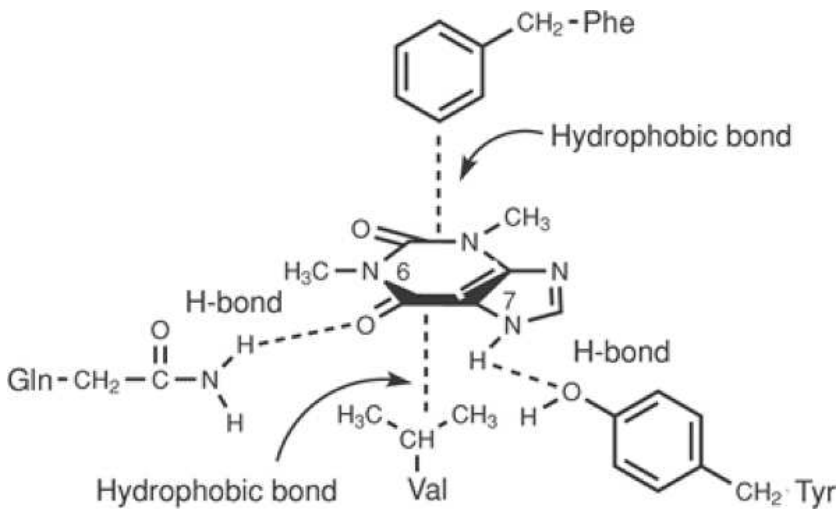


Fig. 44.19. Methylxanthine binding interactions in the catalytic pocket of phosphodiesterase.

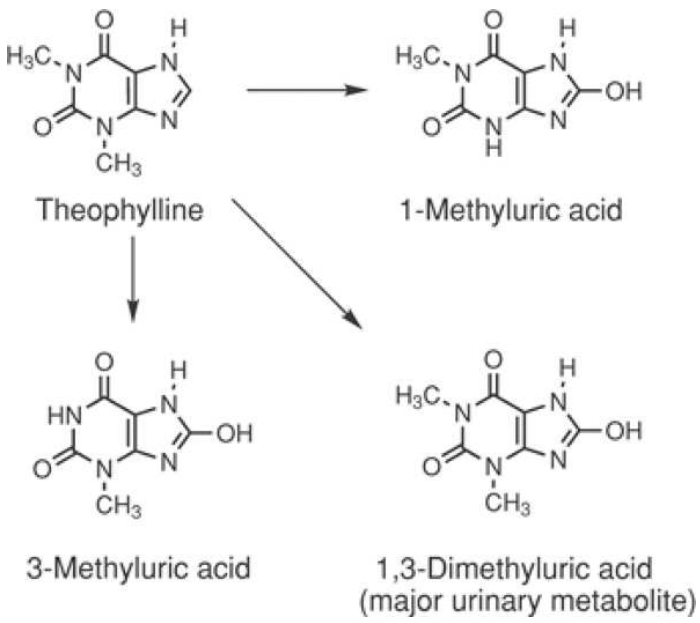

Fig. 44.20. Metabolism of theophylline.

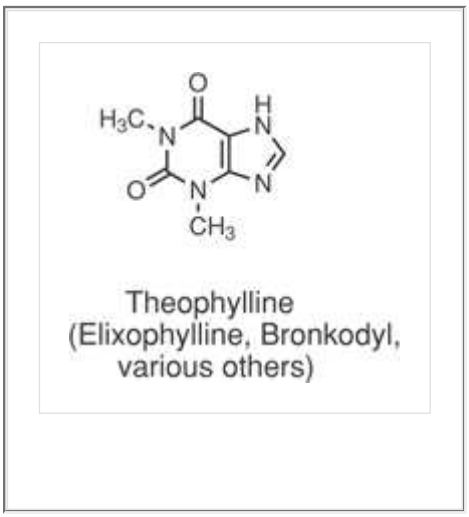
Chemically, theophylline is 1,3-dimethylxanthine and contains both an acidic and a basic nitrogen (N-7 and N-9, respectively). Physiologically, it behaves as an acid (pK_a = 8.6), and its poor aqueous solubility can be enhanced by salt formation with organic bases. Theophylline is metabolized by a combination of C-8 oxidation and N-demethylation to yield methyluric acid metabolites (Fig. 44.20). The major urinary metabolite is 1,3-dimethyl uric acid, which is the product of the action of xanthine oxidase. Because none of the metabolites is uric acid itself,

theophylline can be safely given to patients who suffer from gout.

Methylxanthine Drugs Used to Treat Asthma

Theophylline

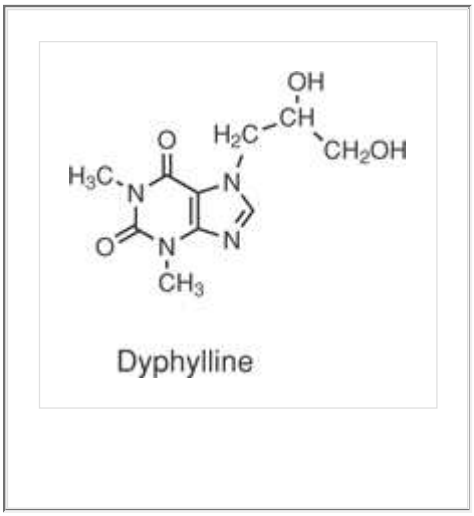


The primary indication for theophylline is as a controller medication for the treatment of bronchospasm of asthma and COPD. In addition to bronchodilation effects, theophylline dilates pulmonary blood vessels, acts centrally to stimulate respiration, acts as a diuretic, increases gastric acid secretion, and inhibits uterine contractions. Dosing requires the determination of plasma levels with 10 to 20 µg/mL being associated with the least incidence of side effects. Overdose of theophylline can result in a quick onset of ventricular arrhythmias, convulsions, or even death

P.1245

without any previous warning. Many drugs increase the plasma concentration of theophylline, including quinolone and macrolide antibiotics, nonselective β-blockers, ephedrine, calcium channel blockers, cimetidine, and oral contraceptives. Theophylline is available in tablet, capsule, liquid, and parenteral dosage preparations. There also are combination products with guaifenesin and ephedrine available as tablet and liquid dosage forms. There are two products that are theophylline salts. Aminophylline is theophylline ethylenediamine, which contains 70% theophylline and is available in tablets, liquid, parenteral, and suppository dosage forms. Oxytriphylline is the choline salt of theophylline, and it contains 64% theophylline in tablets and liquid dosage forms. Care must be taken to correctly calculate the equivalent dose when switching a patient from theophylline to one of its salts.

Dyphylline (Dihydroxypropyl Theophylline)



Dyphylline is the N-7 dihydroxypropyl derivative of theophylline and is not a theophylline salt. Dyphylline does not get metabolized to theophylline in vivo, and even though it contains 70% theophylline by molecular weight ratio, the equivalent amount to theophylline is not known. Dosing must be accomplished independently by monitoring dyphylline blood levels. Dyphylline has a diminished bronchodilator effect compared to theophylline, but it may have lower and less serious side effects. Dosage forms available are an elixir and tablets.

Adrenocorticoids Used to Treat Asthma and COPD

Introduction

Steroids are a large class of tetracyclic terpene compounds that are widely distributed in plants and animals. Many synthetic analogues have been made to take advantages of their various pharmacological activities. There are four major classes of steroids: the adrenocorticoids, the sex hormones, the bile acids, and the vitamins. The adrenocorticoids are formed in the adrenal cortex and are subdivided into the glucocorticoids and mineralocorticoids. The glucocorticoids are so named because they affect glucose homeostasis, but they also have significant anti-inflammatory activity. The mineralocorticoids affect sodium and water retention. The reproductive organs in both the male and female produce steroid hormones that are responsible for the differentiation of the sex characteristics and the development of muscle and hair. The bile acids are derived from cholesterol and are an essential aid to the action of lipase in the digestion of fats, and vitamin D and its derivatives are associated with calcium homeostasis. We will limit our discussion to the glucocorticoids, because their anti-inflammatory activity makes them useful for the treatment of asthma and COPD. Of note, because the major role of the glucocorticoids is to provide the body with levels of glucose that are compatible with life, they should be used with caution in patients with diabetes. Similarly, because the major role of the mineralocorticoids is to maintain blood volume and regulate electrolyte balance, their use in patients with hypertension should be monitored carefully. (For more detail regarding the adrenal corticosteroids, see Chapter 33.)

Steroid Nomenclature

The basic structure of a steroid is a tetracyclic cyclopentanoperhydrophenanthrene, referred to as the sterid nucleus, as depicted in Figure 44.21. The addition of methyl groups at C-10 and C-13 and of an ethyl group at C-17 to the sterid nucleus gives a 21-carbon base structure called pregnane. All glucocorticoids are substituted pregnanes. Rings A, B, and C are in the chair conformation, All ring junctions are *trans*, giving the glucocorticoids a rigid backbone with α and β faces. The glucocorticoids bind to their receptor via the β face. All glucocorticoids have at least

one double bond in ring A and hydroxyl groups at C-11, C-17, and C-21 as well as 3- and 20-keto groups. For example, hydrocortisone is Δ^4- 11β,17α,21-trihydroxy-3,20-pregnenedione. A more complete discussion of steroid nomenclature and stereochemistry has been published elsewhere (31).

Steroid Biosynthesis and Secretion

Steroids are biosynthesized from cholesterol. Cholesterol is obtained through our diet (~0.3 g/day), but the majority is biosynthesized from acetate in the liver (~1 g/day). The complete pathway can be seen in Figure 44.22. Of note is the central branching role played by pregnenolone, leading to both classes of the adrenocorticoids.

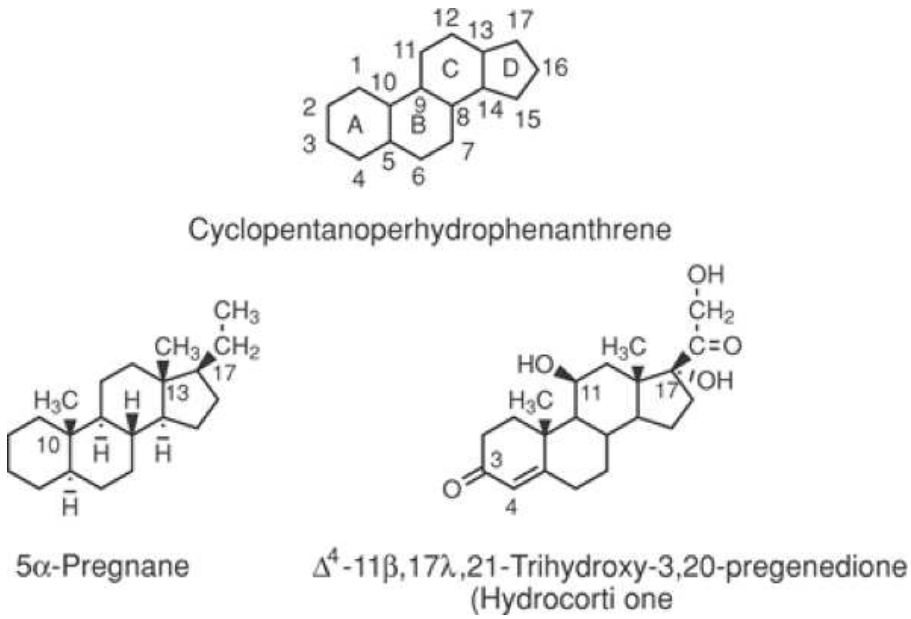


Fig. 44.21. Basic skeletons for steroid structures, numbering and nomenclature.

P.1246

Once formed, the adrenocorticoids are secreted into the circulatory system, and circulating levels are maintained via a feedback mechanism (Fig. 44.23). When circulating levels are low, the hypothalamus secretes corticotrophin-releasing factor (CRF). In turn, CRF stimulates the anterior pituitary to secrete adrenocorticotrophic hormone, which stimulates the adrenal cortex to synthesize and secrete the adrenocorticoids (mainly hydrocortisone and aldosterone). When circulating levels of the adrenocorticoids are sufficiently high, they feedback-inhibit CRF secretion from the hypothalamus and adrenocorticotrophic hormone release from the anterior pituitary gland. It should be noted that chronic use of steroids inhibits the adrenal cortex from producing glucocorticoids. This is known as hypothalamus-pituitary-adrenal (HPA) suppression. If steroid therapy is stopped abruptly, the lack of endogenous glucocorticoids can be life-threatening. A slow and gradual withdrawal from exogenous steroid therapy is always warranted to allow the HPA axis to recover.

Steroid Pharmacological Action

The major pharmacological activities of the glucocorticoids are anti-inflammation, inhibition of cytokines, and inhibition of mast cell release of autocoids. The anti-inflammatory

activity of the glucocorticoids is derived from their ability to affect protein synthesis. Specifically, they stimulate the synthesis of lipocortin, a protein that inhibits phospholipase A_2, which is an enzyme that catalyzes the breakdown of membranes to release arachidonic acid, the first step in the arachidonic acid cascade that results in the production of inflammatory prostaglandins and leukotrienes (Figs. 44.24 and 44.25). Therefore, inhibition of phospholipase A_2 ultimately results in the reduction of the inflammatory prostaglandins and leukotrienes.

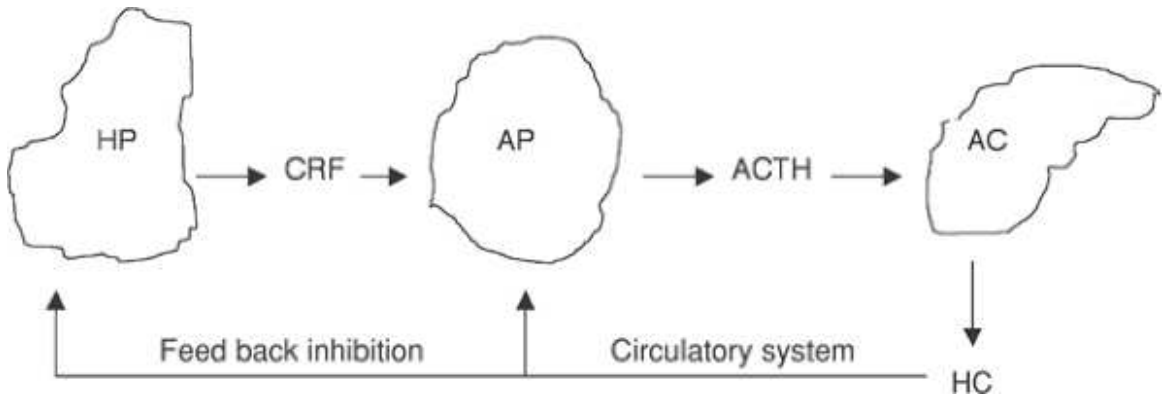

Fig. 44.23. Mechanism of adrenocorticoid secretion and control. HP=hypothalamus, CRF=corticotrophin releasing factor, AP=anterior pituitary, ACTH=adrenocorticotrophic hormone, AC=adrenal cortex, HC=hydrocortisone.

Another way that glucocorticoids are anti-inflammatory involves their ability to inhibit interleukin-1, which stimulates the proliferation of T and B lymphocytes that are responsible for the production of the cytokines and antibodies that are important in the inflammatory and immune responses to antigens. Therefore, the glucocorticoids, by their ability to inhibit interleukin-1, cause a decrease in T and B lymphocytes, which makes them immunosuppressant, and must be used with caution in patients with infection. A third action of glucocorticoids is to inhibit the synthesis and release of histamine and other autocoids from mast cells. These pharmacological activities make the glucocorticoids especially useful for treating the

inflammatory processes associated with asthma and COPD.

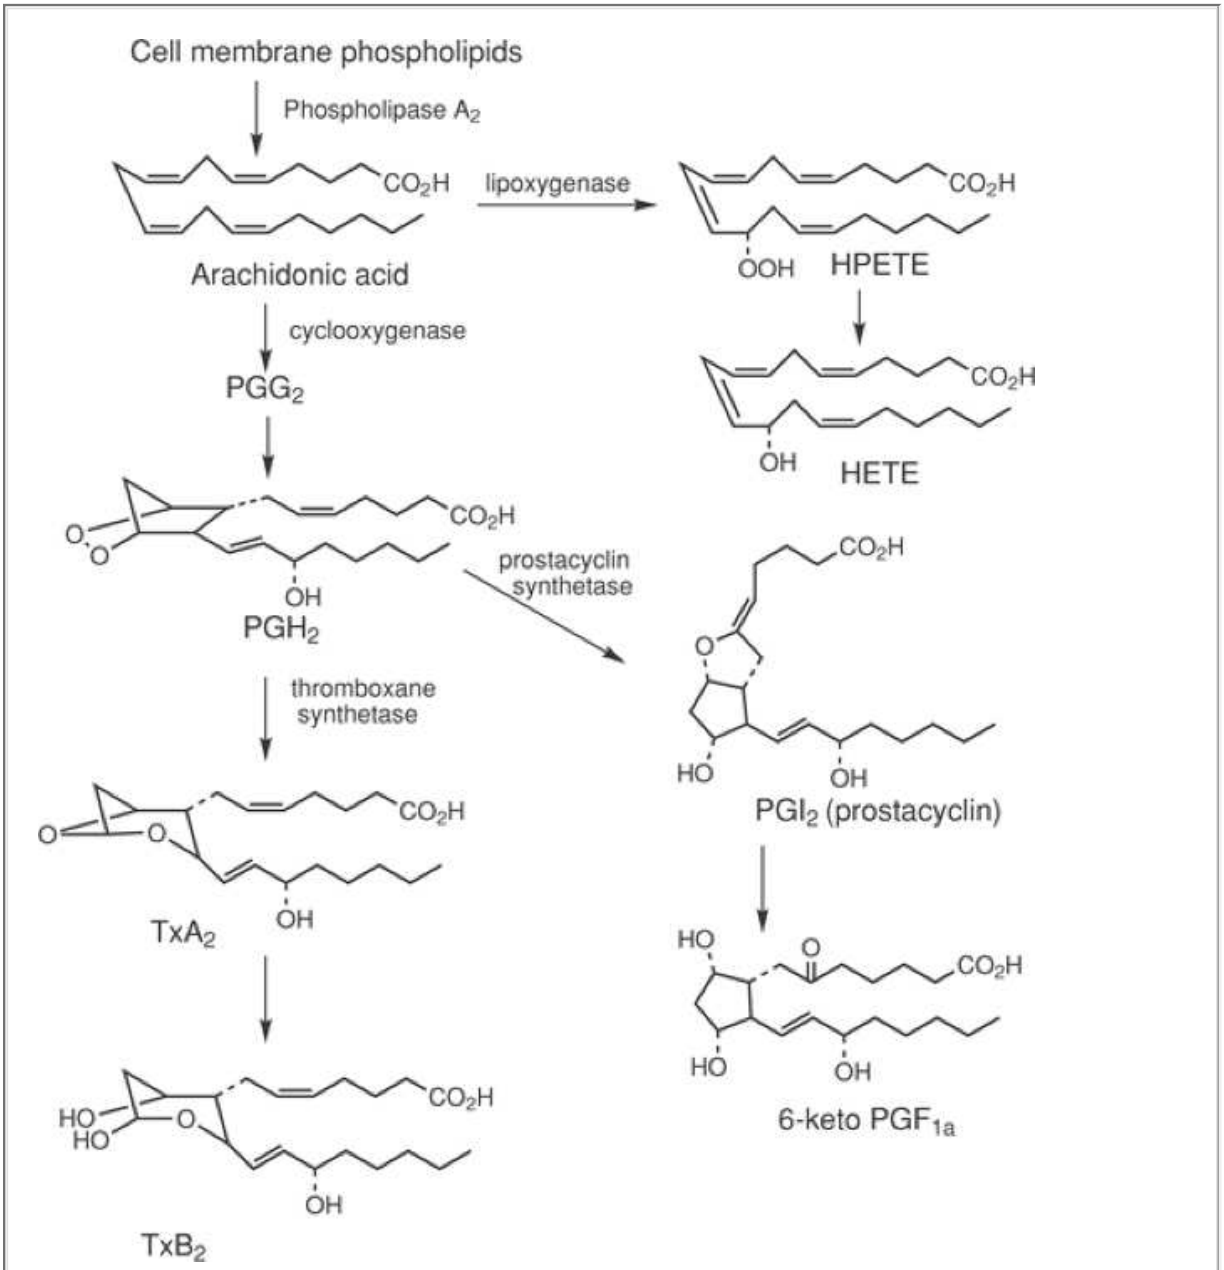

Fig. 44.24. Biosynthesis of thromboxanes, prostacyclin, and prostaglandins.

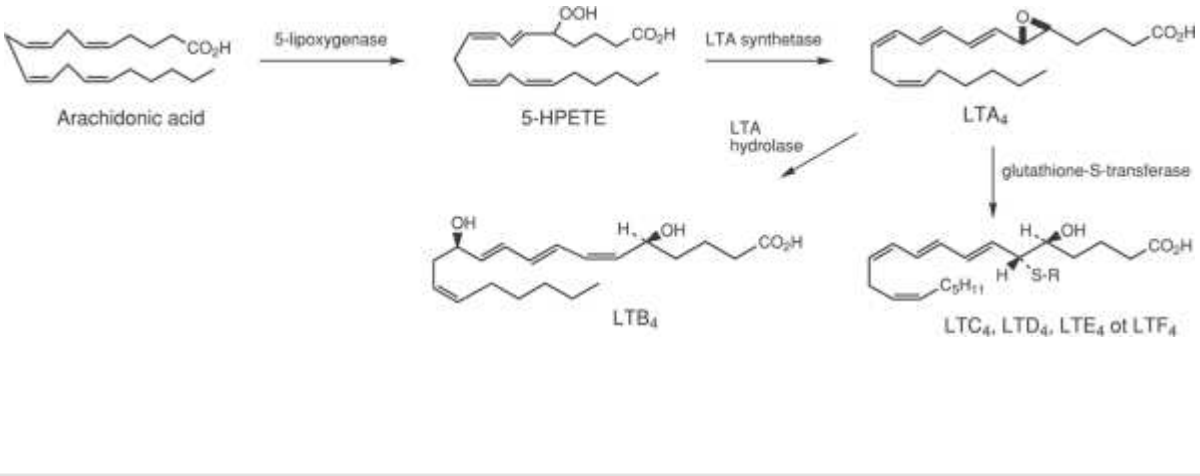

Fig. 44.25. Biosynthesis of leukotrienes.

Steroid Mechanism of Action

How do glucocorticoids and other adrenocorticoids affect the levels of proteins and other biologically important compounds? The short answer is that they bind to their receptor in the cytoplasm and that the glucocorticoid–receptor complex travels into the nucleus, where it binds to DNA and affects gene transcription, which increases and, sometimes, decreases the production of important biologically active compounds. The detail of just how the glucocorticoids accomplish this is quite interesting and is depicted in Fig. 44.26.

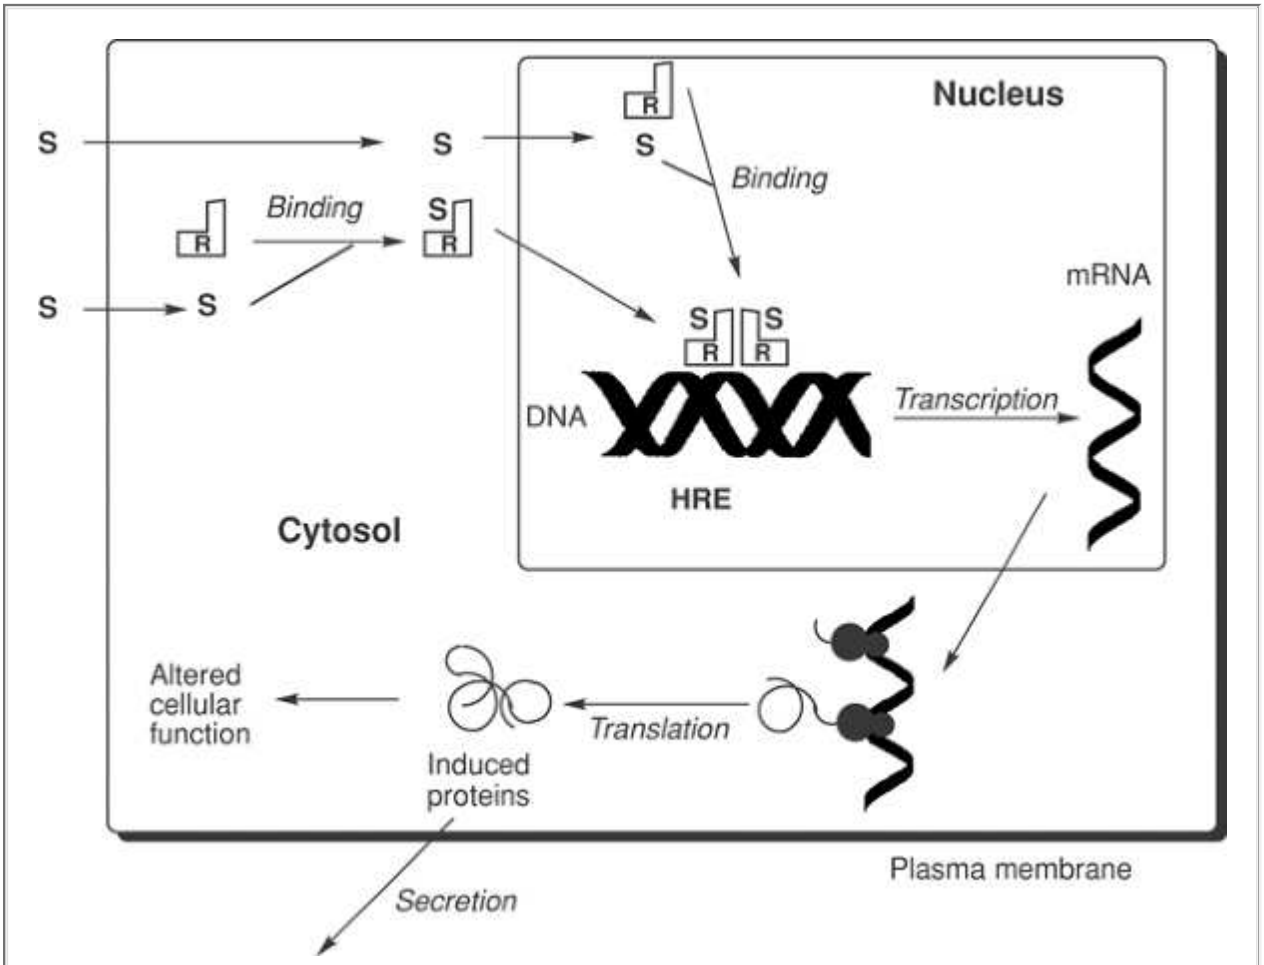

Fig. 44.26. Mechanism of steroid hormone action. (s = steroid; R = receptor).

Circulating glucocorticoids enter the target cell by simple diffusion, because they are relatively lipophilic. The glucocorticoid receptor occurs inside the cell in combination with a heat shock protein. The glucocorticoid receptor has three distinct regions: the amino terminal for maximum activity, a middle region for binding to DNA, and the carboxy terminal, where the glucocorticoids bind. When the glucocorticoid binds to its receptor, the heat shock protein is released, with a conformational change in the steroid–receptor complex and the glucocorticoid–receptor complex then translocates into the nucleus of the cell, where it binds to specific sequences of DNA called hormone-response elements (HREs), which are located in the promoter areas of hormone-responsive

genes. The DNA binding region of the glucocorticoid receptor contains eight cysteine amino acid residues that coordinate two zinc ions that form peptide loops called zinc fingers. When the zinc finger domains bind to the HRE of DNA, it dimerizes the glucocorticoid–receptor complex, placing each subunit in adjacent binding grooves. In most cases, binding causes gene transcription and protein synthesis; however, in some instances, binding will block transcription (32,33).

Steroid Receptor Structure and Glucocorticoid Binding

The glucocorticoid receptor is a member of the nuclear receptor superfamily, which includes the

receptors for the steroid hormones, retinoids, peroxisomal activators, vitamin D, and thyroid hormones. The steroid receptor is a soluble protein found in the cytosol of the cell. The binding domain of all the steroid receptors consists of 11 α-helices and four β-strands. X-ray crystallographic structural analysis, however, has revealed a unique binding pocket for the glucocorticoid receptor, which makes it distinct from the estrogen receptor, androgen receptor, and mineralocorticoid receptor. When a glucocorticoid binds to the receptor, it is completely enclosed within a pocket formed by helices 3, 4, 5, 6, 7, and 10 and β-strands 1 and 2. The strong binding affinity for the glucocorticoids is a result of the hydrophobic and hydrophilic interactions with amino acid residues in the ligand binding domain. Nearly every atom of the glucocorticoid contacts one or more amino acid residues. The most significant contacts are the hydrogen-bonding between every hydrophilic group on the glucocorticoid structure (Fig. 44.27). The carbonyl group on ring A forms hydrogen bonds with both Arg-611 and the amide of Gln-570. The hydroxyls at C-11 and C-21 hydrogen bond with the side chain of Asn-564. The C-17 hydroxyl group hydrogen bonds with Gln-642, and the C-20 carbonyl group bonds with Thr-739. Glucocorticoid binding to the ligand binding domain releases the heat shock protein and stabilizes the receptor in an active form capable of dimerization subsequent to HRE site binding (34,35).

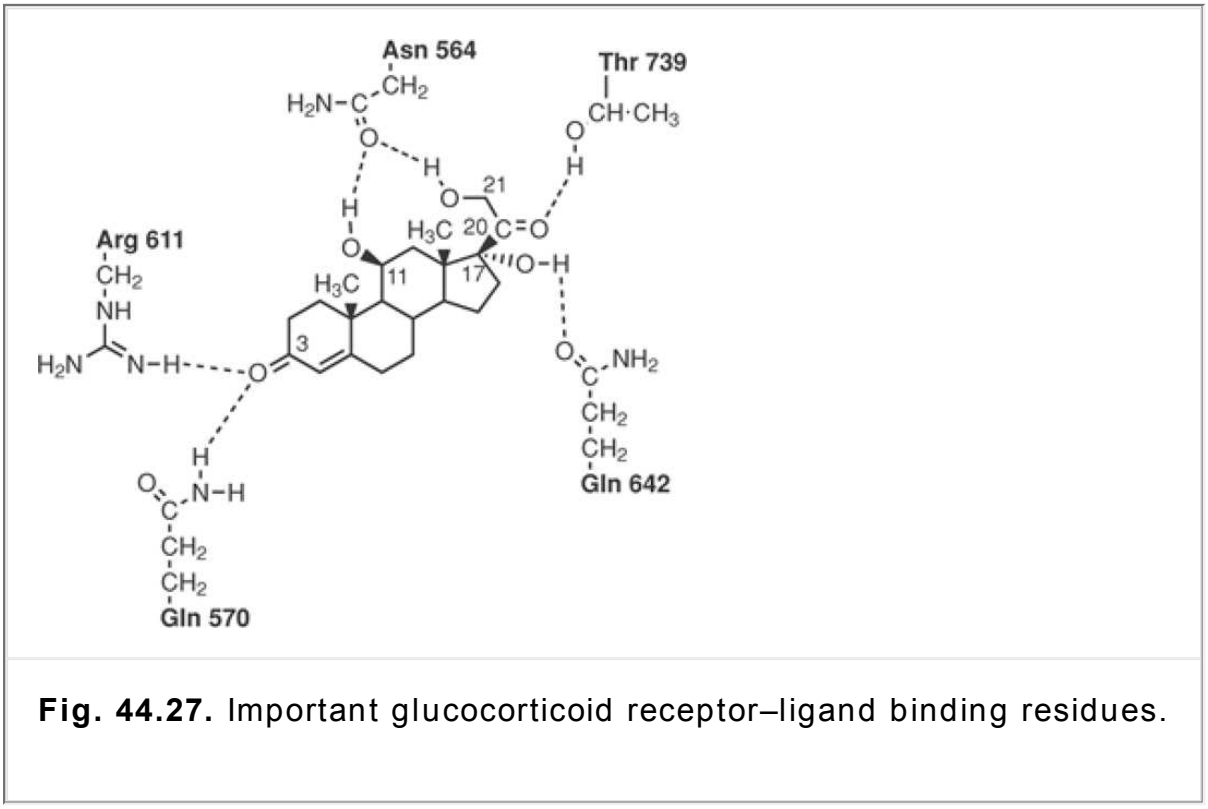

Fig. 44.27. Important glucocorticoid receptor–ligand binding residues.

Glucocorticoid Structure–Activity Relationships

There are essential structural features that are necessary for glucocorticoid activity. The natural glucocorticoids also interact with the mineralocorticoid receptor and, therefore, will have salt-retaining properties. A large number of synthetic analogues have been prepared to decrease the mineralocorticoid effects in favor of increasing the glucocorticoid (anti-inflammatory) effect of the steroids. In addition, many derivatives are prepared to enhance pharmacokinetic parameters, most notably the synthesis of lipophilic and hydrophilic esters.

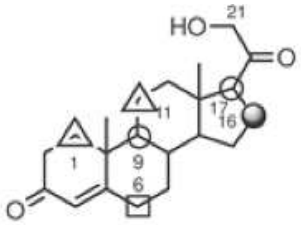
Functional groups that are essential for both mineralocorticoid and glucocorticoid activity include the pregnane skeleton with an all-*trans* backbone, the ring A-en-one system (Δ^4-3-one ring A), and the 17β-ketol side chain (C-20-keto-C-21-hydroxy). The C-21 hydroxyl group must be free for

both mineralocorticoid and glucocorticoid activity. An exception to this rule are the C-21 chloro and C-20 fluoromethyl thio ester (-SCH_2F) derivatives that retain anti-inflammatory activity when applied topically or by inhalation. Glucocorticoids that are used for their anti-inflammatory effects and that have both glucocorticoid and mineralocorticoid activity are hydrocortisone, cortisone, prednisone, and prednisolone.

Many derivatives of the fundamental glucocorticoid skeleton have been synthesized with the intention of enhancing anti-inflammatory activity and decreasing the salt-retaining properties of the glucocorticoids when administered in therapeutic doses. Figure 44.28 depicts those positions where substituents will affect anti-inflammatory and/or mineralocorticoid activity. The triangles indicate those positions where substitutions will increase the anti-inflammatory activity, and the open circles those positions where substituents will increase both anti-inflammatory and mineralocorticoid properties, the closed circle the position where substituents will decrease the mineralocorticoid activity, and the open box where specific substituents can either increase anti-inflammatory activity or decrease mineralocorticoid properties depending on the specific substituent. Therefore, the anti-inflammatory activity will be greatly increased by flattening ring A by adding a double bond at C-1 (Δ^1) and also by adding a hydroxyl group at C-11. A 17α-hydroxy increases both activities, as does 9α-fluoro or 9α-chloro. Mineralocorticoid activity is substantially eliminated by 16α- or 16β-methyl groups, a 16α-hydroxyl group, or a 16α,17α-acetonide. A C-6 α-methyl group only slightly enhances the anti-inflammatory activity, whereas a C-6α-fluoro has twice as much anti-inflammatory effect. Both substituents, in combination with a C-16 substituent, will greatly decrease the mineralocorticoid effects.

Therefore, synthetic compounds can be prepared with marked glucocorticoid activity that are devoid of any

significant mineralocorticoid activity. These include triamcinolone, methylprednisolone, fluticasone, beclomethasone, budesonide, and mometasone.



Both anti-inflammatory and mineralcorticoid activity increased (open circle)	Anti-inflammatory activity increased (triangle and square)	Mineralocorticoid activity decreased (closed circle and square)
17α-OH	1-dehydro	6α-CH_3
9α-F	6α-F	16α-& 16β-CH_3
9α-Cl	11β-OH	16α 17α-acetonide
21-OH		16α-OH

Fig. 44.28. Glucocorticoid structure–activity relationship.

Glucocorticoid Metabolism

If one or more of the essential functional groups on the glucocorticoid skeleton are modified by metabolism, glucocorticoid activity will be lost. There are three major metabolic reactions that will eliminate the glucocorticoid activity. They are ring A reductions, C-17 oxidation, and C-11 keto-enol isomerization. Reduction of the ring A 3-keto to a 3α-hydroxy by 3α-hydroxysteroid dehydrogenase, and the reduction of the 4,5-double bond by 5β-reductase to produce the A/B *cis*-fused ring, gives rise to inactive metabolites (Fig. 44.29). Oxidation of the C-17 side chain to produce a 17-keto steroid requires both the C-17 hydroxyl group and a free C-21 hydroxyl group. Esterification of one or both will inhibit this metabolism and prolong the duration of action. The rapid in vivo equilibrium that exists between cortisone (11-keto) and hydrocortisone (11-β-hydroxy) is catalyzed by 11β-hydroxysteroid dehydrogenase, produces the keto form that is inactive but also the hydroxy form that is highly glucocorticoid enhancing and found on all glucocorticoids. Figure 44.29 summarizes the metabolism of hydrocortisone.

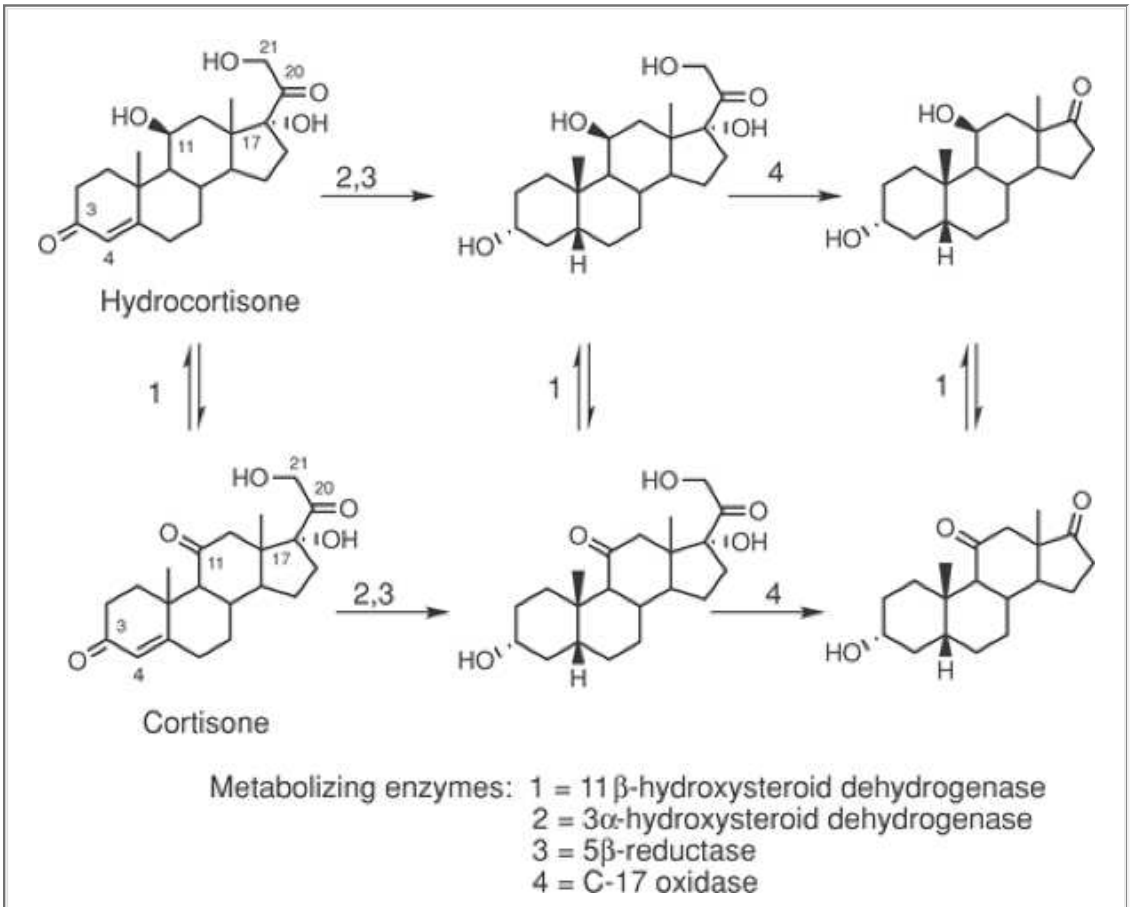


Fig. 44.29. Metabolic pathways for hydrocortisone.

Synthetic Steroid Esters

The glucocorticoids are lipophilic in spite of having at least three hydroxyl groups. The hydroxyl groups can be esterified with an appropriate acid that will either enhance or decrease that lipophilicity. The C-21

hydroxyl group is the most accessible and, therefore, is the easiest to esterify. The C-17 hydroxyl group also is easily esterified, but because it is slightly hindered by the C-17 side chain, it will react more slowly. The C-11 hydroxyl group is highly hindered by the C-10 and C-13 methyl

groups and will not react with acids to form esters. In addition, esterification has an effect on both receptor affinity and glucocorticoid metabolism. Because the C-21 must be free to hydrogen bond to the Arg-564 in the glucocorticoid receptor, C-21 esters are prodrugs requiring hydrolysis to become active. Also, the C-17 hydroxyl group needs to be free to be metabolically oxidized; therefore, esterification of the C-17 hydroxyl group inhibits oxidation to the C-17 keto group, thus prolonging duration of action. Duration also is prolonged because of the fact that the lipophilic glucocorticoid esters do not concentrate in the urine (i.e., they undergo tubular reabsorption following glomerular filtration).

The lipophilicity of a glucocorticoid can be enhanced by esterification with lipophilic acids. Doing so results in a number of effects, including increasing the log P, which provides local activity with less systemic absorption and decreased side effects. The fact that C-21 lipophilic esters are prodrugs means that they have a longer duration of action. They also have a slower onset, because the lipophilic esters generally are bulky and retard hydrolytic enzymes.

These lipophilic prodrugs can be administered orally to treat a variety of conditions, by inhalation to treat asthma and COPD, and topically to treat various types of dermatitis. When administered orally, their longer duration of action means that they can be given less frequently, which often results in better compliance. Figure 44.30 shows the structures of the most common C-21 lipophilic esters found on commercially available glucocorticoids.

Diesters and ketals provide a further enhancement of log P (i.e., increased lipophilicity) and an increased duration of action, because they are slow to metabolize. It should be noted that diesters and hexacatonides (Fig. 44.31) are prodrugs, whereas plain ketals are not (i.e., they already have a free C-21 hydroxyl group). Diesters are formed at C-21 and at either the C-17 or, if present, the C-16 hydroxyl groups. The diesters are prodrugs; however, the esters at C-17 or C-16 are active intact. The most common diesters are either the diacetate or dipropionate.

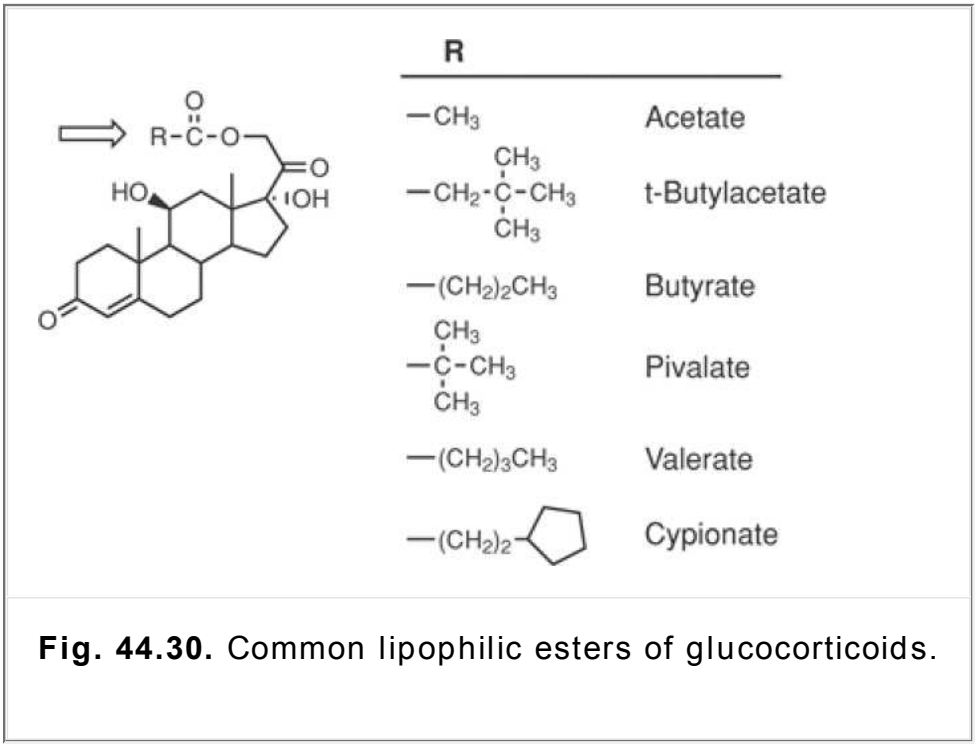

Fig. 44.30. Common lipophilic esters of glucocorticoids.

A ketal is a cyclic derivative formed between hydroxyl groups on adjacent carbons and a carbonyl carbon of a ketone. The most common ketal found in glucocorticoids is called an acetonide and is the condensation product formed between the C-16 and C-17 hydroxyl groups and the carbonyl carbon of acetone (CH_3COCH_3) (Fig. 44.31). If the acetonide is found along with a C-21-*t*-

butylacetate ester, it is named a hexacetonide; the “hex” refers to the total number of carbons found in the butylacetate group. The hexacetonides are prodrugs and must hydrolyze to become active. The buteprate (i.e., probutate) is a diester consisting of a propionate at C-21 and a butyrate at C-17 (Fig. 44.31). It also is a prodrug, and the C-21 ester must be hydrolyzed to yield the active form.

Esterification also can be used to increase the hydrophilicity of the glucocorticoids, making them water-soluble prodrugs. The synthetic approach here is to use either a dicarboxylic acid or phosphoric acid to condense with the C-21 hydoxyl group (Fig. 44.31). This

places an ionizable group (a carboxylate or phosphate) on the prodrug, yielding water-soluble esters. These derivatives are used to prepare aqueous injectable products that can be administered intramuscularly or IV.

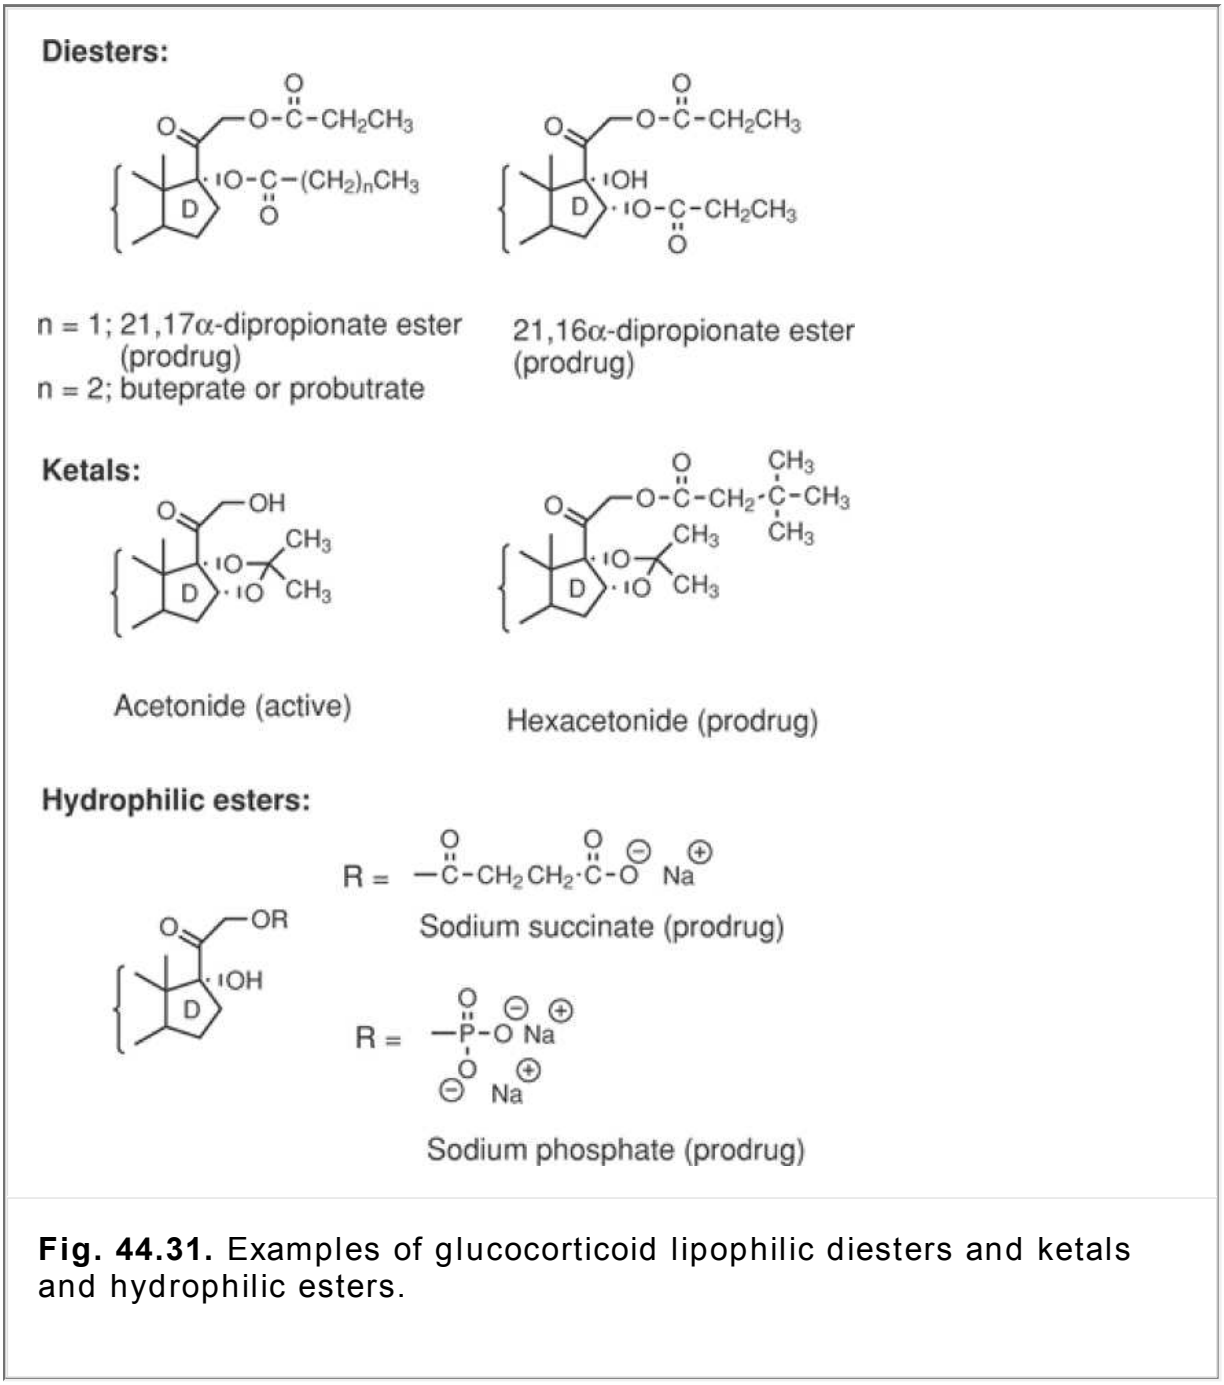

Fig. 44.31. Examples of glucocorticoid lipophilic diesters and ketals and hydrophilic esters.

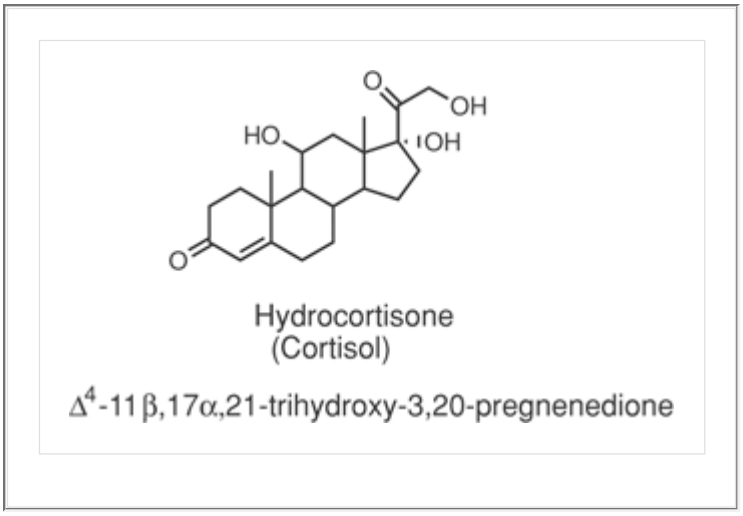
Hydrophilic glucocorticoid prodrugs have a rapid onset, because they are readily hydrolyzed by plasma esterases. In contrast to the lipophilic prodrugs, their water solubility allows them to be easily excreted through the kidney, resulting in a shorter duration of action. Hydrophilic prodrugs have more systemic side effects because of their wide distribution that comes from their high solubility in the blood. Along with their ability to be injected IV, this property makes them useful in asthmatic emergencies (i.e., status asthmaticus) during which the patient is unable to take oral medication.

Glucocorticoid Drugs Used to Treat Asthma

Systemic Glucocorticoids

Hydrocortisone



Hydrocortisone
(Cortisol)

Δ^4-11β,17α,21-trihydroxy-3,20-pregnenedione

Hydrocortisone is endogenous, and it has both glucocorticoid and mineralocorticoid activity. It is the fundamental structure by which the glucocorticoid and mineralocorticoid activities of all other corticosteroids are judged. Functional groups that are essential for both mineralocorticoid and glucocorticoid activity include the pregnane skeleton with an all-*trans* backbone, the ring A-en-one system (Δ^4-3-one ring A) and the 17β-ketol side chain (C-20-keto-C-21-hydroxy). The glucocorticoid activity is enhanced by the C-11 and C-17 hydroxyl groups. Hydrocortisone can be used to treat severe asthmatic attacks that do not respond to conventional treatment. It is available as various ester forms (Table 44.7).

Side Effects

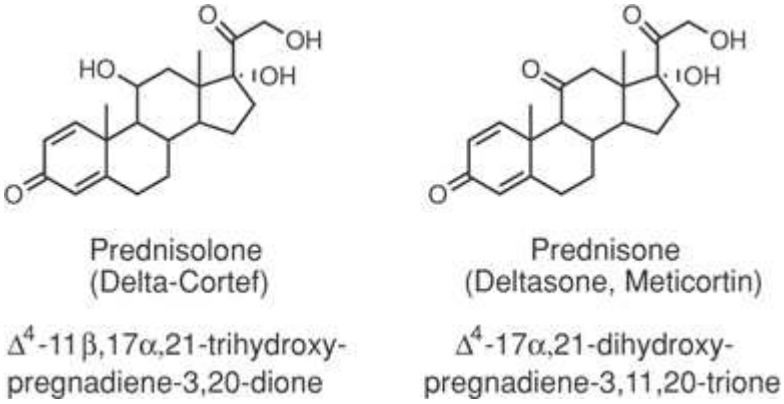
Systemic administration of glucocorticoids can result in a large number of adverse effects on prolonged use. As already stated, there is the severe risk of HPA axis suppression, requiring the slow tapering off of the dose. In addition, glucocorticoids have cardiovascular effects (thromboembolism, hypertension, and arrhythmias), central nervous system effects (convulsions and steroid psychosis), dermatological effects (impaired wound healing and hair growth), endocrine effects (amenorrhea, postmenstrual bleeding, and suppression of growth in children), electrolyte disturbances (sodium and fluid retention, hypertension, and metabolic alkalosis), GI effects (pancreatitis, increased appetite, and peptic ulcer), musculoskeletal effects (muscle weakness, steroid myopathy, and osteoporosis), and ophthalmic effects (cataracts, increased intraocular pressure, and glaucoma).

Table 44.7. Glucocorticoid Prodrug Derivatives

Drug	Trade Name	Site of Ester	Route of Administration
Hydrocortisone derivatives			
Hydrocortisone phosphate		C-21	IM, IV, SC
Sodium succinate	A-Hydrocort Sulucortef	C-21	IM, IV
Cypionate	Cortef	C-21	PO
Acetate	Cortaid	C-21	Topical
Butyrate	Locoid	C-21	Topical
Buteprate	Pandel	C-21	Topical
Valerate	Westcort	C-21	Topical
Prednisolone derivatives			
Phosphate	Hydeltrasol	C-21	IV, IM
Acetate	Key-Pred	C-21	Topical
Di-t-butylacetate (tebutate)	Prednisol TBA	C-17,21	Topical
Methylprednisolone derivatives			
Sodium succinate	Solu-medrol A-Methapred	C-21	IV, IM
Acetate	Depo-Medrol		
	Depoject	C-21	IM

IM, intramuscular; IV, intravenous; PO, oral; SC, subcutaneous.

Prednisolone

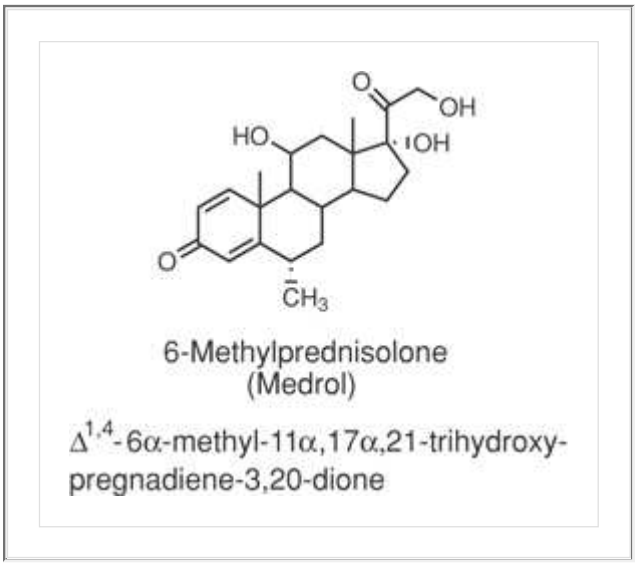


Prednisolone is hydrocortisone to which has been added a Δ^1 double bond. This places two double bonds in ring A, which flattens it and increases glucocorticoid action at the expense of mineralocorticoid activity. Prednisolone has fourfold the glucocorticoid activity of hydrocortisone while having approximately half its mineralocorticoid activity. In addition, prednisolone has an increased duration of action compared to hydrocortisone, because the extra double bond in ring A retards its metabolic reduction.

Prednisolone can be used to treat severe asthmatic attacks that do not respond to conventional treatment, and it is available as the free alcohol for oral administration. The C-21 sodium phosphate (Hydeltrasol) ester is available for parenteral use. Various ester prodrugs are available, as listed in Table 44.7. A prodrug of prednisolone is prednisone. It is the 11-keto analogue of

prednisolone and must be converted in vivo to the active 11β-hydroxy compound, which is necessary to hydrogen bond to Asn-564 in the glucocorticoid receptor. Prednisone should not be used in patients with hepatic dysfunction, because their ability to reduce the 11-keto group with 11β-hydroxysteroid dehydrogenase to the active metabolite may be impaired.

Methylprednisolone



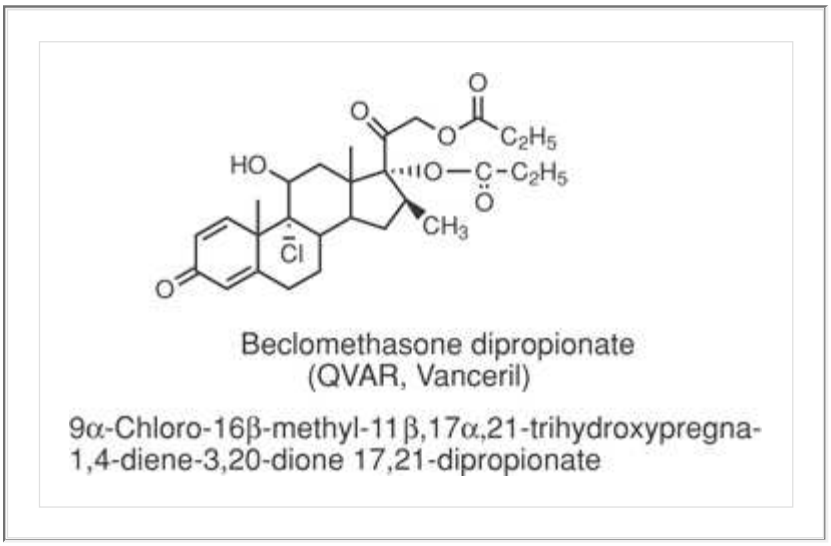
6-Methylprednisolone
(Medrol)

$\Delta^{1,4}$-6α-methyl-11α,17α,21-trihydroxy-pregnadiene-3,20-dione

Adding a 6α-methyl group to prednisolone increases the glucocorticoid activity and effectively abolishes mineralocorticoid action. It has fivefold the glucocorticoid activity of hydrocortisone (prednisolone has fourfold the glucocorticoid activity) and none of its mineralocorticoid properties. It is used almost exclusively as a systemic product and is available as the free alcohol for oral administration and as various esters (Table 44.7).

Glucocorticoids for Inhalation

Beclomethasone dipropionate

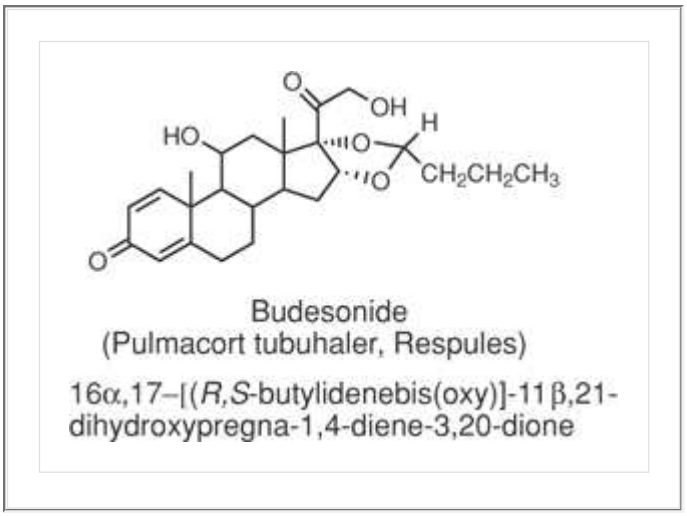


Beclomethasone dipropionate
(QVAR, Vanceril)

9α-Chloro-16β-methyl-11β,17α,21-trihydroxypregna-1,4-diene-3,20-dione 17,21-dipropionate

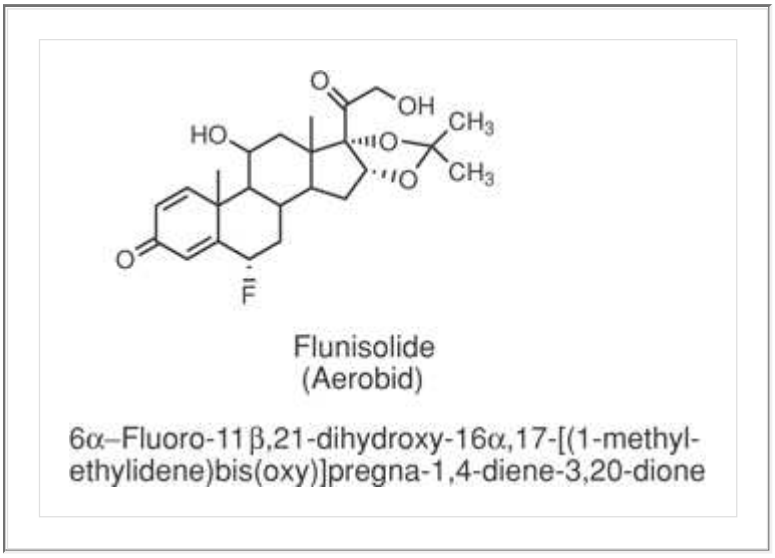
Beclomethasone dipropionate is a lipophilic prodrug that, when inhaled, shows a systemic bioavailability of approximately 20% of the administered dose. The 16β-methyl group decreases mineralocorticoid activity, and the 9α-chloro group increases both the glucocorticoid and mineralocorticoid activity, resulting in potent anti-inflammatory activity with little or no salt-retaining effects. The main adverse effects are headache, sinusitis, and pain. Beclomethasone dipropionate is metabolized to the more active 17α-monopropionate derivative during absorption from the lungs and then further metabolized to the free alcohol in the liver. The dipropionate also is metabolized to the inactive 21-monopropionate in the liver. Beclomethasone dipropionate and its metabolites are mainly excreted in the feces, with less than 10% excreted in the urine.

Budesonide



Budesonide is an acetal formed between the 16α,17α-dihydroxyl groups and butanal. It is a nonhalogenated glucocorticoid with a 16,17-acetal that decreases the mineralocorticoid activity. In receptor affinity studies, the *R*-epimer was twofold more active than the *S*-epimer. Because the C-21 hydroxy is free, budesonide is not a prodrug and is active as administered. Only 34% of the metered dose of inhaled budesonide reaches the lung. Systemically absorbed budesonide is highly protein bound and metabolized to 16α-hydroxyprednisolone and 6β-hydroxybudesonide in the liver. Both metabolites have less than 1% of the glucocorticoid activity of the parent compound. Inhaled budesonide is excreted mainly as metabolites via both the feces (15%) and the urine (32%). Budesonide is available as a powder delivered through an aerosol or as a suspension for inhalation.

Flunisolide



Flunisolide is an acetone ketal (acetonide) with a 6α-fluoro group and a free C-21 hydroxyl group. The acetonide decreases mineralocorticoid activity, and the 6α-fluoro group increases glucocorticoid activity. It is not a prodrug, because it has the free hydroxyl group at C-21. Flunisolide has approximately 20% of the receptor affinity as budesonide, and approximately 40% of the inhaled dose is systemically bioavailable. Flunisolide is quickly metabolized by CYP3A4 to the 6β-hydroxy metabolite, which has less than 1% of the activity of the parent compound. This,

along with the rapid elimination of both flunisolide and its metabolite as glucuronides, greatly

limits any systemic adverse effects. Flunisolide is available as a microcrystalline powder aerosol.

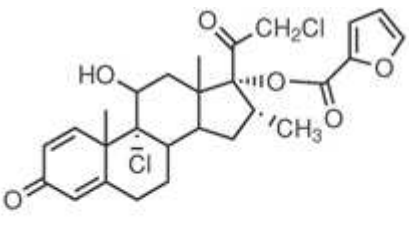
Fluticasone propionate

Fluticasone (Flovent, Flonase)

6α,9α-Difluoro-S-fluoromethyl-11β-hydroxy-16α-methyl-3-oxo-17α-propionyloxyandrosta-1, 4-diene-17α-carbothioate

Fluticasone propionate has a unique C-20 thioflouromethyl group, and that, in combination with the 17α-propionate ester, gives it 36-fold the glucocorticoid receptor affinity as compared to beclomethasone dipropionate and twofold the affinity as compared to budesonide. The 9α-flouro group increases both glucocorticoid and mineralocorticoid activities, and the 6α-flouro group enhances only the glucocorticoid action. Studies have determined that the effectiveness of inhaled fluticasone propionate results from a local rather than a systemic effect. Interestingly, less than 1% of the swallowed dose is bioavailable, in contrast to the fact that the majority of the inhaled dose is systemically available and highly protein bound. Fluticasone propionate is not a prodrug and is extensively metabolized by the liver. The only detectable metabolite is the 17β-carboxylic acid derived from CYP3A4 oxidation. This metabolite has 2,000-fold less affinity for the glucocorticoid receptor than the parent drug. Elimination is through both the feces and the urine, with the relative amounts determined by the route of administration. Fluticasone propionate is available in aerosol and powder inhalation formulations.

Mometasone furoate

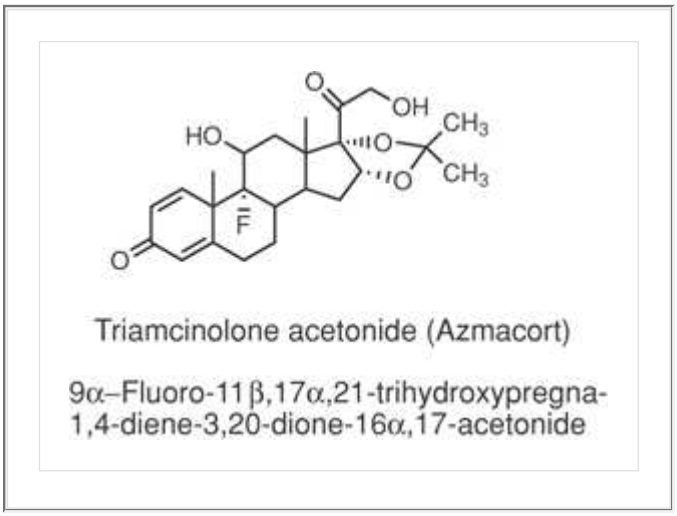


Mometasone furoate (Asmanex twisthaler)

9α,21-dichloro-17α–[(2-furanylcarbonyl)oxy]-11β-hydroxy-16α-methylpregna-1,4-diene-3,20-dione

Mometasone furoate is the most recent glucocorticoid to be developed and commercialized. It has a number of unique functional groups that confer enhanced glucocorticoid activity as well as pharmacokinetic advantages. The combination of the C-21 chloro and the furoic acid ester at C-17 results in the highest glucocorticoid receptor affinity of any topical corticosteroid. The 16α-methyl decreases the mineralocorticoid effects, and the 9α-chloro group increases both glucocorticoid and mineralocorticoid activities. Inhaled mometasone furoate acts locally as an anti-inflammatory treatment for asthma and has the least systemic bioavailability of all the inhaled glucocorticoids (<1%). It is extensively metabolized, with 6β-hydroxymometasone and 21-hydroxymometasone being found among the metabolites. Inhaled mometasone furoate in mainly excreted in the feces (~74%) as metabolites and only minimally excreted in the urine (~8%). It has a relatively long half-life in the lung and is administered once daily, usually in the evening.

Triamcinolone acetonide



Triamcinolone acetonide (Azmacort)

9α–Fluoro-11β,17α,21-trihydroxypregna-1,4-diene-3,20-dione-16α,17-acetonide

Triamcinolone acetonide has the acetonide function, which greatly decreases its mineralocorticoid activity. The 9α-flouro group increases both the glucocorticoid and the mineralocorticoid activities. Triamcinolone acetonide has a receptor affinity that is 10-fold that of beclomethasone dipropionate but sixfold less that of mometasone furoate. After oral inhalation, as much of 25% of triamcinolone acetonide can be detected systemically; a good proportion of that is assumed to be from swallowing and absorbed from the GI tract unchanged. It is metabolized in the liver to a number of metabolites, including 6β-hydroxytriamcinolone acetonide and the C-21 carboxy-6β-hydroxytriamcinolone acetonide, both of which are readily excreted via the kidneys. The acetonide remains intact during metabolic reactions and, therefore, is highly resistant to hydrolytic cleavage. Triamcinolone acetonide is excreted mainly as metabolites in the urine (40%) and in the feces (60%), with less than 1% being excreted unchanged.

Mast Cell Degranulation Inhibitors

Introduction

The discovery that a Middle Eastern herb, *Ammi visnaga* (Khella, Bishop's weed), had mild bronchodilation effects led to the isolation of a benzopyrone (a chromone), khellin. Khellin had only weak bronchodilator effects, so synthetic analogues were prepared in an attempt to enhance the bronchodilation. All analogues

were less active; however, it was noted by Dr. Roger Altounyans, who was experimenting on himself with these analogues, that one of them, if inhaled before an asthmatic attack, gave

excellent protection against the attack's severity (36). The active compound was identified as a bischromone and named cromolyn sodium in the United States and sodium cromoglycate in Europe (Fig. 44.32).

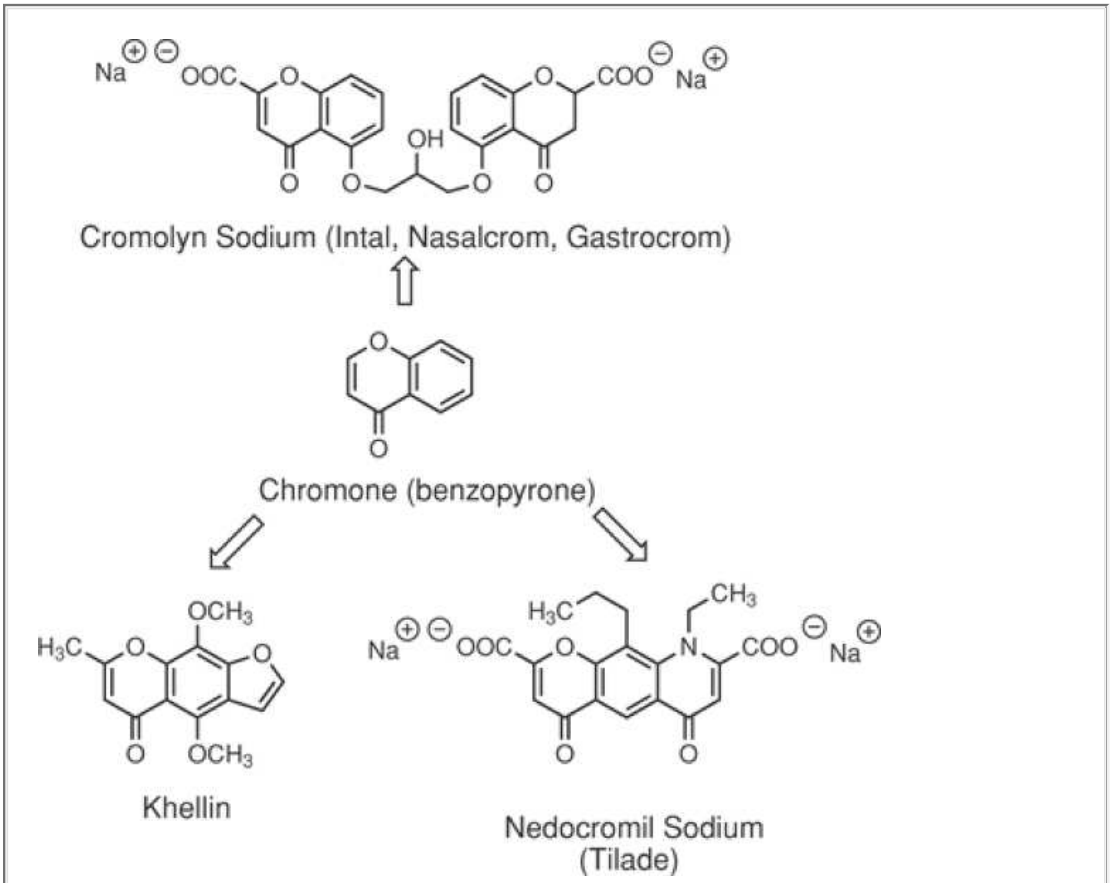


Fig. 44.32. Structures of several chromone mast cell stabilizers.

This class of mast cell degranulation inhibitors prevents the release of histamine, leukotrienes, prostaglandins, and other inflammatory autocoids by interaction with the sensitized mast cell before antigenic challenge and does not inhibit the binding of IgE to the mast cell or the antigen to IgE. The exact mechanism of action is still not completely understood; however, it is clear that inhibition of the role of calcium in the degranulation process is involved. A number of membrane and cellular proteins that bind cromolyn sodium are known to regulate intracellular calcium levels and include basophilic membrane protein, nucleoside diphosphate kinase, calgranulins B and C, and annexins I through V (37,38). Mast cell degranulation inhibitors also are used topically in the eye to treat allergic reactions; in addition to cromolyn sodium, they include nedocromil sodium, lodoxamide tromethamine, and pemirolast potassium. (For additional details about this class of compounds, see Chapter 37.)

Mast Cell Stabilizers Used to Treat Asthma

Cromolyn sodium

Cromolyn sodium is a bischromone that contains the fundamental benzopyrone moiety of khellin (Fig. 44.32). The two chromone rings are necessary for activity and must be coplanar, with a linking chain of no longer than six carbons. If one changes the linking chain to positions 8 and 8′,

coplanarity cannot be maintained, and the compound loses all activity. Cromolyn sodium is poorly absorbed from the lungs (~8%), insignificantly from the eye (~0.07%), and by approximately 1% from the GI tract. What little that finds its way into systemic circulation is eliminated intact in the urine and the bile. For the treatment of asthma, cromolyn sodium is available as a solution for both intranasal and inhalation administration. There also is an oral concentrate (100 mg/5 mL), which is administered as a 200-mg dose given four times a day.

Nedocromil Sodium

Nedocromil sodium was developed by changing the furan ring of khellin to a piperidinone ring (Fig. 44.32). In vitro, nedocromil sodium inhibits the release of inflammatory response mediators from a variety of cells, including neutrophils, mast cells, macrophages, and platelets. Inhaled nedocromil sodium is poorly absorbed into the systemic circulation, with approximately 3% of an inhaled dose excreted in the urine during the first 6 hours after administration. Only 2% of orally dosed nedocromil sodium is bioavailable, 89% of which is protein bound. When administered IV, nedocromil sodium is not metabolized and is excreted unchanged in the bile and the urine. Nedocromil sodium is available in aerosol canisters for oral inhalation via a mouthpiece.

Leukotriene Modifiers

Introduction

It has been known for more than 40 years that a substance called SRS-A (slow-reacting substance of anaphylaxis) produced a slowly developing, long-lasting contraction of isolated guinea pig ileum and that this same substance was associated with the pathophysiology of asthma. Subsequently, it was determined that SRS-A actually was a mixture of triene-containing lipids, designated as cysteine-leukotrienes: LTC_4, LTD_4, and LTE_4. Determination of the chemical structure of these biologically active compounds led to the development of biosynthesis inhibitors as well as receptor antagonists that are useful in the treatment of asthma (39).

Biosynthesis of leukotrienes

The leukotrienes occur in a variety of inflammatory cells that are abundant in asthma, including eosinophils, mast cells, and macrophages. They are derived from arachidonic acid via a branch of the common pathway to the prostacyclins and thromboxanes. Arachidonic acid itself is produced by the action of phospholipase A_2 on cell walls. Unlike the prostacyclins and thromboxanes, excess arachidonic acid does not activate the pathway. Instead, the first step in the conversion of arachidonic acid to produce the leukotrienes is controlled by an activating protein, 5-lipoxygenase–activating protein, which

regulates the interaction of 5-lipoxygenase with its substrate. Figure 44.33 depicts the biosynthetic pathway and shows that 5-lipoxygenase oxidizes arachidonic acid to the unstable peroxide intermediate, 5-hydroperoxyeicosatetraenoic acid, which is quickly dehydrated to LTA_4, which in turn is further metabolized by LTA_4 hydrolase to LTB_4 and by LTA_4 synthase to the glutathione adduct, LTC_4. Cleavage of γ-glutamic acid by γ-glutamyl transpeptidase converts LTC_4 to LTD_4, which in turn is converted to LTE_4 by the removal of glycine under the action of dipeptidase. The three leukotrienes produced from LTA_4 have strong bronchoconstrictive activity: LTD_4 is the most potent bronchoconstrictor, with the fastest onset of action; however, LTB_4 has no bronchoconstrictive activity but is a potent neutrophil chemotactic agent.

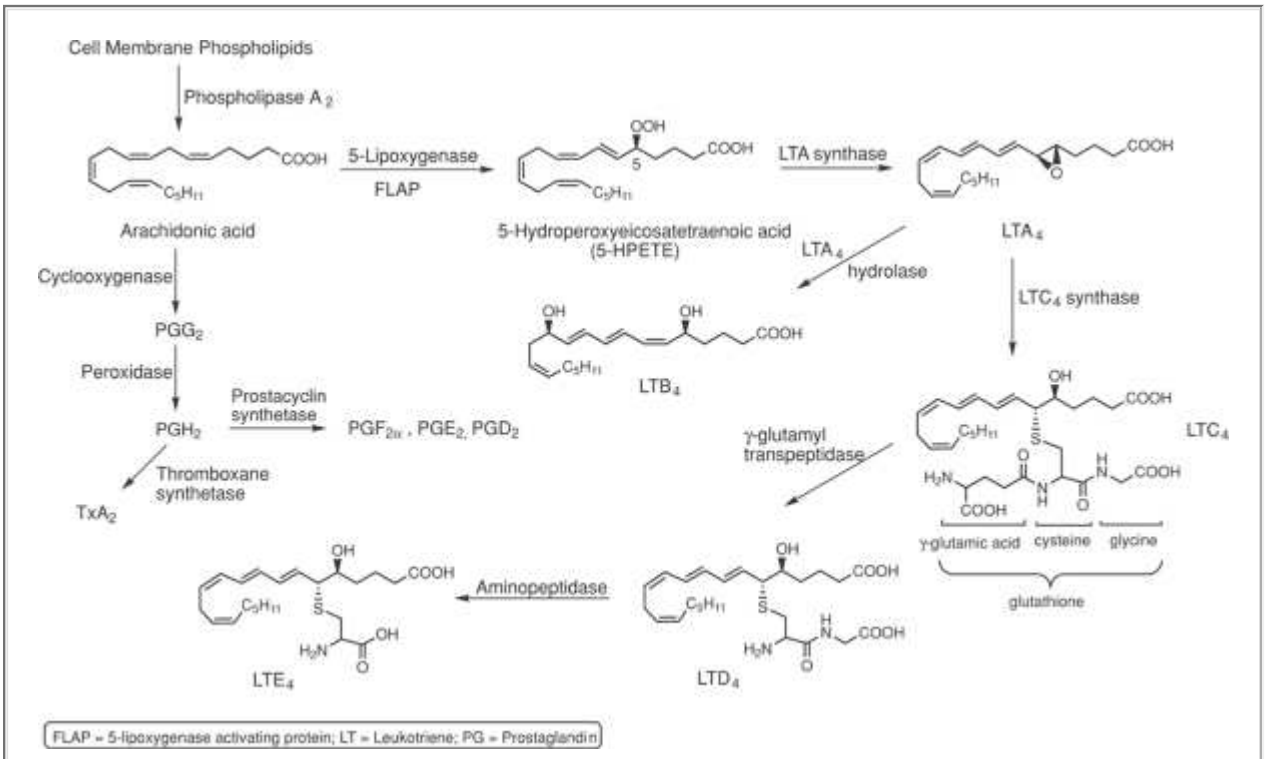

Fig. 44.33. Biochemical pathways leading to the leukotrienes.

Leukotriene Receptors

The cysteinyl leukotriene (cysLT) receptors are of the rhodopsin family of the G protein–coupled receptor family. As such, they consist of seven transmembrane-spanning helices that activate intracellular signaling pathways in response to their endogenous ligands (LTC_4, LTD_4, and LTE_4). Studies have identified two distinct cysLT receptors, and molecular biologists have cloned the human genes for both the $cysLT_1$ receptor and the $cysLT_2$ receptor (40). Pharmacology studies distinguished between the two cysLT receptors by evaluating their interaction with known antagonists, showing that the $cysLT_1$ receptor is competitively inhibited from binding LTD_4 whereas the $cysLT_2$ receptor was not. In addition, there is a slight difference in ligand-binding affinities between the two receptors. The $cysLT_1$ receptors have an affinity profile of $LTD_4 > LTC_4 = LTE_4$, whereas the $cysLT_2$ receptors show an affinity profile of $LTC_4 = LTD_4 > LTE_4$. Both receptor types occur in the lungs and spleen. The $cysLT_1$ receptor is found only in the placenta and small intestines, whereas the $cysLT_2$ receptor occurs only in the heart, lymph nodes, and brain. The incomplete overlap of tissue distribution along with their distinct ligand-binding properties suggests the $cysLT_1$ receptors and the $cysLT_2$ receptors might serve different functions in vivo (41), and because the $cysLT_1$ receptors are inhibited by selective antagonists, they have importance in the treatment of leukotriene related bronchoconstriction in asthma.

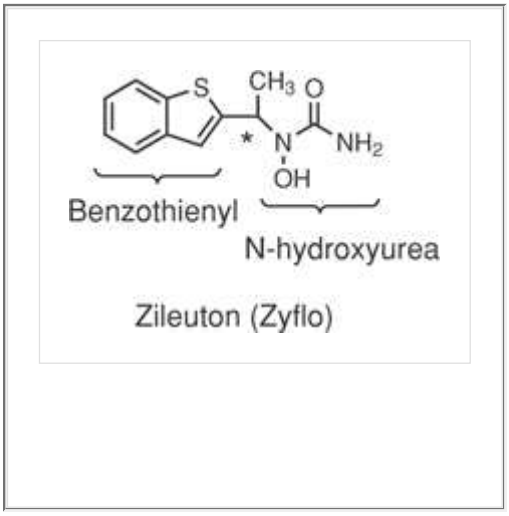
Leukotriene Modifier Drugs

Two approaches to the development of leukotriene modifiers have been taken. The first approach was to block their biosynthesis by looking for compounds that inhibit one or more of the enzymes involved in the biochemical pathway. The second approach was to identify antagonists with selective affinity for the $cysLT_1$ receptors.

Leukotriene Biosynthesis Inhibitors

The search for orally active 5-lipoxygenase inhibitors has resulted in only a few classes of compounds that are effective in animals and humans with the N-hydroxyureas, yielding a useful product (42). The 5-lipoxygenase inhibitors block the production of LTB_4 as well as LTC_4, LTD_4, and LTE_4, thereby decreasing both the bronchoconstrictive and chemotactic effects of the leukotrienes.

Zileutin



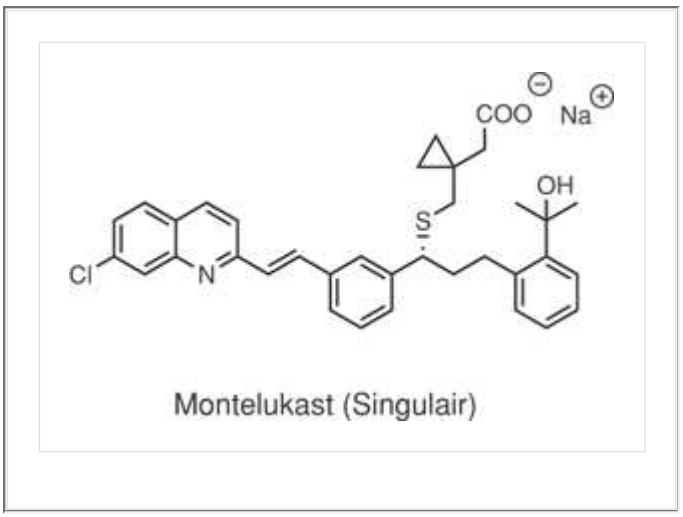
Zileutin is the first N-hydroxyurea 5-lipoxygenase inhibitor to be marketed. It is the ethylbenzothienyl derivative of N-hydroxyurea and occurs as the racemic mixture of *R*-(+)- and *S*-(–)-enantiomers, both of which are pharmacologically active. The N-hydroxyl group is essential for inhibitory activity, with the benzothienyl group contributing to its overall lipophilicity. Zileutin is rapidly absorbed orally and is 93% protein bound in the plasma. Metabolism occurs in the liver, with the inactive O-glucuronide being the major metabolite, along with less than 0.5% inactive N-dehydroxylated and unchanged zileutin. The glucuronidation is stereoselective, with the *S*-isomer being metabolized and eliminated more quickly (43). Greater than 90% of an oral dose is bioavailable, and 95% is excreted as metabolites in the urine, with a half-life of 2.5 hours, thus requiring four-times-a-day dosing. Zileutin increases the plasma levels of propranolol, theophylline, and warfarin, and dosing of these drugs should be reduced and the serum levels monitored carefully in patients taking both drugs. The most serious side effect of zileutin is elevation of liver enzymes; if symptoms of liver dysfunction (e.g., nausea, fatigue, pruritis, jaundice, or flu-like symptoms) occur, the drug should be discontinued.

Leukotriene receptor antagonists

The search for leukotriene receptor antagonists began without the aid of ligand–receptor binding data and took the form of three approaches. These included the design of leukotriene structural analogues, quinoline analogues, and the random screening of compounds. The combination of these efforts led to a simple SAR: The lipophilic tetraene tail of LTD_4 can be mimicked by a variety of more stable aromatic rings, the thioether of the glycinylcysteinyl dipeptide can be replaced by an alkyl carboxylic acid, and the C_1 carboxylate of LTD_4 needs to be retained. Additional research focusing on the three-dimensional requirements for antagonist binding to the cysLT receptors further clarified that the pharmacophore needs to consist of an acidic or negative ionizable functional group, a hydrogen-bond acceptor function, and three hydrophobic regions (44). Based on this background, synthetic efforts resulted in the development of montelukast and zafirlukast as $cysLT_1$ receptor antagonists. Figure 44.34 demonstrates how both

these antagonists fit the pharmacophore model.

Montelukast



Montelukast (Singulair)

Montelukast was developed from other weakly antagonistic quinoline derivatives. A number of changes can be made to the structure without the loss of activity. These include changing the double bond between the two aromatic rings to an ether linkage, reducing the quinoline ring, changing the chlorine to a fluorine, and/or exchanging the sulfur for an amide group. Montelukast is a high-affinity, selective antagonist of the $cysLT_1$ receptor. It is rapidly absorbed orally, with a bioavailability of 64%. Montelukast is 99% bound to plasma proteins and is extensively metabolized in the

liver by CYP3A4 and CYP2C9 to oxidated products. CYP3A4 oxidizes the sulfur and the C-21 benzylic carbon, whereas CYP2C9 is selectively responsible for the methyl hydroxylation. Figure 44.35 shows the primary metabolic pathway for montelukast in humans (45). More than 86% of an oral dose is eliminated as metabolites through the bile. Montelukast did not demonstrate any significant adverse effects greater than placebo in clinical trials; however, because it is metabolized by the cytochrome P450 (CYP450) enzymes, its plasma levels should be monitored when coadministered with CYP450-inducing drugs, such as phenobarbital, rifampin, and phenytoin. Montelukast is available in tablet, chewable tablet, and granules for administration mixed with food.

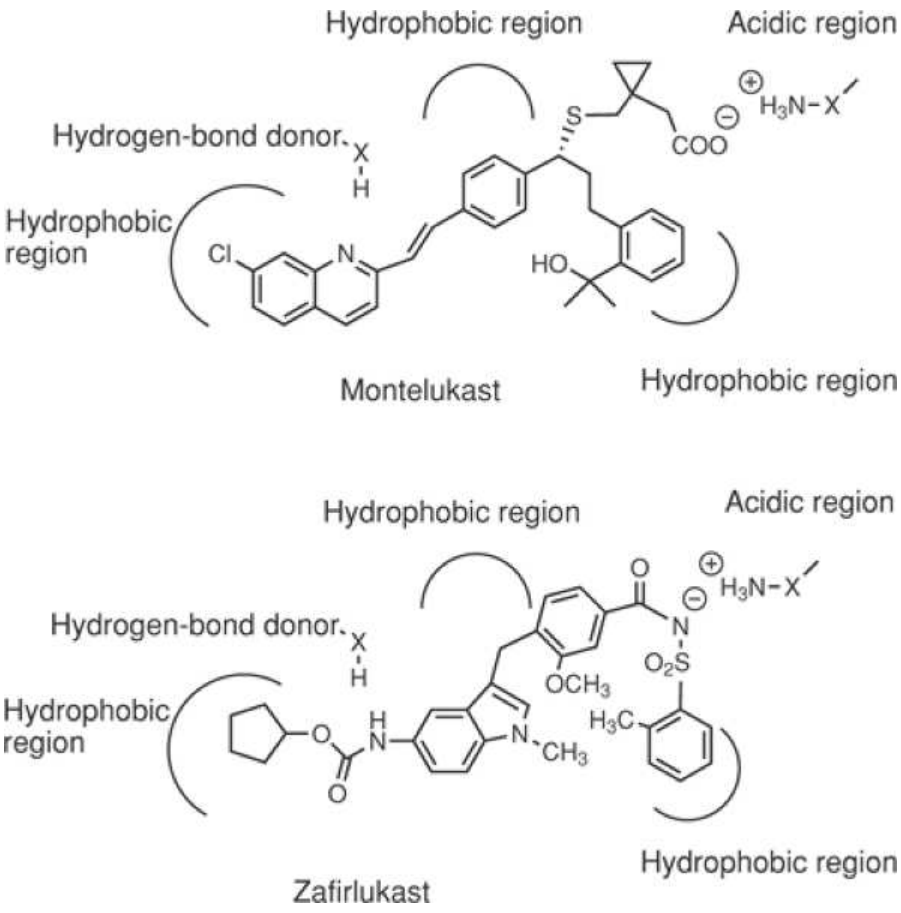


Fig. 44.34. Interaction of montelulast and zafirlukast with cysteinyl leukotriene (cysLT) receptor model.

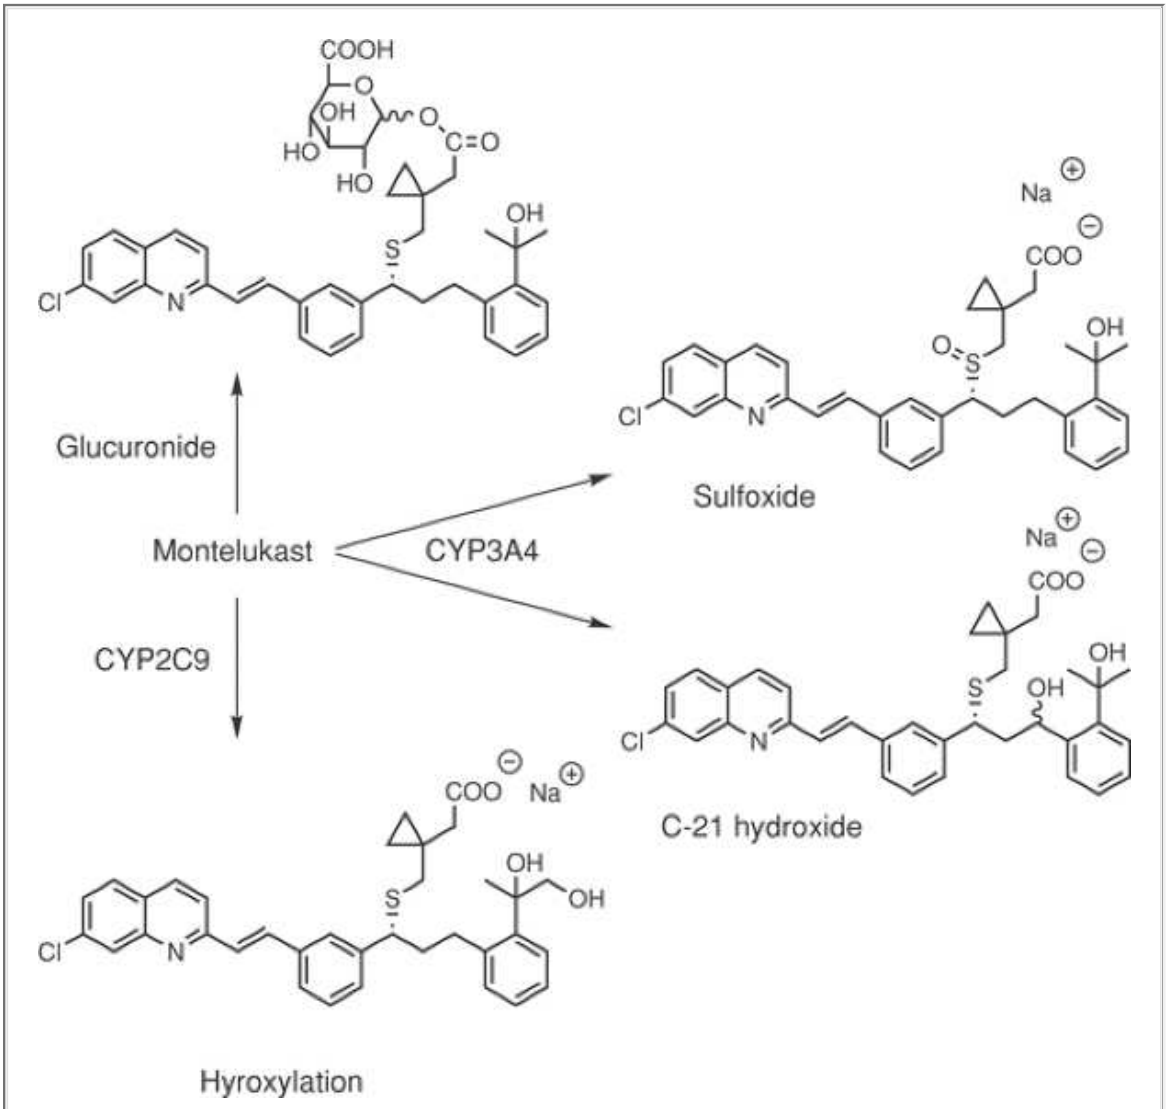

Fig. 44.35. Metabolism of montelukast.

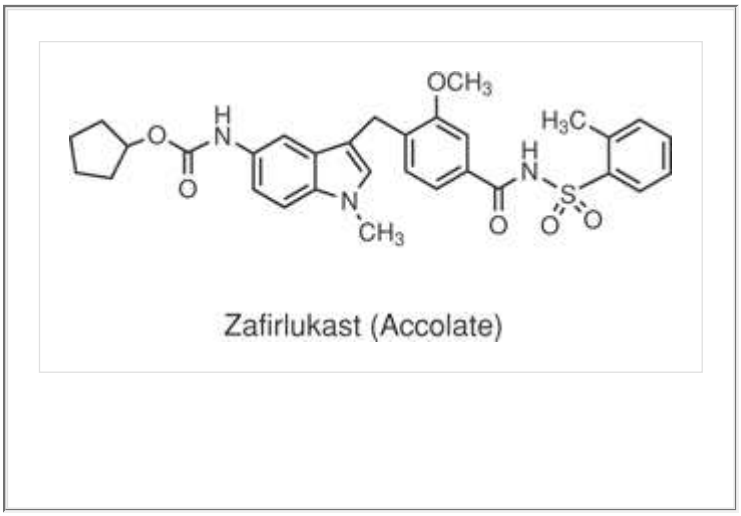
Zafirlukast



Zafirlukast (Accolate)

Zafirlukast is an indole derivative with a sulfonamide group that fulfills the need for an ionizable moiety on the pharmacophore. A large number of analogues have been prepared; however, they all resulted in a decrease in antagonist activity. Zafirlukast, like montelukast, is a selective antagonist for the cysLT$_1$ receptor and antagonizes the bronchoconstrictive effects of all leukotrienes (LTC$_4$, LTD$_4$, and LTE$_4$). Zafirlukast is well absorbed orally; however, food will decrease its absorption by as much as 40%. Zafirlukast is primarily metabolized in the liver by CYP2C9 and CYP3A4 to hydroxylated metabolites (46). Zafirlukast also has been shown to undergo carbamate hydrolysis, followed by N-acetylation. Additionally, zafirlukast in known to produce an idiosyncratic hepatotoxicity in susceptible patients. This is appears to result from the formation of an electrophilic α,β-unsaturated iminium intermediate evidenced by the formation of a glutathione adduct on the methylene carbon bridging the indole ring to the methoxybenzene moiety of the molecule (47).

Figure 44.36 summarizes the metabolism of zafirlukast. More than 90% if its metabolites are excreted in the feces, with the remaining found in the urine. Zafirlukast inhibits CYP3A4 and CYP2C9 in concentrations equivalent to clinical plasma levels and, therefore, should be used with caution in patients taking drugs metabolized by these enzymes. Specifically, coadministration with warfarin results in a significant increase in prothrombin time. Other drugs metabolized by CYP2C9 are phenytoin and carbamazepine. In

addition, CYP3A4-metabolized drugs are cyclosporine, cisapride, and the dihydropyridine class of calcium channel blockers. Of particular interest is the fact that aspirin increases the plasma levels of zafirlukast, and theophylline decreases the plasma levels of zafirlukast. Care should be taken when coadministering with erythromycin, because this decreases the bioavailability of zafirlukast. Zafirlukast is only available in tablet formulations.

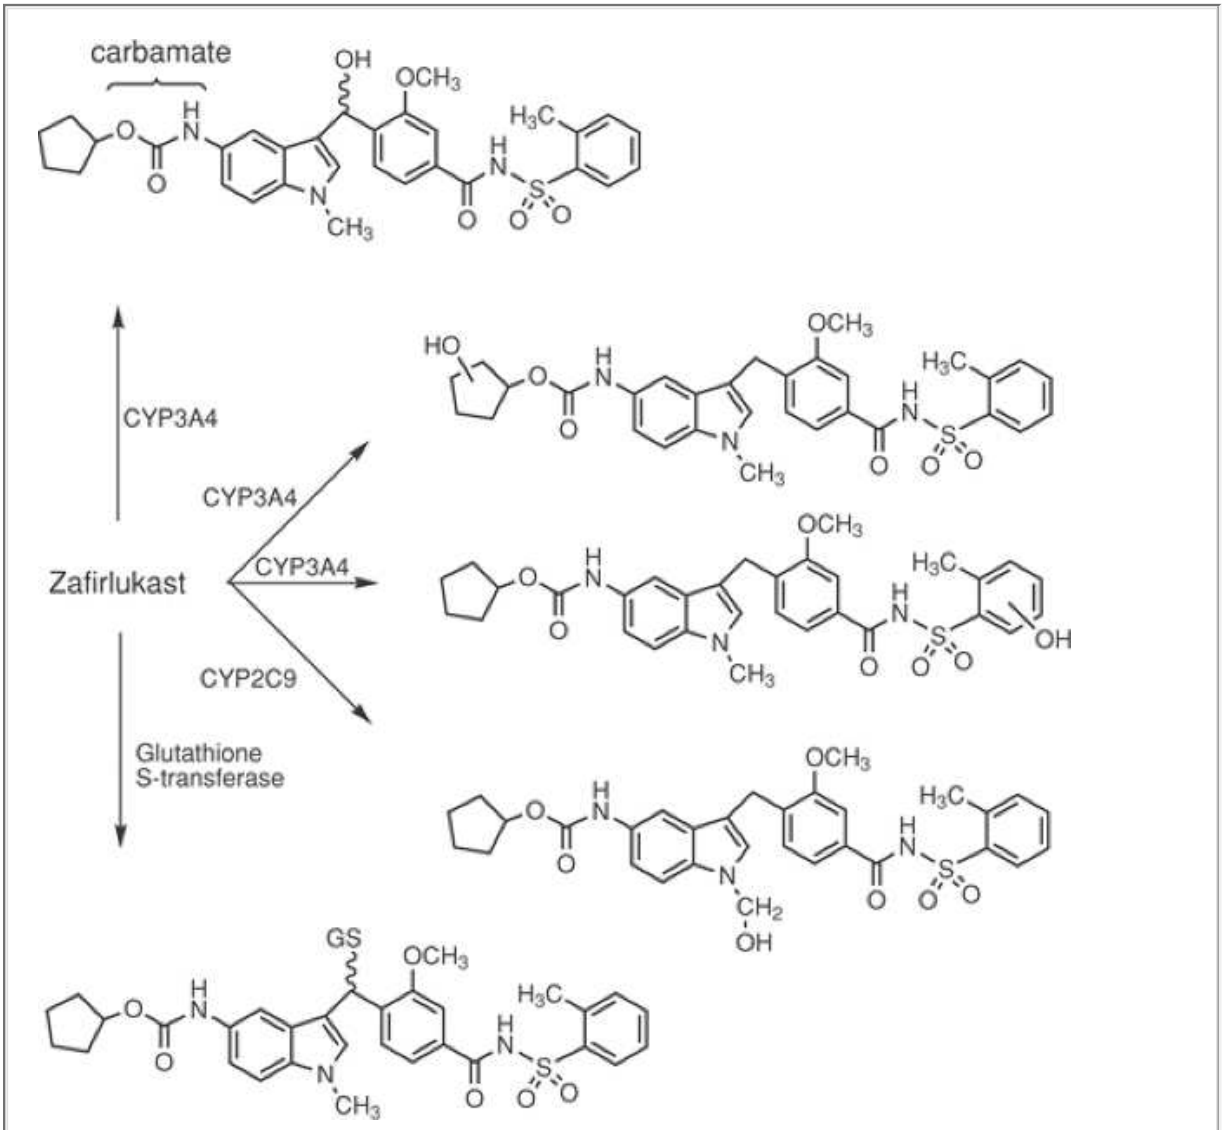


Fig. 44.36. Metabolism of zafirlukast to oxidative products and a glutathione adduct.

Monoclonal Anti-IgE Antibody

Introduction

The pathophysiology of allergic asthma, as already discussed, involves the dendritic processing of the allergen, which ultimately results in the production of allergen-specific IgE by activated B lymphocytes. The IgE binds to high-affinity (FcεRI) receptors on mast cells. The site where IgE binds to the receptor is located on the Fc fragment area of the C-ε-3 region, hence the acronym FcεRI (Fig. 44.37A). Subsequent allergen exposure causes cross-linking of bound IgE molecules, which triggers degranulation of these cells, resulting in the release of asthma mediators. Monoclonal anti-IgE antibody development is designed to moderate the role of IgE in activating mast cells, thereby decreasing the severity of allergic asthmatic attacks, and may have beneficial effects in treating seasonal allergic rhinitis.

Omalizumab Development and Pharmacology

Omalizumab is a monoclonal antibody developed through somatic cell hybridization techniques and was identified as a murine anti-human IgE antibody, originally called MAE11 (48). It is designed to interact with the site that binds to FcεRI on mast cells. Additional amino acid sequences have been incorporated into the antibody so that a humanized product resulted that only differs by 5% nonhuman amino acid residues.

In vitro, omalizumab has been shown to complex with free IgE, forming trimers consisting of a 2:1 complex of IgE to omalizumab or a 1:2 complex of IgE to omalizumab. In addition, larger complexes also are formed, consisting of a 3:3 ratio of each (Fig. 44.37B). Omalizumab does not bind to IgE already bound to mast cells and, therefore, does not cause the degranulation that might be expected from such interaction. Thus, omalizumab effectively neutralizes free IgE and, aside from the obvious decrease of available IgE, also causes the down-regulation of FcεRI receptors on the mast cell surface, resulting in a decrease of IgE bound to the mast cell.

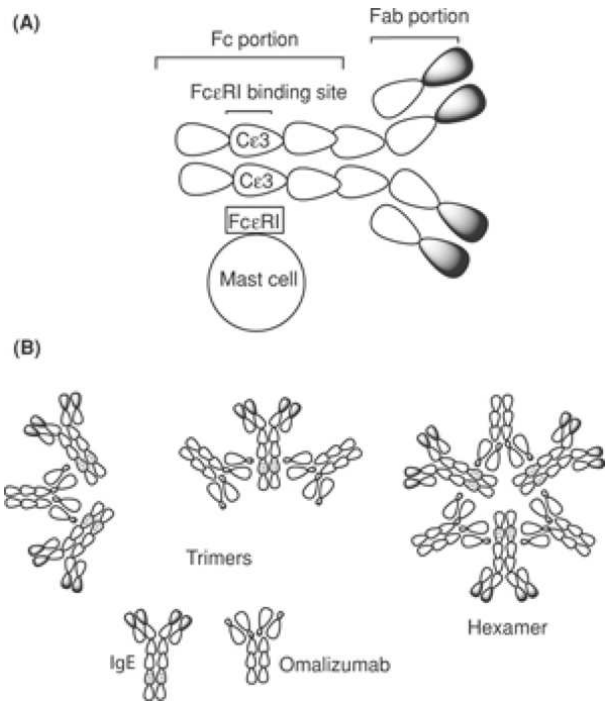

Fig. 44.37. (A) Graphic representation of IgE binding to the FCεRI on a mast cell. (B) Graphic representation of immune complexes formed between omalizumab. Hexamers predominate when components are in a 1:1 ratio, and the trimers predominate when one of the components is in excess.

Omalizumab (Xolaire)

The clinical role for omalizumab is in the treatment of allergic asthma. It is approved for the treatment of adults and adolescents 12 years of age and older whose symptoms are not controlled with inhaled glucocorticoids and who have a positive skin test for airborne allergens. The bioavailability after subcutaneous administration is 62%, with slow absorption resulting in

peak serum levels in 7 to 8 days from a single dose. Steady-state plasma concentration is reached in 14 to 29 days with multiple dosing regimens. The elimination of omalizumab is not clearly understood; however, studies have determined that intact IgE is excreted via the bile and that omalizumab:IgE complexes are cleared faster than uncomplexed omalizumab and slower than free IgE. This means that over time, total IgE concentrations (free and complexed IgE) increase, because the complex is cleared more slowly. The metabolism of omalizumab is not known, and the clearance of the complex is similar to the liver elimination of another immunoglobulin, IgG. The reticuloendothelial system degrades IgG, and it is believed that the same process occurs for the omalizumab:IgE complex. Omalizumab is available as a lyophilized powder for injection in single-use, 5-mL vials.

Chronic Obstructive Lung Disease

Definition and Epidemiology

Chromic obstructive lung disease is characterized by persistent breathing difficulty that is not completely reversible and is progressive over time. It usually is the result of an abnormal inflammatory response to airborne toxic chemicals. Thus, COPD is a general term and most commonly refers to chronic bronchitis and emphysema. Asthma is considered to be a disease entity unto itself and is not included in the definition of COPD. Both COPD and asthma are both considered to be inflammatory diseases; however, the nature of the inflammation is different. Asthma is associated with the release of inflammatory mediators from mast cells and eosinophils, whereas chronic bronchitis is primarily associated with neutrophils and emphysema with alveoli damage. In addition, asthma is more often than not allergenic, whereas chronic bronchitis and emphysema have no allergic component. Finally, it is uncommon for asthma to be associated with smoking, whereas there is a very high incidence of both chronic bronchitis and emphysema in smokers.

Patients with COPD display a variety of symptoms, ranging from chronic productive cough to severe dyspnea requiring hospitalization. Other chronic illnesses, including cardiac, endocrine, and renal disease, often occur along with COPD in many patients. In the United States, COPD is the fourth leading cause of death, being responsible for more than 100,000 deaths per year (49). It has been estimated that between 16 and 24 million people in the United States have COPD and that those with chronic bronchitis outnumber those with emphysema. Rates of COPD-related death among women have tripled over the last 30 years, and this is being attributed to their increase in smoking. Chronic obstructive pulmonary disease is recognized as a global health problem, and in 2001, the NIH and the World Health Organization developed the Global Initiative for Chronic Lung Disease (GOLD) guidelines, which present only evidence-based recommendations for the treatment of COPD (50,51).

Pathogenesis

The single most important risk factor for the development of COPD is smoking. It is estimated that 85% of COPD cases are attributable to cigarette smoking. Not all people who smoke, however, develop the disease, which means other factors are involved. It seems that genetics, environmental pollutants, and infection along with bronchial hyperreactivity all play an important role.

Cigarette smoke attracts inflammatory cells into the lungs and stimulates the release of the proteolytic enzyme elastase. Elastase breaks down elastin, which is a needed structural component of lung tissue. Normally, the lung is protected from elastase by an inhibitor, α_1-antitrypsin (ATT). Cigarette smoke, however, causes an abnormal amount of elastase to be produced that ATT

cannot counter, leading to lung damage. Smokers with an inherited deficiency of ATT have a greatly increased risk of developing emphysema, especially at an early age. Patients with COPD show an accelerated decline in lung function (50–90 mL FEV_1/year) as compared to nonsmokers (20–30 mL/year) (see earlier discussion of FEV under General Therapeutic Approaches to the Treatment and Management of Asthma). Patients with COPD who stop smoking slow down the progression of the disease. Unfortunately, however, they do not improve, because the symptoms are an indication of irreparable lung tissue damage.

The role of other risk factors for developing COPD is not clear. Air pollution and occupational exposure to gases and particulates from the incomplete combustion of coal, diesel, and gasoline are related to the development of cough and sputum, but development of COPD seems to occur only in susceptible individuals. Passive cigarette smoke comes from the burning end of the cigarette and actually is higher in toxic substances compared with exhaled smoke. It has been established that respiratory infections as well as cough and sputum production are more common in children who live in households where one or both parents smoke. Chinese and Afro-Caribbean races have a reduced incidence of COPD, whereas COPD in American blacks is on the rise (49).

Permanent destructive enlargement of the airspaces distal to the terminal bronchioles without obvious fibrosis is the pathological characteristic of emphysema. On the other hand, chronic bronchitis is characterized by hypersecretion of mucus, most of which is produced by the trachea and first branches of the bronchi. The smaller bronchi and terminal bronchioles, however, are the site of the increased airway resistance in chronic bronchitis. In the early stages of chronic bronchitis, the mucus and inflammation contribute to “smoker's cough,” with little effect on airway obstruction. As inflammation continues, cell wall edema and the production of large amounts of mucus contribute to airway narrowing and the difficulty in breathing associated with COPD. Even though bronchospasm may seem to be involved in COPD, there is little related pathogenesis. Chronic obstructive pulmonary disease is a disease of the small airways and their adjacent alveoli. In chronic bronchitis, there are structural changes in the small airways as a result of persistent inflammatory irritation, which leads to airway narrowing. Emphysema on the other hand is the result of loss of lung elastic recoil because of inflammation and alveolar wall destruction. Both diseases often occur together, with one predominate over the other. An important clinical manifestation between chronic bronchitis and emphysema is that there is significant hypoxia and carbon dioxide retention with chronic bronchitis, which does not happen with emphysema. Because of this, emphysema patients are referred to as “pink puffers,” whereas patients with chronic bronchitis are called “blue bloaters” (52).

Pharmacotherapy

All the medications used to treat COPD have already been covered in the previous section on asthma. The GOLD guidelines base their treatment protocols on a classification of disease severity divided into five stages (50,51). Stages O and I are defined as “at risk” (O) and mild COPD (I). In stage O, the patient has normal lung function, with chronic cough and sputum production. Treatment at this stage is to counsel the patient to reduce risks and, especially, to stop smoking. In stage I, there is minor airway limitation, characterized as $FEV_1/FVC < 70\%$ but $FEV_1 \geq 80\%$ of the predicted value. Stage I treatment is to use a short-acting bronchodilator, usually as needed, but regular use is effective in patients with concurrent asthma. The most frequently used short-acting bronchodilator is the β_2-agonist albuterol, although pirbuterol and the anticholinergic ipratropium can be just as effective, but with a slightly longer onset of action. The patient also should take precautions to avoid bacterial or viral infections by receiving vaccinations against influenza and pneumococcal pneumonia.

Stage II COPD is a moderate disease condition in which the patient demonstrates shortness of breath on exertion and spirometry reveals $FEV_1/FVC < 70\%$ and FEV_1 between 50 and 80% of the predicted value. Stage II drug treatment requires the addition of a long-acting bronchodilator

along with the short-acting bronchodilator. Salmeterol and formoterol are long-acting β_2-agonists, and tiotropium is the long-acting anticholinergic most often used. Alternatively, the addition of ipratropium along with the short-acting β_2-agonist also can be effective at this stage. Extended-release theophylline is an option for patients who do not receive adequate relief of symptoms or who cannot tolerate other bronchodilators.

Stage III is a severe form of COPD, with $FEV_1/FVC < 70\%$ and FEV_1 between 30 and 50% of the predicted value. The patient experiences increasing dyspnea that affects his or her ability to perform routine tasks (i.e., climbing stairs). A course of oral glucocorticoids (i.e., prednisone) may be used to control a severe attack. The role of inhaled glucocorticoids is not clearly established, and no evidence suggests that an inhaled glucocorticoid has any advantage in patients who can maintain their FEV_1 with bronchodilators. As of this writing, no inhaled glucocorticoids are approved for the treatment of COPD; however, there is one combination formulation of fluticasone propionate and salmeterol dosage (250 µg/50 µg) approved for twice-daily administration.

Stage IV is the most severe form of COPD, with airflow restriction of $FEV_1/FVC < 70\%$ and $FEV_1 < 30\%$ of the predicted value along with chronic respiratory failure. At this stage, the patient is experiencing debilitating exacerbations that are not controlled by medication and requires

daily oxygen for respiratory failure. Surgery also is an option, but it is not without serious risks. Surgical options include bullectomy (removal of large blebs in the lungs), lung transplant (uncommon), and lung volume reduction surgery (removal of lung sections affected by emphysema).

Patients with emphysema that is associated with ATT deficiencies can receive weekly IV infusions of to maintain acceptable antiprotease activity that can minimize their disease progression. The three approved ATT products are Aralast, Prolastin, and Zemaira. Because these protein products are derived from human plasma, there is the risk of transmission of viral infection and Creutzfeldt-Jakob disease.

New Drug Classes for Treatment of Asthma and COPD

Phosphodiesterase Inhibitors

Introduction

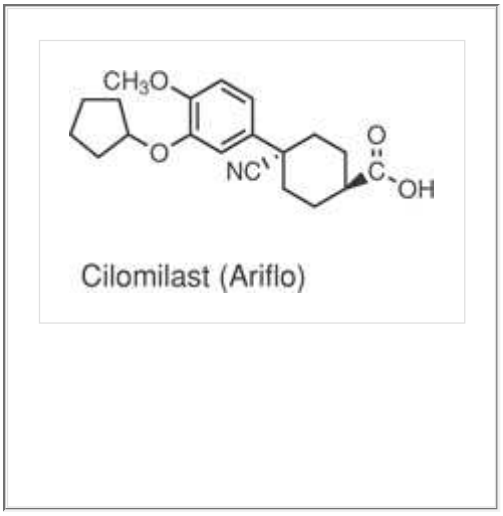
A number of important therapeutic agents owe their pharmacological action to their ability to inhibit the enzyme PDE. In the treatment of asthma, theophylline, at least in part, relaxes bronchospasm by relaxing bronchiole smooth muscles; amrinone and milrinone are ionotropic agents that relax vasculature, causing vasodilation; sildenafil and vardenafil relax smooth muscle of the vasculature in the penis; dipyramidole inhibits platelet aggregation; and the alkaloid papaverine relieves smooth and cardiac muscle spasms through its ability to inhibit PDE. These pharmacological effects are the result of inhibiting the ability of PDE to break down cAMP and cGMP and prolong their action as secondary messengers within a variety of cell types throughout the body. The PDE inhibitors also are implicated in an anti-inflammatory role by increasing cAMP and cGMP levels in cell types associated with the release of inflammatory chemicals from T and B cells, monocytes, neutrophils, and eosinophils. This last discovery is the impetus to develop new PDE inhibitors to treat asthma (eosinophils) and COPD (neutrophils).

New Phosphodiesterase Inhibitors

Progress in the development of PDE inhibitors to treat COPD and asthma awaited the basic pharmacological research that identified the specific PDE isoforms associated with inflammatory

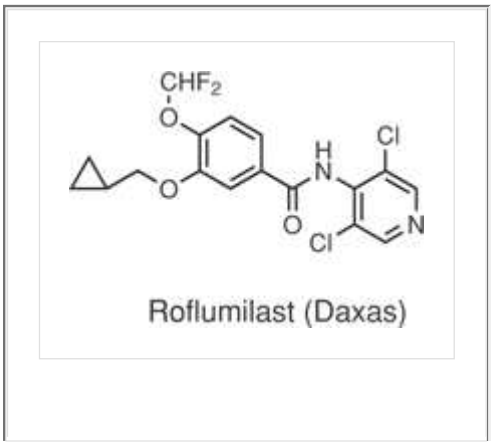
cells so that selective inhibitors could be designed and synthesized (53). (For additional discussion of PDE inhibitors and the structural characteristics of the PDE4 binding site, see Chapter 17.) As mentioned earlier, there are 11 families of PDEs, with PDE4 being associated with inflammatory processes. Specifically, three PDE4 subtypes (PDE4A, PDE4B, and PDE4D) are found in inflammatory cells (with PDE4B being predominant). Therefore, recent efforts in this area have been directed toward the development and synthesis of selective PDE4 inhibitors. Two PDE4 inhibitors are being investigated for their possible use in treating asthma and COPD. In the United States, cilomilast is being investigated for the treatment of COPD, and in Europe, roflumilast is being investigated for the treatment of both asthma and COPD.

Cilomilast



Cilomilast contains the dialkoxyphenyl ring characteristic of selective PDE4 inhibitors. The ether oxygens hydrogen bond to a glutamine in the binding pocket, and the cyclopentyl ring adds additional hydrophobic interactions. The oxygen atoms of the carboxyl group form hydrogen bonds with water that is coordinated with Mg^{2+} located in the distal end of the binding pocket. Orally administered cilomilast is 96% bioavailable. Food does not interfere with the overall absorption; however, food does slow down the rate. Cilomilast is 99% bound to albumin in the plasma and is metabolized in the liver by CYP2C8. The metabolism is extensive and results in oxidation, carboxyl group glucuronidation, and dealkylation of the cyclopentyl group, followed by glucuronidation or sulfation. A major difficulty with cilomilast is that in therapeutic doses, patients during clinical trials have experienced significant diarrhea and nausea. These effects appear to be tolerable and, theoretically, result from its inhibition of the PDE4D receptor subtype.

Roflumilast



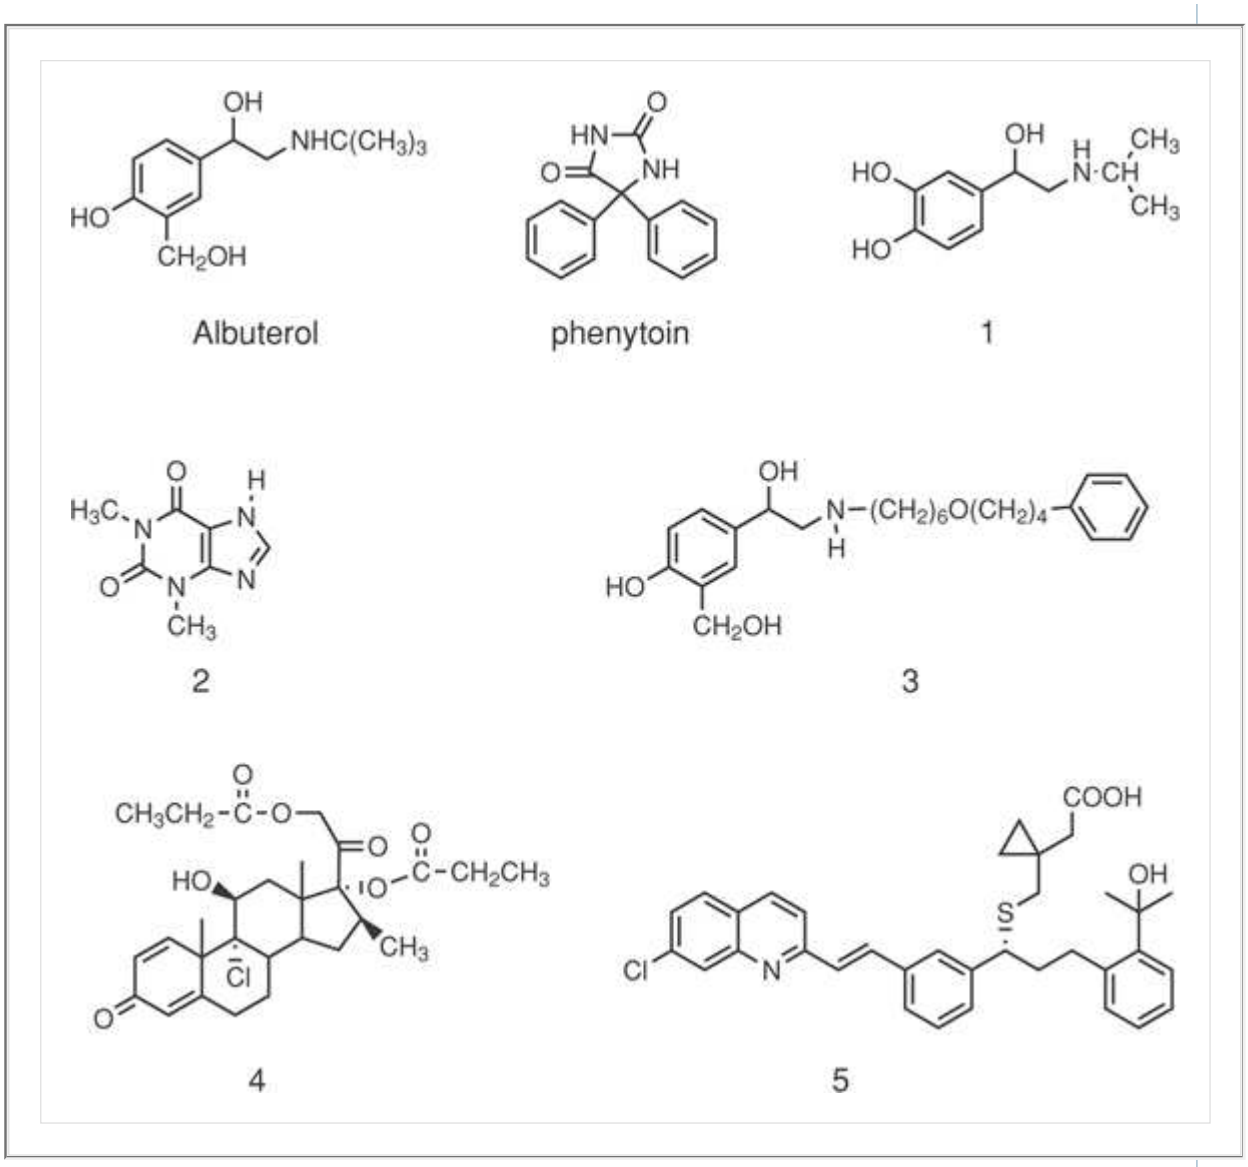
The PDE4 receptor binding of roflumilast is similar to that of cilomilast. The dialkylphenyl oxygens hydrogen bonds to a glutamine deep inside the binding pocket. The diflouromethoxy group and the cyclopropyl group contribute hydrophobic bonds; however, the cyclopentyl group on cilomilast makes far more interactions compared with the cyclopropyl group. The water molecule coordinated to the Mg^{2+} hydrogen bonds to the dichloropyridyl group just like the carboxylic acid oxygens in cilomilast. These structural differences make roflumilast a more potent inhibitor than cilomilast toward PDE4B (54). Roflumilast is well absorbed on oral administration and has a half-life of 10 hours. Roflumilast is metabolized in the liver to its N-oxide derivative, which also is a PDE4 inhibitor, and it has a plasma half-life of 20 hours (see Chapter 17). Roflumilast is currently undergoing clinical trials in Europe for use in the treatment of both asthma and COPD.

Case Study

Victoria F. Roche

S. William Zito

BJ is a Las Vegas blackjack dealer. He is a 38-year-old Caucasian man who has mild intermittent asthma treated with inhaled albuterol for occasional exacerbations. He works nights and sleeps during the day. He shows up at the emergency room early one morning complaining that he is not sleeping well lately. He says he wakes up about once a week gasping for breath. In addition, he has been having increased episodes of acute asthma during his job, which have caused him to use his inhaler at least once a night. He finds that his clients are disturbed by his wheezing and audible gurgling, and he fears he will lose his job unless something is done about it. On further inquiry, you determine that BJ is taking phenytoin (100 mg t.i.d.) to control the epilepsy he has had since he was an adolescent. The attending physician determines that BJ's asthma has progressed to the mild persistent stage and wants to prescribe an appropriate medication. Evaluate the following choices for use in this case.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure-activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient specific factors and desired therapeutic outcomes and make a therapeutic decision.
5. Counsel your patient.

Chapter 45

Men's Health

Duane D. Miller

Robert W. Brueggemeier

James T. Dalton

Drugs covered in this chapter:

Testosterone products

- Oral testosterone
  - Methyltestosterone
  - Fluoxymesterone
- Testosterone esters
- Transdermal patches
- Transdermal gels
- Buccal

Anabolic agents

- Nandrolone
- Oxandrolone
- Oxymetholone
- Stanozolol
- Testolactone

α_1-Adrenergic Antagonists

- Alfuzosin
- Doxazosin
- Tamsulosin
- Terazosin

Antiandrogens

- Bicalutamide
- Flutamide
- Nilutamide

Inhibitors of androgen biosynthesis

- 5α-Reductase inhibitors
  - Finasteride
  - Dutasteride
- 17α-Hydroxylase/17,20-lyase inhibitors
- Luteinizing hormone–releasing hormone agonists

- Buserelin
- Goserelin
- Leuprolide

Drugs for treatment of erectile dysfunction

- Phosphodiesterase-5 inhibitors
  - Sildenafil
  - Vardenafil
  - Tadalafil
- Other Drugs
  - Prostaglandin E_1
  - Papaverine
  - Phentolamine

Introduction

This chapter focuses on the physiology, pharmacology, metabolism, and structure–activity relationships for therapeutic and emerging classes of drugs that are used almost exclusively in men. Major differences in endocrine hormones and the anatomy and physiology of the reproductive system and genitourinary tract between males and females make men uniquely susceptible to a variety of disorders, including aging-related androgen insufficiency (hypogonadism and andropause), prostate and testicular cancer, benign prostatic hyperplasia (BPH), and erectile dysfunction (ED). The majority of these disorders and their treatments are associated with the male sex hormones (i.e., androgens), their pharmacological target (i.e., the androgen receptor [AR]), and the tissues that rely on the androgens.

Prostate problems are common in older men, particularly those aged 50 years and older. A man may have prostate problems for a number of reasons, including an infection of the prostate (prostatitis), a noncancerous enlargement of the prostate (BPH), or prostate cancer, the second most common cancer in men. Risk of prostate cancer increases with age; approximately 70 percent of all cases of the disease are diagnosed in men aged 65 years and older. Prostate problems often are discovered by men themselves. The signs of prostate problems include frequent urge to urinate, blood in the urine, painful or burning urination, difficulty urinating, or inability to urinate.

Aging-related androgen insufficiency (male hypogonadism) is a physiological condition characterized by the inability of the testes to produce sufficient testosterone to maintain sexual function, muscle strength, bone mineral density, and fertility (spermatogenesis). One in five men older than 50 years will exhibit symptoms of this condition. Symptoms of aging-related androgen insufficiency may include lethargy or decreased energy, decreased libido or interest in sex, ED (with loss of erections), muscle weakness and aches, inability to sleep, hot flashes, night sweats, depression, infertility, thinning of bones or bone loss, and cardiovascular disease. By the time that men are between the ages of 40 and 55 years, some may experience a phenomenon similar to the female menopause, called andropause. Whether andropause is more common than hypogonadism in the aging male is a matter for debate. The decline in testosterone occurs very gradually in men over several decades and may be accompanied by loss of bone mass (osteoporosis), loss of muscle mass and strength, and changes in fat distribution, cholesterol levels, spermatogenesis, sexual performance, quality of life, and impotence (i.e., ED). Studies show that a decline in testosterone actually can put men at risk for other health problems, such as heart disease and weak bones. Psychological stress, alcohol abuse, injuries or surgery, medications, obesity and infections, tobacco, and drugs, such as decongestants, antihypertensives, tranquilizers, statins, or antiseizure agents, can contribute to the

onset of these conditions. There is no way of predicting who will experience the symptoms of androgen insufficiency that are of sufficient severity to seek medical help; neither is it predictable at what age the symptoms of aging-related androgen insufficiency will occur in a particular individual. Each man's symptoms also may be different. Because all this happens at a time of life when many men begin to question their values, accomplishments, and direction in life, it often is difficult to realize that the changes occurring are related to more than just external conditions.

Clinical Significance

Significant research is currently underway in the area of men's health. In less than a decade, we have gone from having minimally effective pharmacological agents for erectile dysfunction (ED) to having several options. The widespread use of these phosphodiesterase (PDE5) inhibitors is acknowledged by the fact that Viagra (sildenafil) was one of the Top 200 drugs dispensed in 2004.

There are advantages and disadvantages to each of these PDE5 inhibitors. Some can be taken with food and other cannot. Some have optimal durations of action, and others are much shorter. All, however, have been known to have adverse effects and drug interactions in common. Some of these adverse effects can be rather severe, and the drug interactions with nitrates can be fatal.

The development of newer, more effective, and less deleterious agents is essential for ED. Agents that are more selective for PDE5 and avoid other PDEs are critical to this endeavor. By studying the structure–activity relationships between the PDEs and the inhibitors, this can be achieved. Minor changes to the side chains or functional groups of the currently available PDE inhibitors can potentially eliminate the adverse effects and drug interactions that limit the use of these agents. As new agents become available, clinicians continually compare and contrast these new agents to the ones that are currently available in an effort to improve patient care. This is an ongoing, joint effort by chemists and clinicians alike to optimize patient care either indirectly or directly by continually making adjustments to either chemical structures or therapeutic treatment plans for the patient.

Clinical Assistant Professor, Department of Clinical Sciences and Administrations, University of Houston, College of Pharmacy

Now that men are living longer, there is heightened interest in aging-related androgen insufficiency, its risks for other health problems, and its treatment.

Testicular cancer is the most common form of cancer among males aged 15 to 44 years and is approximately four times more common in white men than in African–American men. After motor vehicle accidents and suicide, cancer is the leading cause of death in this age group, followed by homicide, heart disease, and HIV. Testicular cancer is known as “young man's cancer.” Early detection is the key to survival. Testicular cancer is androgen-dependent, with a very fast onset. because the tumors can be very aggressive. When the cancer is confined to the testicles, there often is no pain, but by the time pain develops, it often is a sign that the cancer has already spread. Survival rates increase significantly if treatment has begun before the cancer has a chance to metastasize. Testicular cancer most often is discovered by men. Therefore, all men should conduct testicular self-examinations at least monthly and, preferably, every time they shower for any changes or lumps and to see a doctor immediately if any changes noted. The diagnosis is noninvasive and involves using ultrasound to look at the density, size, and shape of the testicles and other masses in the scrotum.

Men who experience any of these symptoms associated with the prostate, aging-related androgen insufficiency, and testicular cancer should see a doctor to find out the cause of the problem and to talk about possible treatment.

The discovery and clinical development of selective estrogen receptor modulators transformed the therapeutic use of estrogens (1). Similarly, nonsteroidal selective AR modulators (SARMs), with the ability to selectively stimulate or maintain muscle and bone mass or to reduce prostate mass in BPH without the androgenic effects of testosterone and 5α-dihydrotestosterone (DHT), now are leading a similar revolution in the therapeutic use of androgens. The discovery of SARMs not only provides a potentially significant therapeutic advance for androgen replacement therapy but also provides model compounds to further study the molecular mechanism of action of the AR (2). Results from in vitro and in vivo animal studies suggest that the therapeutic promise of SARMs as a treatment of muscle wasting, osteoporosis, hormonal male contraception, and BPH may be soon realized.

Testosterone and its metabolite, DHT, are the primary endogenous androgens and play crucial physiological roles in establishing and maintaining the male phenotype (3). Their actions are essential for the differentiation and growth of male reproductive organs, initiation and regulation of spermatogenesis, and control of male sexual behavior. In addition, androgens are important for the development of male characteristics in certain extragenital structures, such as muscle, bone, hair, larynx, skin, lipid tissue, and kidney (4). In females, the precise physiological roles of androgens are not completely understood, but the aging-related decline in circulating androgen levels has been linked to symptoms such as decreased libido and sexuality, lack of vigor, diminished well-being, and loss of bone mineral density in postmenopausal women (5,6,7).

The Sex Hormones

The sex steroid hormones are steroid molecules that are necessary for reproduction in females and males and that affect the development of secondary sex characteristics in both sexes. The sex steroids are comprised of three

classes: estrogens, progestins, and androgens (Fig. 45.1). The two principal classes of female sex steroid hormones are estrogens and progestins (for further discussion, see Chapter 46). Chemically, the naturally occurring estrogens are C-18 steroids and have in common a planar unsaturated A ring with a 3-phenolic group that aids in separation and purification from nonphenolic substances. The most potent endogenous estrogen is estradiol (Fig. 45.1). The naturally occurring progestins are C_{21} steroids and have in common a 3-keto-4-ene structure in the A ring and a ketone at the C-21 position. The most potent endogenous progestin is progesterone (Fig. 45.1). The principal class of the male sex steroid hormone is the androgens. The naturally occurring androgens are C-19 steroids and have in common oxygen atoms (as either hydroxyl or ketone groups) at both the C-3 and C-17 positions. The potent androgen found in the blood is testosterone (Fig. 45.1), with the more potent metabolite formed in certain androgen target tissues being DHT (Fig. 45.1). All three classes of endogenous steroids are present in both males and females. The production and circulating plasma levels of estrogens and progestins are higher in females, however, and the production and circulating plasma levels of androgens are higher in males.

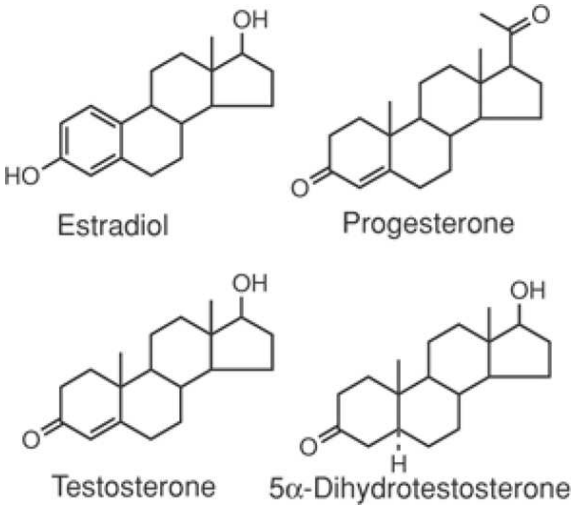

Fig. 45.1. The sex hormones.

Discovery of Androgens

One of the early and unusual experiments with testicular extracts was carried out in 1889 by the French physiologist Brown-Séquard. He administered such an extract to himself and reported that he felt an increased vigor and capacity for work (8). In 1911, Pézard showed that extracts of testicular tissue increase comb growth in capons (9). Early attempts to isolate pure male hormones from the testes failed, because only small amounts are present in this tissue.

The earliest report of an isolated androgen was presented by Butenandt (10) in 1931. He isolated 15 mg of crystalline androsterone from 15,000 L of human male urine. A second crystalline compound, dehydroepiandrosterone, which has weak androgenic activity, was isolated by Butenandt and Dannenberg (11) in 1934. During the following year, testosterone was isolated from bull testes by David et al. (12). This hormone was shown to be 6 to 10 times as active as androsterone.

Shortly after testosterone was isolated, Butenandt and Hanisch (13) reported its synthesis. In that same year, extracts of urine from males were shown to cause nitrogen retention as well as the expected androgenic effects (14). Many steroids with androgenic activity have subsequently been synthesized. Steroid hormones may have many potent effects on various tissues, and slight chemical alterations of androgenic steroids may increase some of these effects without altering others.

Testosterone was the first androgen to be used clinically for its anabolic activity. New sources of the hormone were needed, however, because only 270 mg could be isolated from a ton of bull testes (15). Commercially, testosterone is prepared from various steroids, including sarsasapogenin, diosgenin, and certain androgens found in stallion urine. Because of its androgenic action, testosterone is limited in its use in humans as an anabolic steroid. Many steroids were synthesized in an attempt to separate the androgenic and the anabolic actions. Because testosterone had to be given parenterally, it also was desirable to find orally active agents.

In the United States, most of the androgens and anabolic steroid products are subject to control by the U.S. Federal Control Substances Act as amended by the Anabolic Steroid Control Act of 1990 as Schedule III drugs.

Androgen Physiology

The overall physiological effects of endogenous androgens are contributed by testosterone and its

active metabolites, DHT and estradiol. Testosterone and DHT execute their actions predominantly through the AR, which belongs to the nuclear receptor superfamily and functions as a ligand-dependent transcription factor. Circulating testosterone is essential for the differentiation and growth of male accessory reproductive organs (e.g., prostate and seminal vesicles), control of male sexual behavior, and the development and maintenance of male secondary characteristics that involve muscle, bone, larynx, and hair. Healthy young adult men produce approximately 3 to 10 mg of testosterone per day, with circulating plasma levels ranging from approximately 500 to 1,000 ng/dL in eugonadal (normal) men. Circulating testosterone participates in the feedback regulation of androgen production by the hypothalamus- pituitary-testis axis, as shown in Figure 45.2. Testosterone, luteinizing hormone (LH), and LH-releasing hormone (LHRH; a.k.a. gonadotropin-releasing hormone) constitute the elements of a negative feedback control mechanism, whereby testosterone controls its own release. Low circulating testosterone levels increase the hypothalamic secretion of LHRH, which leads to increased production of LH and, consequently, increased testosterone production by the Leydig cells. More than 95% of circulating testosterone is synthesized and secreted by the Leydig

cells in the testes. High testosterone levels, on the other hand, inhibit LHRH release, thus suppressing both LH secretion and testosterone secretion. The LHRH is released from the hypothalamus in short, intermittent pulses every 2 hours and at greater magnitude in the morning, which in turn stimulates the pulsatile secretion of LH and follicle-stimulating hormone (FSH) from the pituitary. Follicle-stimulating hormone stimulates the Sertoli cells controlling spermatogenesis and development of the testis. Thus, testosterone secretion likewise is pulsatile and diurnal, with the highest concentration occurring at approximately 8:00 AM and the lowest at approximately 8:00 PM. In older men, especially those older than 60 years, the body does not produce enough testosterone that is needed to do all the intended work, and the testosterone levels remain relatively constant, without the morning pulses observed in young adult men. Average plasma testosterone concentrations in older men peak in the morning, with daily ranges of approximately 300 to 550 ng/dL by 70 years of age. The diurnal cycling is blunted as men age (16). In women, testosterone levels range from 15 to 100 ng/dL. Starting at approximately 40 years of age, testosterone levels drop by approximately 10 percent every decade. In the normal functioning of the male hormonal system, 97 to 98% of plasma testosterone is bound to sex hormone binding globulin, making it unavailable to the body's tissues. The remaining 2 to 3% is known as “bioavailable” or free testosterone. Furthermore, the receptor sites where testosterone must bind to be effective also can be occupied by estradiol, an estrogen also found in men that increases with age and body weight.

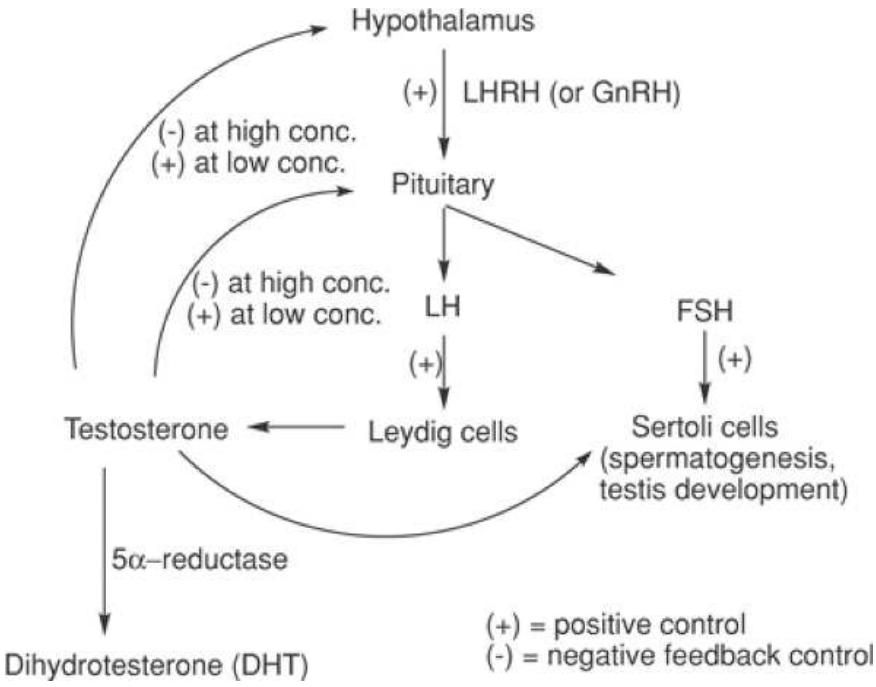

Fig. 45.2. Hypothalamus-pituitary-testicular axis. (+), positive control; (–), negative feedback control.

In the testis, FSH directly interacts with FSH receptors expressed in Sertoli cells and stimulates spermatogenesis, whereas LH indirectly stimulates spermatogenesis through testosterone synthesized by Leydig cells. Testosterone and its aromatized metabolite (estradiol) negatively regulate circulating levels of testosterone in the hypothalamus and pituitary. Activin and inhibin produced by Sertoli cells stimulate or inhibit, respectively, the secretion of FSH from the pituitary (17). High concentrations of intratesticular testosterone are essential for the initiation and maintenance of spermatogenesis, as evidenced by the infertility of hypogonadal men. Results from both animal models and humans, however, support the idea that both FSH and testosterone are required to achieve quantitative and qualitative spermatogenesis.

Androgens also are needed for the development of secondary sex characteristics. The male voice deepens because of thickening of the laryngeal mucosa and lengthening of the vocal cords. In both men and women, they play a role first in stimulating the growth of hair on the face, arms, legs, and pubic areas and later in the recession of the male hairline. The fructose content of human semen and both the size and the secretory capacity of the sebaceous glands also depend on the levels of testosterone.

Testosterone causes nitrogen retention by increasing the rate of protein synthesis and muscle mass while decreasing the rate of protein catabolism. The positive nitrogen balance therefore results from both decreased catabolism and increased anabolism of proteins that are used in male sex accessory apparatus and muscle. The actions of androgen in the reproductive tissues, including prostate, seminal vesicle, testis, and accessory structures, are known as the androgenic effects, whereas the nitrogen-retaining effects of androgen in muscle and bone are known as the anabolic effects. Although the precise mechanism of androgen action on muscle remains unknown, the common hypothesis is that androgens promote muscle protein synthesis. Evidence supports the idea that testosterone supplementation increases muscle protein synthesis in elderly men (18) and young hypogonadal men (19). Also, androgen-induced increases in muscle mass appear to arise from muscle fiber hypertrophy rather than hyperplasia (i.e., cellular enlargement rather than cellular

proliferation) (20).

The thickness and linear growth of bones are stimulated and, later, limited by testosterone because of closure of the epiphyses. Androgens affect bone mineral density by changing overall osteoblast (bone-forming cell) activity and osteoclast (bone-resorbing cell) activity, resulting from changes in the total number of each cell type and individual cell functional capacity (21,22). Androgens seem to have the ability to decelerate the bone remodeling cycle and tilt the focal balance of that cycle toward bone formation. The loss of androgens is thought to increase the rate of bone remodeling by removing the restraining effects on osteoblastogenesis and osteoclastogenesis.

Androgen Biosynthesis

The major pathways for the biosynthesis of the sex steroid hormones are summarized in Figure 45.3. Cholesterol is

stored in endocrine tissues and is converted to androgen, estrogen, or progesterone when the tissue is stimulated by a gonadotropic hormone. Androgens (male sex hormones) primarily are synthesized from cholesterol in the testes, whereas estrogens are biosynthesized chiefly in the ovary in mature, premenopausal women. This is not surprising, because androgens are intermediates in the biosynthesis of estrogens. In the liver, androgens are formed from C-21 steroids. During pregnancy, the placenta is the main source of estrogen biosynthesis and pathways for production change (23,24). Small amounts of these hormones also are synthesized by the adrenal cortex, the hypothalamus, and the anterior pituitary in both sexes. The major source of estrogens in both postmenopausal women and men is adipose tissue (25).

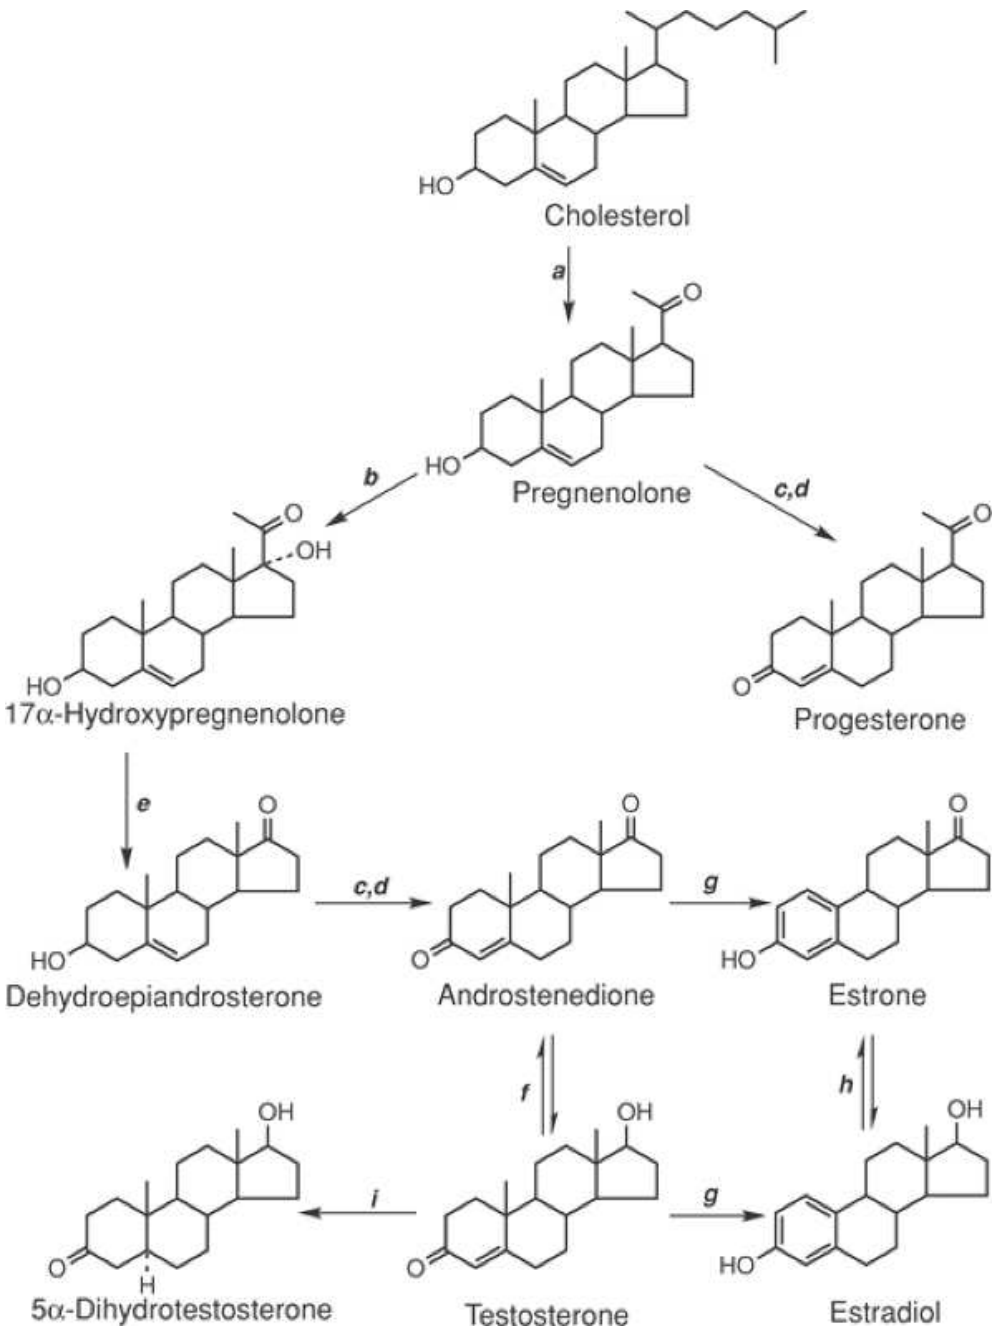

Fig. 45.3. Biosynthesis of androgens and other sex steroid hormones. The enzymes involved in this biosynthesis are (a) side-chain cleavage, (b) 17α-hydroxylase (c) 5-ene-3β-hydroxysteroid dehydrogenase, (d) 3-oxosteroid-4,5-isomerase, (e) 17,20-lyase, (f) 17β-hydroxysteroid dehydrogenase, (g) aromatase, (h) estradiol dehydrogenase, and (i) 5α-reductase.

Luteinizing hormone binds to its receptor on the surface of the Leydig cells to initiate testosterone biosynthesis. As in other endocrine cells, the binding of gonadotropin activates the G_S signal transduction pathway, increasing intracellular cyclic adenosine monophosphate (cAMP) levels via activation of adenylate cyclase. One of the processes influenced by elevated cAMP levels is the

activation of cholesterol esterase, which cleaves cholesterol esters and liberates free cholesterol. The free cholesterol is then converted in mitochondria to pregnenolone via the side-chain cleavage reaction (Fig. 45.3). Pregnenolone is converted by 17α-hydroxylase to 17α-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA; a C-19 steroid) via 17-20 lyase, which involves cleavage of the C-17 to C-20 carbon–carbon bond and loss of the 17β-acetyl side chain (26). The 17α-hydroxylase is found in the endoplasmic reticulum membrane and is comprised of the cytochrome $P450_{17\alpha}$ protein and the ubiquitous NADPH-cytochrome P450 reductase. Cytochrome $P450_{17\alpha}$ is expressed by the *CYP17* gene found on chromosome 10 in humans. Alternatively, progesterone can be formed from pregnenolone via the action of 5-ene-3β-hydroxysteroid dehydrogenase and

3-oxosteroid-4,5-isomerase. These same enzymes are responsible for the conversion of DHEA to the 17-ketosteroidal androgen, androstenedione.

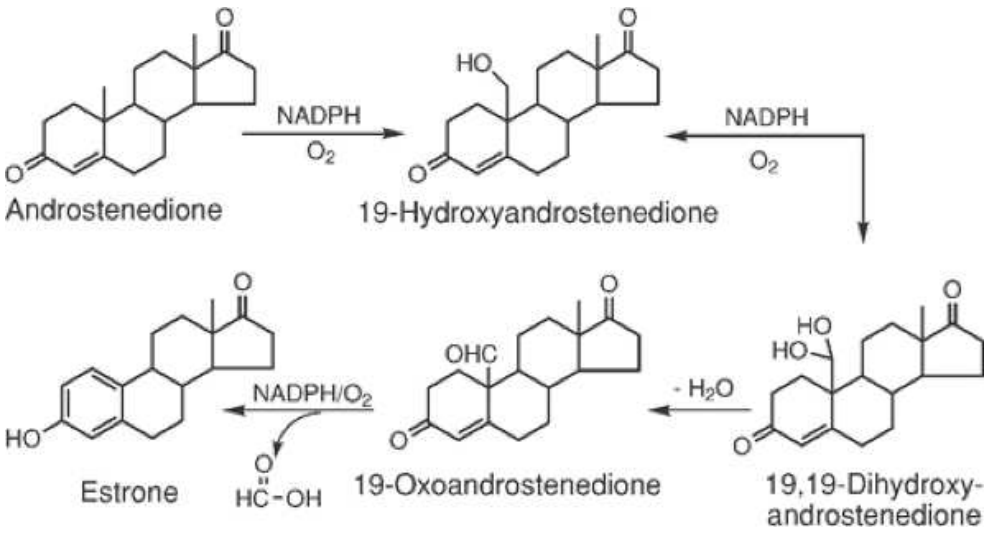

Fig. 45.4. Aromatase mechanism.

Testosterone is formed by reduction of the 17-ketone of androstenedione by 17β-hydroxysteroid dehydrogenase (27,28). Testosterone and androstenedione are metabolically interconvertible. Loss of the C-19 angular methyl group and aromatization of the A ring of testosterone or androstenedione is catalyzed by the microsomal cytochrome P450 enzyme complex, called aromatase, and results in the C-18 steroids—namely, 17β-estradiol or estrone, respectively—as shown in Figure 45.4. 17β-Estradiol and estrone are metabolically interconvertible, catalyzed by estradiol dehydrogenase. Research interests in the aromatization reaction continue to expand from basic endocrinology and reproductive biology studies to aromatase inhibition for the treatment of estrogen-dependent cancers, as illustrated in several conferences and reviews (29,30,31,32). Androstenedione is the preferred substrate for aromatization, and three molecules of NADPH and three molecules of oxygen are necessary for conversion of one molecule of androgen to estrogen (33).

The most potent endogenous androgen is the 5α-reduced steroid, DHT, which is biosynthesized by two 5α-reductase isoforms, Type 1 and Type 2 (Fig. 45.1). Type 1 5α-reductase is expressed predominantly in sebaceous glands of the skin, scalp, and liver. Type 1 5α-reductase is responsible for approximately one-third of the circulating DHT. Type 2 5α-reductase is found primarily in prostate, seminal vesicles, epididymides, genital skin (scrotum), hair follicles, and liver, and it is responsible for two-thirds of the circulating DHT. Approximately 6 to 8% of testosterone is converted to DHT. 5α-Reductase has been found in both the microsomal fraction and the nuclear membrane of homogenized target tissues, and it catalyzes an irreversible reduction reaction, which requires

NADPH as a cofactor, that provides the α-hydrogen at C-5 (34,35). Conversion to DHT amplifies the action of testosterone by three to five times because of the greater binding affinity of DHT as compared to testosterone for the ARs (36).

Androgen Metabolism

Testosterone can be metabolized in either its target tissues or the liver (37,38,39), as shown in Figure 45.5. In androgen target tissues, testosterone can be converted to physiologically active metabolites. In the prostate gland, skin, and liver (40), testosterone is reduced to DHT by 5α-reductase (Types 1 and 2) (41). On the other hand, a small amount of testosterone (0.3%) also can be converted to estradiol by aromatase through cleavage of the C-19 methyl group, and aromatization of ring A, which mainly occurs in adipose tissue. This process also occurs in the ovaries of women. In men, approximately 80% of the circulating estrogen arises from aromatization of testosterone in the adipose tissue (42), with the other 20% being secreted by the Leydig cells in the testes (43).

Both 5α-reduction and aromatization are irreversible processes. In addition to these pathways, testosterone also can be further inactivated in the liver through reduction and oxidation, followed by glucuronidation and renal excretion. It can be metabolized to androstenedione through oxidation of the 17β-OH group and to androstanedione with 5α-reduction of ring A. Androstanedione can be further converted to androsterone after 3-keto group reduction. Alternatively, androstenedione also can be converted to etiocholanolone through 5β- and 3-keto reduction. Similarly, DHT can be converted to androstanedione, androsterone, and androstanediol (44).

After the administration of radiolabeled testosterone, approximately 90% of the radioactivity is found in the urine, and 6% is recovered in the feces through enterohepatic circulation (45). Major urinary metabolites include androsterone and its 5α-diastereoisomer etiocholanolone, both of which are inactive metabolites. They are excreted mainly as glucuronide conjugates or, to a lesser extent, as sulfate conjugates (46). The reduction of testosterone to its *cis* A/B ring juncture (5β) conformation, etiocholanolone, explains its complete loss of activity, because the *cis* A/B ring no longer has affinity for the AR, as shown in Figure 45.6. Most of the other metabolites mentioned above undergo extensive glucuronidation of

the 3α- or 17β-OH groups as well, either in the target tissues or in the liver (46), and are further excreted in the urine. Therefore, following oral administration, the plasma testosterone half-life is less than 30 minutes because of extensive hepatic metabolism. Approximately 90% of an oral dose of testosterone undergoes first-pass metabolism before it reaches the systemic circulation. A number of minor metabolites of testosterone also have been isolated from urine and identified as 5α-androstanes and 5β-androstanes with a 3α-hydroxyl function. Most 17-ketosteroids isolated from the urine result from catabolism of the adrenocorticoids rather than from metabolism of androgens.

Mechanisms of Androgen Action

Testosterone, DHT, and other androgens execute their actions predominantly through the AR. The AR is mainly expressed in androgen target tissues, such as the prostate, skeletal muscle, liver, and central nervous system, with the highest expression level being observed in the prostate, adrenal gland, and epididymis (47). Testosterone binds preferentially to the AR in muscle, bone, brain, and bone marrow, whereas DHT binds to the AR in genitalia, prostate, skin, and hair follicles. It is a member of the steroid and nuclear receptor superfamily, which is composed of more than 100 members and continues to grow. Among this large family of proteins, only five vertebrate steroid receptors (estrogen, progesterone, androgen, glucocorticoid, and mineralocorticoid receptors) are known. Like other steroid receptors, AR is a soluble protein that functions as an intracellular transcriptional factor. The

AR function is regulated by the binding of androgens, which initiates sequential conformational changes of the receptor that affect receptor–protein interaction and receptor–DNA interactions (48).

The AR gene is more than 90 kb long and codes for a protein of 919 amino acids that has three major functional domains, as illustrated in Figure 45.7. The N-terminal domain, which serves a modulatory function, is encoded by exon 1 (1,586 bp). The DNA binding domain (DBD) is encoded by exons 2 and 3 (152 and 117 bp, respectively). The ligand binding domain (LBD) is encoded by five exons, which vary from 131 to 288 bp in size. There also is a small hinge region between the DBD and LBD. Two transactivation functions have been identified. The N-terminal activation function (AF1) is not conserved in sequence and is ligand-independent (constitutively active), whereas the C-terminal activation function (AF2) is conserved in sequence and functions in a ligand-dependent manner (49). A nuclear localization signal spans the region between the DBD and the hinge region.

Similar to the other steroid receptors, unbound AR is mainly located in the cytoplasm and associated with a complex of heat shock proteins through interactions with LBD (50). On agonist binding (51), AR goes through a series of conformational changes: The heat shock proteins dissociate from AR, and the transformed AR undergoes dimerization, phosphorylation, and translocation to the nucleus, which is mediated by the nuclear localization signal, as shown in Figure 45.7. Translocated receptor

then binds to androgen-response elements (AREs) in DNA, which are characterized by a six-nucleotide half-site consensus sequence 5′-TGTTCT-3′ spaced by three random nucleotides and are located in the promoter or enhancer region of AR gene targets. Recruitment of other transcription coregulators (including coactivators and corepressors) and transcriptional machinery further ensures the transactivation of AR-regulated gene expression. All these complicated processes are initiated by the ligand-induced conformational changes in the LBD.

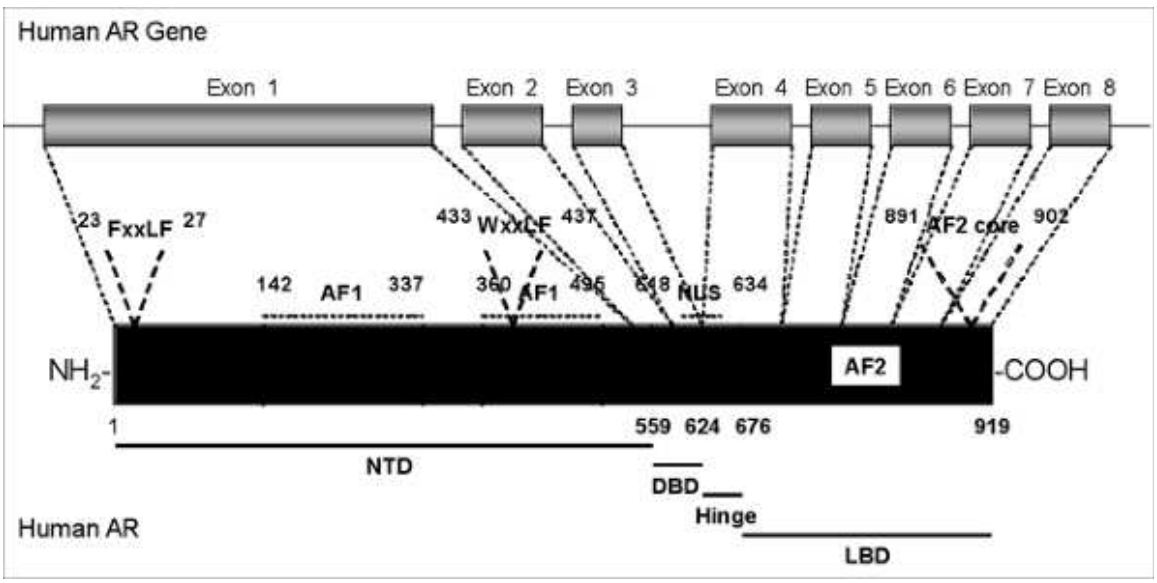

Fig. 45.7. Structural domains of the androgen receptor gene and protein.

Ligand-induced AR conformational changes provide the structural basis for the recruitment of cofactor proteins and transcriptional machinery, which also is required for the assembly of AR-mediated transcription complexes (52), as shown in Figure 45.8. The formation of an activation complex is known to involve AR, coactivators, and RNA polymerase II recruitment to both the enhancer and promoter, whereas the formation of a repression complex involves factors bound only at the promoter and not at the enhancer. Because the formation of a functional AF2 region provides a structural basis for ligand-induced protein–protein interaction, ligand-specific recruitment of coregulators might be crucial for the agonist or antagonist activity of AR ligands.

Binding of DNA also is required for AR-regulated gene expression, which is known as the classic genomic function of AR. The ARE half-site sequence can be arranged either as inverted repeats or as direct repeats (52,53), and AR recognizes and binds to the ARE site through two zinc fingers located in the DBD. Like other steroid receptors, ligand-bound AR forms homodimers and appears to form “head-to-head” dimers (54) even when it is bound to the direct repeats of ARE. Selective recognition of specific ARE sequences could be regulated by ligand binding (55) and/or the presence of other transcriptional factors, which bind to their own DNA binding sites as well (combinatorial regulation) (56).

Besides the genomic pathway, the nongenomic pathway of AR also has been reported in oocytes (57), skeletal muscle cells (58), osteoblasts (59,60), and prostate cancer cells (61,62). As compared to the genomic pathway, the nongenomic actions of steroid receptors are characterized by the rapidity of the action, which varies from seconds to an hour or so, and by interaction with plasma membrane–associated signaling pathways (63). Nevertheless, the structural basis for nongenomic action is direct interactions between AR and cytosolic proteins from different signaling pathways, which could be closely

related to the ligand-induced conformational change of the LBD or, indirectly, the N-terminal domain. Functionally, the nongenomic action of androgen involves either rapid activation of kinase-signaling cascades or modulation of intracellular calcium levels, which could be related to stimulation of gap junction communication, neuronal plasticity, and aortic relaxation (64). Separation of the genomic and nongenomic functions of steroid receptors using specific ligands also was proposed as a new strategy to achieve tissue selectivity (63,65).

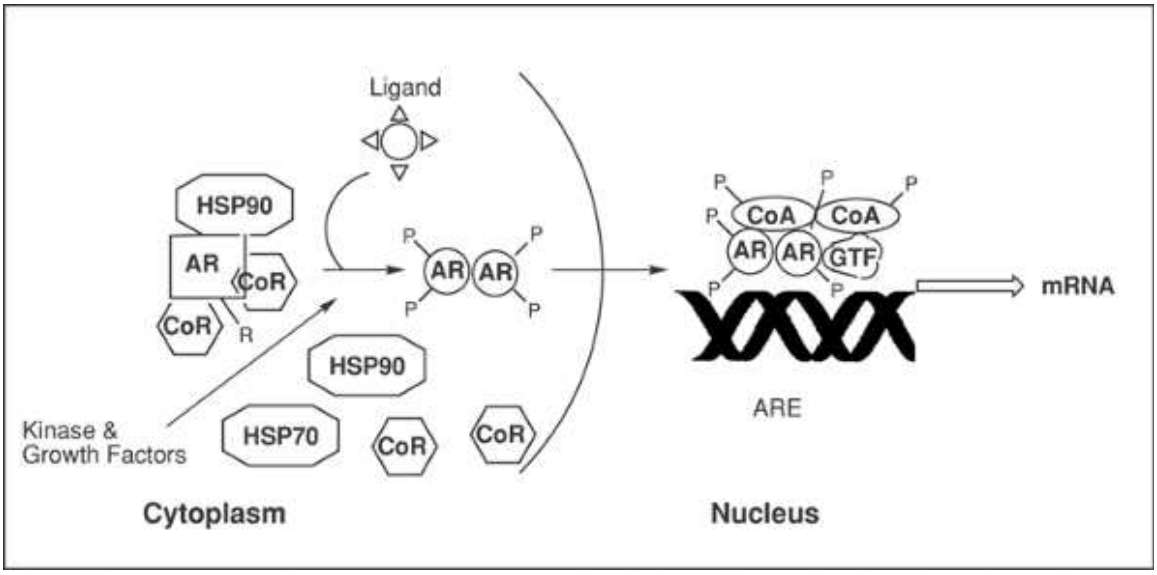

Fig. 45.8. Mechanism of androgen action. The androgen receptor (AR) is maintained in an inactive complex by heat shock protein (HSP) 70, HSP 90, and corepressors (CoR). On ligand binding, it homodimerizes and enters the nucleus. The receptor is basally phosphorylated (P) in the absence of hormone, and hormone binding increases the phosphorylation status of the receptor. The AR binds to the androgen-response element (ARE) on the promoter of androgen responsive genes, leading to the recruitment of coactivators (CoA) and general transcription factors (GTF), leading to gene transcription.

Drugs Used in the Treatment of Aging-Related Androgen Insufficiencies

Male Hypogonadism

Male hypogonadism (testosterone deficiency) is the inability of the testes to produce sufficient testosterone to maintain sexual function, muscle strength, bone mineral density, and fertility (spermatogenesis). In men, there is a gradual decline of approximately 1% per year in the production of testosterone beginning around 40 years of age. For most men, testosterone levels naturally decline with advancing age but still remain within the physiological range throughout their lifetimes, causing no significant problems. Approximately 20% of men older than age 60 years and 30 to 40% of men older than 80 years have plasma testosterone levels indicative of hypogonadism (<325 ng/dL). Male hypogonadism is most commonly primary hypogonadism (testicular failure to produce testosterone for various reasons), secondary hypogonadism (hypothalamic-pituitary failure to stimulate testicles to produce testosterone), or a combination of both.

Testosterone and structurally related steroidal androgens have been used for decades to treat male hypogonadism, Klinefelter's syndrome (a chromosomal abnor- mality resulting in testicular dysfunction), anemia secondary to chronic renal failure, aplastic anemia, protein wasting diseases associated with cancer, burns, traumas, AIDS, short stature, breast cancer (as an antiestrogen), or hereditary angioedema (46). However, these agents have been demoted to the therapy of final resort because of serious hepatotoxicity and the recent development of more effective therapies (e.g., erythropoietin, aromatase inhibitors, and taxanes). Although severe hypogonadism is uncommon, aging-related androgen insufficiency is much more frequent. Low endogenous testosterone concentrations are associated with sarcopenia and frailty arising from decreased fat-free mass, lessened muscle strength, and reduced bone mineral density (osteoporosis). Low testosterone concentrations also are associated with decreased sexual libido and ED. More than 30 million men older than 40 years in the United States are estimated to suffer from ED. Although androgens are not essential for erection (66), transdermal and intramuscular (IM) testosterone replacement therapy often is employed in hypogonadal men with ED (67). Furthermore, selective phosphodiesterase (PDE5) inhibitors that increase penile blood flow are considered to be the treatment of choice for men with ED. Hormone replacement therapy with testosterone in aging men also improves body composition, bone and cartilage metabolism, and memory and cognition, and it even decreases cardiovascular risk (68).

Low testosterone concentrations frequently are seen in patients with ED, aging, type II diabetes, HIV/AIDS, osteoporosis, depression, obesity, alcohol abuse, anabolic steroid abuse, chronic inflammatory disease, cancer, and glucocorticoid use.

Andropause

Andropause was first described in the medical literature in the 1940s, but the ability to diagnose it is relatively new. The idea that men, as well as women, might be subject to sex hormone fluctuations in later life has been a topic of debate among endocrinologists and men's health professionals (69). Andropause affects men between the ages of 40 and 55 years, but unlike women, men do not have a clear-cut signpost, such as the cessation of menstruation to mark this transition. Men's “transition” may be much more gradual and expand over many decades, and men will very likely experience andropausal symptoms to include ED, loss of muscle mass, irritability, generalized fatigue, and even problems with memory and cognition. A decline in testosterone levels will occur in virtually all men, and there is no way of predicting who will experience andropausal symptoms of sufficient severity to seek medical help. It is estimated that 30% of men in their fifties, and up to 50% of men older than 65 years, will have testosterone levels low enough to cause noticeable symptoms. Once andropause is discovered, the process of replacing the missing testosterone is either by injection, locally applied hormone gel, transdermal patch, or implanted cartridge.

Testosterone Replacement Therapy

The acceptance of testosterone replacement therapy (TRT) has been hampered by the lack of orally active preparations with good efficacy and, particularly, a safe profile (70). Progress has been limited over the last three decades in developing synthetic molecules that could separate the desirable physiological functions normally regulated by endogenous androgens from the undesirable or dose-limiting side effects. The abuse of synthetic anabolic steroids by athletes and body builders has contributed to the general perception of certain undesirable side effects, such as aggressive behavior, liver toxicity, acne or impotency.

Table 45.1. Testosterone Replacement Therapy

Benefits	Risks

Improved sexual performance and desire	Stimulated growth of preexisting prostate cancer
More energy and improved quality of life	Greater chance for benign prostatic hyperplasia
More energy and sense of well-being	Increased hemoglobin levels to above the physiological range
Increased bone mineral density Improved muscle mass strength	Problems with voiding; symptoms includes poor urine flow and hesitancy before urinating
Improved (lower) low-density lipoprotein profile	Increased potential for liver damage from oral preparations Sleep apnea (stopping of breathing during sleep)
Decreased irritability and depression	Breast tenderness and swelling (gynecomastia)
Improved cognitive function	Testicular shrinkage (testicular atrophy)
Increased hemoglobin levels to the physiological range	Infertility (decreased spermatogenesis) Skin reaction from patches or gel
Thickened body hair and skin	Pain, soreness, or bruising from injection Increased fluid retention Increased skin problems (acne, oily skin) Increased body hair

Current androgenic formulations for TRT largely are restricted to injectable formulations of testosterone esters, transdermal delivery formulations (scrotal or nonscrotal patches or gel), or buccal testosterone. Marketed injectable forms of testosterone esters (e.g., testosterone enanthate, propionate, or cypionate) produce undesirable fluctuations in testosterone blood levels, with supraphysiological concentrations early and subphysiological levels toward the end of the period before the next injection. These fluctuations provide an unsatisfactory benefits profile and, in some cases, undesired side effects. Skin patches provide a better blood level profile of testosterone, but skin irritation and daily application limit the usefulness and acceptability of this form of therapy. Oral

preparations such as fluoxymesterone and 17α-methyltestosterone are not currently used because of concerns about liver toxicity linked to the 17α-alkyl group and because of somewhat lower efficacy (70). Thus, these oral androgens are considered to be obsolete and do not represent a viable form of therapy.

Benefits and Risks of Testosterone Replacement Therapy

Multiple large-scale and long-term clinical trials of TRT have been conducted in aging men to evaluate the risk–benefit ratio of TRT in aging men, but no agreement exists regarding the benefits and risks of TRT (Table 45.1) (for review, see (69,70). The potential benefits of TRT include increase in bone mineral density as well as improvement in muscle mass and strength, cognitive function, mood, and sexual function. The potential risks of TRT, however, including those in the cardiovascular system, blood (e.g., hematocrit and hemoglobin levels), and prostate, are routinely experienced. An

emerging class of drugs known as SARMs may soon transform the therapeutic landscape of androgen use by selectively stimulating anabolic targets and avoiding steroid- related side effects. Because of the long-term effects of TRT in otherwise healthy men remain unclear, the Institute of Medicine recommends that TRT not be used to prevent or to relieve the physical or psychological effects of aging (71).

Clearly, TRT is beneficial for hypogonadal men with androgen insufficiency to restore sexual function and muscle strength, to prevent bone loss, and to protect against heart disease (atherosclerosis) (70). Increasing testosterone levels with TRT, however, may pose problems by stimulating the growth of the prostate. Long-term TRT could cause prostate gland enlargement, which might fuel the growth of prostate cancer that is already present and could cause breast enlargement in men (gynecomastia). This is especially worrisome, because prostate cancer is common in older men and many men may have prostate cancer that is undiagnosed.

In elderly men, testosterone effects on muscle mass and strength have not been consistent or impressive, possibly because of the low dosages used in clinical trials. The high correlation between the dose (and plasma concentration) and the anabolic actions of androgen in muscle suggests that androgen administration of higher doses in elderly men may significantly increase muscle mass and strength, but high doses might increase the adverse effects and the aromatization of testosterone to estrogen.

Types of Testosterone Replacement Therapy

Several types of TRT exist. Choosing a specific therapy depends on the patient's preference of a particular delivery system, the side effects, and the cost. Types include injection, transdermal, buccal mucosal, and oral (Table 45.2).

Injection

Because orally administered testosterone is ineffective in the treatment of male androgen insufficiency syndromes as a result of extensive presystemic first-pass metabolism, IM injections bypass the problems of first-pass metabolism. Intramuscular testosterone injections are depot esters that undergo differing rates of in vivo ester hydrolysis to release free testosterone over an extended period of time. Typically, the depot esters are administered IM into a large muscle once every 2 to 4 weeks depending on the depot ester used (Table 45.2). They are safe, effective, and the least expensive androgen preparations available. The major disadvantage with the IM route for the depot esters is that testosterone plasma concentrations exhibit a saw-toothed pattern, with supraphysiological levels within 2 to 4 days following the IM injection and subphysiological levels before the next injection. A more satisfactory physiological replacement therapy without the fluctuations in free testosterone plasma levels would be to IM administer a lower dose (i.e., 100 mg) on a weekly or biweekly schedule. Because IM injection of testosterone or its esters causes local

irritation, the rate of absorption may be erratic.

Among the esters of testosterone available for IM administration include the 17β-propionate, 17β-enanthate, and the cypionate (17β-cyclopentylpropionate) (Fig. 45.9). Testosterone enanthate and cypionate are the depot esters commonly used with comparable pharmacokinetics. Testosterone enanthate (Delasteryl) is formed by esterification of the 17β-hydroxy group of testosterone with heptanoic acid and testosterone cypionate with cyclopentanepropionic acid. Sterile solutions of these esters are available in a suitable vegetable oil, such as cottonseed oil. Unlike oral testosterone, with a half-life of 10 to 100 minutes, IM testosterone administration avoids first-pass metabolism. Generally, the amount of sex hormone binding globulin in plasma determines the distribution of testosterone between free and bound forms, and free testosterone concentrations determine the drug's half-life. The bulky cypionate and enanthate esters of testosterone have a duration of action of up to 2 to 4 weeks, whereas the shorter propionate ester has a shorter duration of action of 1 to 2 weeks. Doses may be adjusted by aiming for midphysiological (400–600 ng/dL) testosterone values after 1 week or at the low end (300–400 ng/dL) just before the next injection is due.

Transdermal

Transdermal TRT systems are, perhaps, the most commonly used systems for delivering testosterone to bypass the rapid first-pass metabolism associated with oral testosterone. Clinical studies have shown that these formulations are effective forms of testosterone replacement, with peak response within 3 to 6 months. Discontinue use of the transdermal formulation if the desired response is not reached within this time period. Skin irritation is more common with the transdermal formulations, with more than 50% experiencing some form of skin irritation at some point during the treatment. Pretreatment with corticosteroid creams (not with the ointment) has been shown to reduce the severity and incidence of skin irritation without significantly affecting testosterone absorption from the formulation. With the transdermal formulations, testosterone levels were maintained within physiological values, and a beneficial effect was observed on general mood and sexual functioning. A plasma concentration in the midphysiological range (400–600 ng/dL) is the goal.

Matrix-Type Transdermal Systems

This type of patch (scrotal patch; Testoderm®) must be applied to dry, clean (shaven) scrotal skin, which is 5 to 30 times more permeable to testosterone than other skin sites, every 24 hours to produce an adequate testosterone plasma concentration. The matrix system is described as a “drug-in-adhesive film,” in which the drug is located on the adhesive layer of the film; thus, it is thinner and less bulky than the reservoir system. The advantage of the matrix system is that it produces supraphysiological levels of DHT

P.1276

P.1277

because of the high 5α-reductase enzyme activity of the scrotal tissue. The patches have an occlusive backing that prevents sex partners from coming in contact with the active drug. A matrix transdermal system will not produce adequate plasma testosterone concentrations if applied to nonscrotal skin. Plasma testosterone concentrations are reached in approximately 2 to 4 hours. Although testosterone is absorbed throughout a 24-hour period, concentrations do not simulate the circadian rhythm of endogenous testosterone in normal (eugonadal) males. Within 24 hours after application of the matrix system, plasma testosterone concentration gradually falls to 60 to 80% of the peak plasma concentration, and when the system is removed, testosterone plasma concentration declines to baseline within 2 hours. Inadequate scrotal size and adherence problems are limitations. Skin irritation does occur in those with sensitive scrotal skins.

Table 45.2. Testosterone Products and Pr

Product	Trade Name	Onset of	Duration	Time to	Time t

		Peak Response	Duration of Action	Peak Conc.	Steady Conc.
Methyltestosterone	Android Testred Virilon Oreton Methyl	—	24 hours	2 h	—
Fluoxymesterone Android-F	Halotestin	—	24 hours	—	—
Testosterone undecanoate	Andriol	6 hours	10 hours	~6 hours	—
Testosterone propionate	Testex	6–24 hours	1–2 wks	3–36 hours	—
Testosterone cypionate	Andronate Depotestosterone Depotest	6–24 hours	2–4 weeks	24 hours	—
Testosterone enanthate	Andro-LA Andryl Delatesteryl Delatest Everone Testamone Testrin-PA	6–24 hours	2–4 weeks	24 hours	—
Trandermal patches	Androderm Testoderm TTS Testoderm	3–6 months	24 hours	2–4 hours	2–3
Transdermal gels	AndroGel Testim	3–6 months	5 days	4 (2–6) hours	2–3
Buccal muscosal	Striant	—	24 hours	5 (0.5–12) hours	2–3

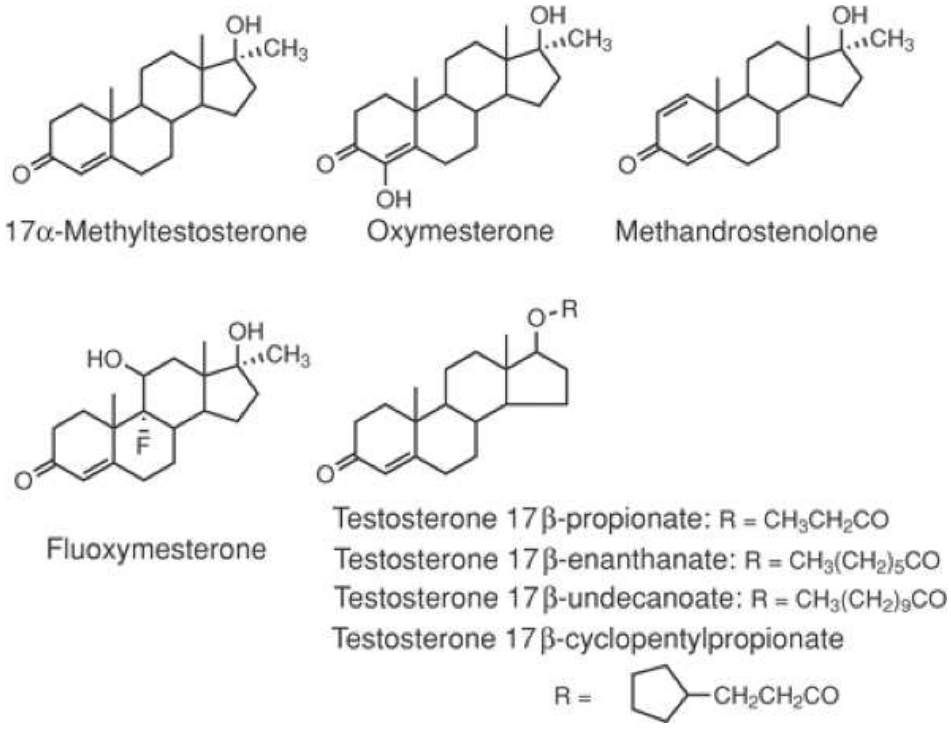

Fig. 45.9. Testosterone esters and synthetic testosterone derivatives.

Reservoir-Type Transdermal Systems

The reservoir-type patch (nonscrotal patch; Androderm, Testoderm TTS) is not applied to scrotal skin but, rather, to the abdomen, back, thighs, or upper arms every 24 hours (see Table 45.4 for dosage strength). This type of patch is membrane-controlled for the drug to diffuse continuously over 24 hours from the reservoir into the skin. Thus, this type of patch is thicker than the matrix (scrotal) patch. The patches have an occlusive backing that prevents sex partners from coming in contact with the active drug. The site of the application is rotated at 7-day intervals between applications to lessen skin reactions at the same application site. The advantage of the reservoir transdermal system is that it achieves normal testosterone circadian rhythm as seen in younger men, peaking in the morning and decreasing throughout the rest of the day. The reservoir-type patch, when applied to nonscrotal skin, produced physiological DHT and estradiol plasma concentrations. Steady-state plasma concentrations of testosterone, which are approximately 10 times baseline values, are reached in about 6 hours (range, 4–10 hours depending on application patch location), which then fall to 60 to 80% of the peak plasma concentration within 24 hours after application of the transdermal system. Thus, physiological plasma testosterone concentrations are maintained over 24 hours with this type of patch. Drug accumulation does not occur with repeated applications. When the system is removed, testosterone plasma concentrations decline to baseline within 2 hours. A usual dose for the reservoir-type transdermal results in the systemic absorption of 2 to 10 mg daily in hypogonadal men.

Gel

Testosterone gel (AndroGel, Testim) is a 1% testosterone hydroalcoholic gel that provides continuous transdermal delivery of testosterone for 24 hours once the gel is rubbed into the skin on the lower abdomen, upper arm, or shoulder; do not apply to scrotal tissue (Table 45.2). Because there is a continuous release of testosterone over 24 hours, the normal circadian rhythm is not observed. As the gel dries, approximately 10% of the testosterone is absorbed through the skin. Gel application of TRT appears to cause fewer skin reactions than occur with the patches. Avoid showering or bathing for several hours after an application to ensure adequate absorption. A potential side effect of the gel is the possibility of transferring the medication to your partner; skin-to-skin contact should be avoided either until the gel is completely dry or by covering the area after an application. Following the application of 5 g of gel, which will deliver 50 mg of testosterone, the mean peak testosterone concentrations are reached in approximately 2 hours, which are about two to three times baseline values. For optimum results, the gel is best applied in the evening to allow

maximum concentration to occur early in the morning hours. Doses of the gel may be adjusted by aiming for midphysiological (400–600 ng/dL) testosterone values after 1 week. When the gel treatment is discontinued, plasma testosterone levels remain in the physiological range for 24 to 48 hours, then return to their pretreatment levels within 5 days following the last application. An increase in plasma testosterone can be observed within 30 minutes of application. Plasma concentrations approximate the steady-state level by the end of the first 24 hours and are at steady state by the second or third day of dosing.

Buccal Mucosal

Striant is a gel-like substance that adheres to the gumline, which softens to deliver physiological amounts of testosterone to the systemic circulation, thereby producing circulating testosterone concentrations in hypogonadal males that approximate physiological levels seen in healthy young men (400–700 ng/dL). One buccal system (30 mg) is applied to the gum region twice daily, morning and evening, approximately 12 hours apart. Because there is a continuous release of testosterone over 24 hours, the normal circadian rhythm is not observed. Peak plasma testosterone concentrations are reached within 10 to 12 hours and are stable within a few days of the buccal preparation. The buccal preparation is difficult for patients to get used to, because the side effects may include gum irritation or pain, bitter taste, or headache. A study found that this form of TRT delivers a steadier dose of testosterone throughout the day without significant adverse effects, comparable to the gel.

Oral

Orally administered testosterone is ineffective in the treatment of male androgen deficiency syndromes because of extensive presystemic first-pass metabolism, primarily to inactive 17-ketosteroid, etiocholanolone and androsterone, and androstanediol metabolites in the gastrointestinal mucosa during absorption and in the liver (Fig. 45.5). Oral administration results in supraphysiological elevations of testosterone and undesirable variability of plasma concentrations. The plasma half-life of testosterone is less than 30 minutes. Generally, the amount of sex hormone binding globulin in plasma determines the distribution of testosterone between free and bound forms, and free testosterone concentrations determine the drug's half-life. Approximately 90% of a dose of testosterone is metabolized, and its metabolites are excreted in the urine primarily as glucuronide conjugates, with approximately 6% of a dose being excreted in the feces as unmetabolized testosterone. Comparative dosage ranges for testosterone and its synthetic preparations are shown in Table 45.2. Taking testosterone orally (Android, Testred) is not recommended for long-term replacement. Oral testosterone may cause an unfavorable cholesterol profile and increase your risk of blood clots and heart and liver problems.

The androgenic activity of lipophilic long-chain ester testosterone 17β-undecanoate (Android

Testocaps is not approved for use in the United States) (Fig. 45.9) has been attributed to formation of testosterone via systemic ester hydrolysis of lymphatically transported testosterone undecanoate (72). Its oral bioavailability was approximately 3%. Lymphatically transported testosterone undecanoate accounted for between 90 and 100% of the systemically available ester and that 83 and 85% of the systemically available testosterone resulted from systemic hydrolysis of lymphatically transported testosterone undecanoate. These data demonstrate that intestinal lymphatic transport of testosterone undecanoate produces increased systemic exposure of testosterone by avoiding the extensive first-pass hepatic metabolism responsible for the inactivation of testosterone after oral administration.

Testosterone also has been compressed into 75- or 200-mg testosterone pellets, which release 1 to 3 mg of testosterone/day. One to two pellets are implanted under the skin, typically in the buttocks or abdomen, through a special needle under local anesthesia. They usually are replaced every 3 to 4 months. Although the pellets have been used experimentally for approximately 15 years, the use of testosterone pellets is not approved by the U.S. Food and Drug Administration. Reportedly, the pellets offer the advantage of very consistent testosterone blood levels. Some users have reported problems with the pellets working their way out from under the skin.

Synthetic Derivatives of Testosterone

Some of the early studies with androgens included structural modifications of the naturally occurring hormones to avoid first-pass metabolism. Blocking the metabolism of the 17β-hydroxy group with substituents in the 17α-position resulted in androgens with an increased bioavailability and duration of action when given orally. The synthetic androgens include methyltestosterone and fluoxymesterone (Fig. 45.9). The long-term use of oral androgens has been related to liver cancer.

17α-Methyltestosterone

The synthesis of 17α-methyltestosterone made available a compound that was orally active (73) in daily doses between 10 and 50 mg, which is equivalent to a 400 mg oral dose of testosterone. The presence of a 17α alkyl group reduces susceptibility to hepatic oxidative metabolism, thereby increasing oral bioavailability by slowing metabolism. Following oral administration, methyltestosterone is well absorbed from the gastrointestinal tract, with a half-life of approximately 3 hours. This drug has the androgenic and anabolic activities of testosterone. Although orally active, it is more effective when administered sublingually. The alkylated oral androgens should be viewed as potentially hepatotoxic and should not be used.

Fluoxymesterone

By substituting a 9α-fluoro group onto an analog of 17α-methyltestosterone, fluoxymesterone has 20 times the anabolic and 10 times the androgenic activity of 17α-methyltestosterone (Fig. 45.9) (73). It has a mean half-life of 9 hours, and less than 5% of the drug is excreted unchanged. An adverse effect of fluoxymesterone is sodium and water retention that could lead to edema.

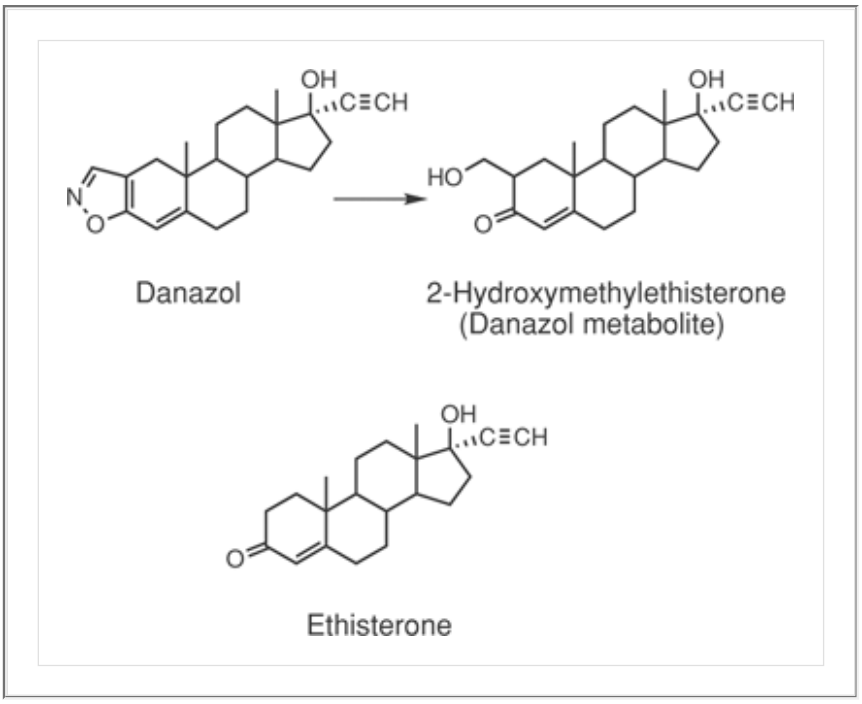
Structure–Activity Relationships of Steroidal Androgens

For a substance to have androgenic activity, it must contain a steroid skeleton (74). Oxygen functional groups normally occurring at positions 3 and 17 are not essential, because the basic nucleus, 5α-androstane, has androgenic activity (Fig. 45.1). This appears to be the minimal structural requirement for hormonal activity. For derivatives of etiocholane, in which the hydrogen is in the 5β-position, thereby affording a *cis* A/B ring juncture, no active androgens and anabolic agents are known (74). Generally, both ring expansion (to form homo derivatives by inserting a methylene group into one of the rings in the steroid nucleus) or ring contraction (by removing a methylene group) significantly reduces or destroys the androgenic and anabolic activities.

Introduction of a 3-ketone function or a 3α-OH group enhances androgenic activity. A hydroxyl group

in the 17α-position of androstane contributes no androgenic or anabolic activity; no known substituent can approach the effectiveness of a 17β-OH group. Evidence indicates that the longer-acting esters of the 17β-OH compounds are hydrolyzed in vivo to the free alcohol, which is the active species. It is thought that the 17β-oxygen atom is important for attachment to the receptor site and that 17α-alkyl groups are important for preventing metabolic changes at this position (73). Such 17α-substituents render the compounds orally active.

Increasing the length of the alkyl side chain at the 17α-position, however, resulted in decreased activity, and the incorporation of other substituents, such as the 17α-ethynyl group, produced compounds with useful progestational activity (progestins) (see Chapter 46), such as ethisterone. Attaching an isoxazole ring to ethisterone produced danazol (Danatrol, Danocrine), which exhibited potent antigonadotropic properties, weak androgen and anabolic properties, and no estrogen or progestin activity. As a gonadotropin inhibitor, danazol suppresses the surge of LH and FSH from the pituitary, thus suppressing ovarian steroidogenesis. For this reason, it is used in the treatment of endometriosis. Previous treatment of endometriosis had been surgical or medical, with progestins or a combination of estrogen and progestin. Danazol is metabolized by CYP3A4 to its inactive metabolite, 2-hydroxymethylethisterone.



Several modifications of 17α-methyltestosterone lead to potent, orally active anabolic agents. Two hydroxylated analogs include oxymesterone (Fig. 45.9) and oxymetholone (Fig. 45.10). These drugs have at least three times the anabolic and half the androgenic activity of testosterone (73).

Halogen substitution produces compounds with decreased activity except when inserted into positions 4 or 9 (e.g., fluoxymesterone). Replacement of a carbon atom in position 2 by oxygen has produced the only clinically successful heterocyclic steroid among a number of azasteroids and oxasteroids. Some of the 2-oxasteroids are potent anabolic agents.

Introduction of a sp^2 hybridized carbon atom into the A ring renders the ring more planar, and in turn, this may be responsible for greater anabolic activity. The 19-norsteroids are of interest, because these agents seem to produce a more favorable ratio of anabolic to androgenic activity. Vida (73) has extensively reviewed the replacement of various hydrogens on the androgen steroid skeleton by other functional groups. It appears that certain substitutions at positions 1, 2, 7, 17, and 18 may result in compounds with favorable activities that will be of clinical importance.

Adverse effects

Testosterone replacement therapy can have undesirable side effects depending on the type of delivery system used. The adverse effects from oral testosterone include stomach upset, headache, acne, increased hair growth on the face or body, jaundice (liver toxicity), anxiety, change in sex drive, sleeplessness, increased urination, depression, enlargement of breasts, and increased frequency and duration of erections (46). Breast enlargement can develop because testosterone can be converted to estradiol via aromatase. Other adverse effects include water retention, liver toxicity, cardiovascular disease, sleep apnea, and prostate enlargement. These risks are relatively uncommon when the dosage is closely monitored to maintain physiological plasma testosterone concentrations. Testosterone replacement therapy is contraindicated in men with carcinoma of the breast or with known or suspected carcinoma of the prostate. Therefore, pretreatment screening for any prostate dysfunction is mandatory before starting TRT.

Anabolic Agents

Because complete dissociation of anabolic and androgenic effects is not possible, many of the actions of anabolic

steroids are similar to those of androgens. Comparative dosage ranges for the anabolic steroids are shown in Table 45.2.

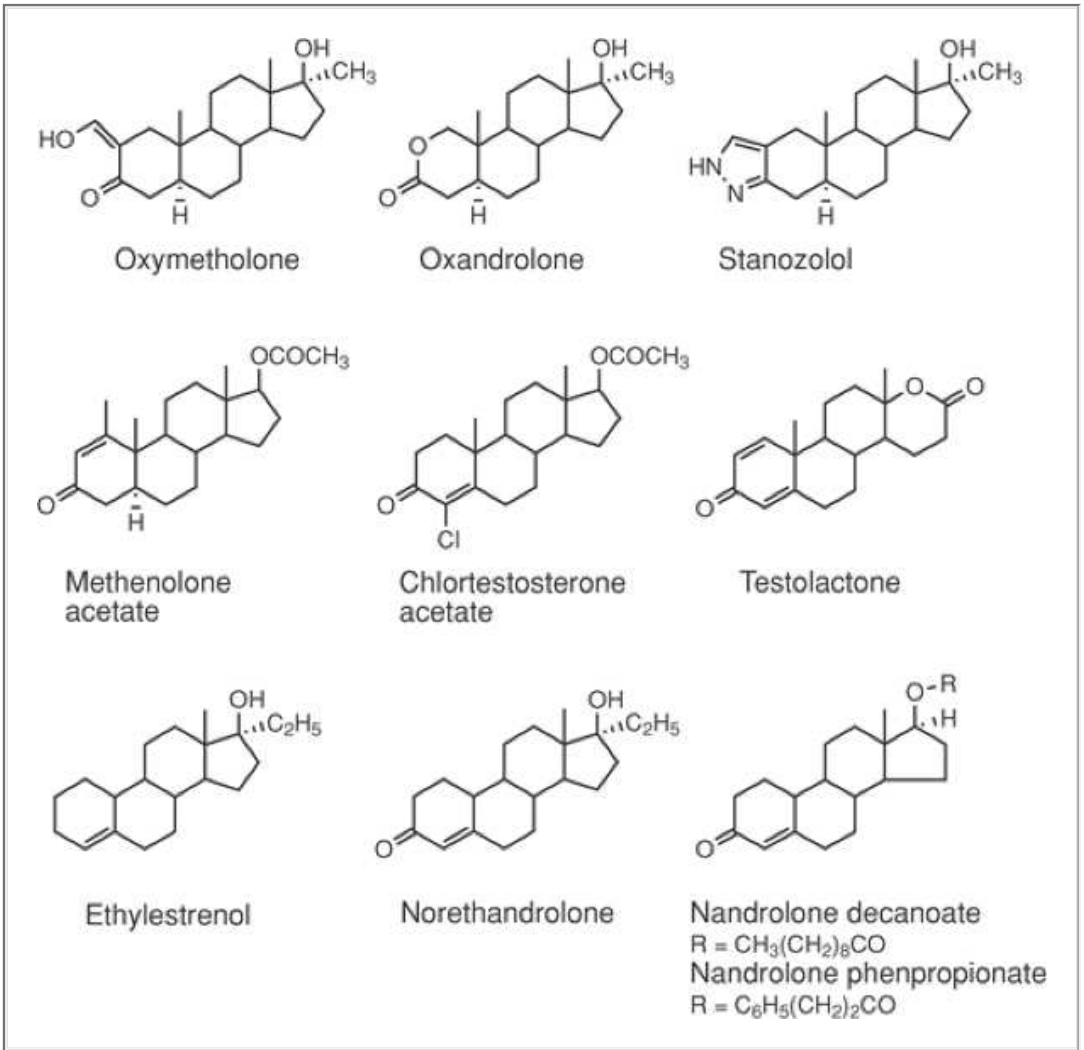


Fig. 45.10. Anabolic steroids.

Selenium dioxide dehydrogenation of 17α-methyltestosterone yields the 1,4-diene analogue, methandrostenolone, as shown in Fig. 45.10, which has several-fold the anabolic activity of the starting material. It has low androgenic activity but, apparently, can produce mammogenic effects in men. These effects are thought to result from estrogenic metabolites.

The 17α-alkylated anabolic steroids in clinical use are oxandrolone (Anavar, Oxandrin), oxymetholone (Anadrol-50), stanozolol (Winstrol), nandrolone decanoate (Deca-Durabolin, Hybolin), and phenpropionate, as shown in Figure 45.10.

A 2-oxasteroid analogue of 17α-methyltestosterone is oxandrolone, which contains a lactone in the A ring (oxygen bio-isostere of ring A) and, therefore, is susceptible to in vivo hydrolysis. It has three times the anabolic activity of 17α-methyltestosterone but exhibits slight androgenic activity (75). A pyrazole heterocyclic compound used for its anabolic effects is stanozolol (75).

The anabolic steroid oxymetholone is used primarily to stimulate production of erythropoietin in the treatment of anemias resulting from bone marrow failure.

Testolactone (Teslac), a 18-oxasteroid, is a D-homo-oxoandrostandienedione analogue, with ring D being a 6-membered lactone ring. Although testolactone possesses some anabolic activity with weak androgenic effects, it is used primarily in the treatment of breast cancer as a noncompetitive irreversible inhibitor of aromatase to suppress the formation of estrogens that would stimulate the growth of breast tissue (46). It is primarily excreted in the urine unchanged, but it is metabolized in the liver by partial reduction of the 4-ene double bond in ring A to the 5β-metabolite (*cis* A/B ring juncture). Testolactone is available in both parenteral and oral forms.

Alkylation in the 1, 2, 7, and 18 positions of the androstane molecule generally increases anabolic activity (73). One of these derivatives, methenolone acetate, is an example of a potent anabolic agent that does not have an alkyl substituent at the 17α-position. A halogenated anabolic agent used in about the same dosage is chlortestosterone acetate.

Androgens, having no methyl group in position 10 of the steroid nucleus, are an important class of anabolic agents often referred to as the 19-norandrogens, as shown in Fig. 45.10. The removal of the 19-CH_3 group of the androgen results in reduction of its androgenic properties but retention of its anabolic, tissue-building properties. These steroids can be synthesized by the Birch reduction of the aromatic A ring of a 3-methoxy estrogen to a 2,5(10)-estradiene. Cleavage of the enol ether with HCl results in the 19-nortestosterone derivative. In animal assays, 19-nortestosterone has about the same anabolic activity as the propionate ester of testosterone, but its androgenic activity is much lower. Because 19-nortestosterone showed some separation of anabolic and androgenic activities, related analogues were synthesized and biologically investigated. Two of the more potent members of the series are norethandrolone and ethylestrenol, are shown in Figure 45.10. Norethandrolone has a better ratio of anabolic to

androgenic activity than either 19-nortestosterone or 17α-methyl-19-nortestosterone does (46). Both androgenic and progestational side effects have been observed with this agent. Ethylestrenol is more potent than norethandrolone as an anabolic agent and is used in a dosage of 4 mg per day orally.

Nandrolone phenpropionate and nandrolone decanoate are esters of 19-nortestosterone, as shown in Figure 45.10, that when administered IM, slow in vivo hydrolysis of the ester occurs releasing free 19-nortestosterone over a prolonged period. Nandrolone decanoate is the longer-acting ester intended for deep IM injection, preferably into the gluteal muscle, in the treatment of anemia associated with renal insufficiency. Nandrolone phenpropionate has a shorter duration of action than the decanoate and is used in the treatment of metastatic breast cancer in women.

Abuse of Steroidal Anabolic Agents to Enhance Athletic Performance

Performance-enhancing substances are now a point of major interest for athletes, government, and news media. These substances are having a major impact on sports and the public in general. It

appears that we are headed for much greater antidoping efforts in sports. A great deal of interest has recently been shown in "designer" anabolic steroids for their high-muscle-building effects, as shown in Fig. 45.11. Tetrahydrogestrinone and desoxymethyltestosterone (DMT), as shown in Figure 45.11, brought a great deal of interest to the performance-enhancing area, because their use was very difficult to detect (77,78). Tetrahydrogestrinone is thought to have been derived from gestrinone, a substance that has been used for the treatment of a variety of gynecological disorders. Tetrahydrogestrinone also is related to trenbolone, which has been used by body builders and by ranchers to build up cattle before marketing. Before tetrahydrogestrinone, both gestrinone and trenbolone had been on the banned anabolic steroid list of the International Olympic Committee. Tetrahydrogestrinone was very difficult to trace, however, because it was unstable under the normal conditions of testing for anabolic steroids. Once a suitable assay was developed, it was possible to go back and test samples of athletes around the world, and several were found to have taken tetrahydrogestrinone.

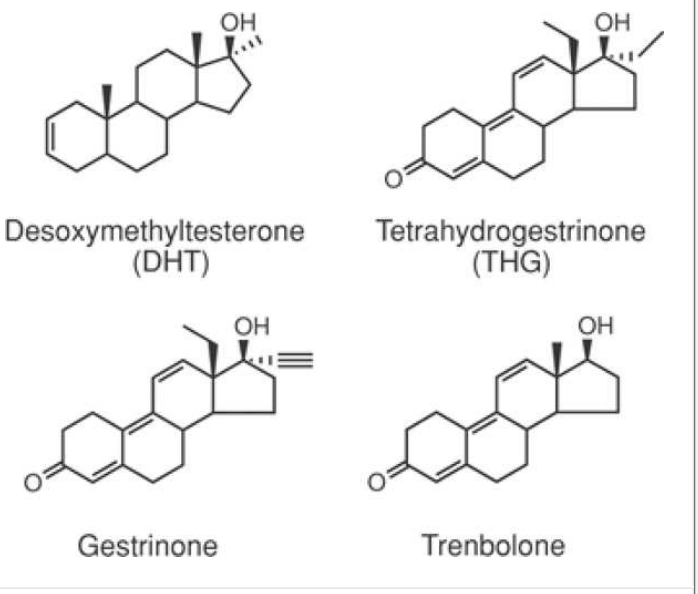

Fig. 45.11. Illegal anabolic agents.

Nonsteroidal Androgens

Selective Androgen Receptor Modulators

In the past several years, the successful marketing and clinical application of selective estrogen receptor modulators (see Chapter 46) has raised the possibility of developing selective ligands for other members of the nuclear receptor superfamily. The concept of SARMs (2,78,79) also emerged —namely, a compound that is an antagonist or weak agonist in the prostate but agonist in the bone and muscle and is orally available with low hepatotoxicity. For an ideal SARM, the antagonist or weak agonist activity in the prostate will reduce concern for the potential to stimulate nascent or undetected prostate cancer; whereas the strong agonist activity in the muscle and bone can be used to treat muscle-wasting conditions, hypogonadism, and/or aging-related frailty. Currently, research on SARMs is in its early stages—namely, preclinical discovery and the early phase of clinical development. Phase II studies planned for the next 2 to 3 years, however, should reveal the true promise of this exciting new therapeutic class of drugs.

The SARM pharmacophores can be classified into four categories: N-arylpropionamide (81,82), bicyclic hydantoin (83), tricyclic quinolines (84), and tetrahydroquinoline (85) analogs, as shown in

Figure 45.12. These nonsteroidal AR ligands are not substrates for aromatase or 5α-reductase but exhibit affinity as full AR agonists in anabolic organs (e.g., muscle and bone) or as partial AR agonists in androgenic tissues (e.g., prostate and seminal vesicles).

Structure–activity relationships for the N-arylpropionamides

The majority of published preclinical research has focused on a series of N-arylpropionamide analogues as AR agonists or partial agonists, utilizing the key structural elements of bicalutamide, an androgen antagonist (see below for a comparison of both structures) (2,81,82). A

series of chiral bicalutamide analogs, which bear electron-withdrawing groups (either a cyano or a nitro group at the 4-position and a trifluoromethyl group at the 3-position) in ring A, with a fluoro or acetylamino substituents at the para position in ring B (R_2) demonstrated high in vitro AR binding affinity and in vivo androgenicity and anabolic activity in rats (86,87). The *R*-isomer analogs which have a trifluoromethyl group instead of an Me group at the R2 position exhibited higher AR binding affinity and more potent activity than their corresponding *S*-isomers (88). The sulfide analogs (replacement of ether oxygen with sulfur) exhibited greater AR binding affinity, except that hepatic oxidation of the sulfur linkage led to rapid in vivo inactivation and reduced efficacy. Partial androgen agonist activity was observed when position 3 of ring A was substituted with a trifluoromethyl group (89). Replacing the aromatic ring A with a heterocyclic ring derivative failed to retain AR binding affinity, which probably arose from steric hinderance on binding with the AR; however, a heterocyclic B ring retained AR binding affinity. Small size electron-withdrawing moieties at R2, such as fluoro, chloro, nitro, or cyano groups, are optimum. Because aromatic nitro groups are associated with hepatotoxicity, the nitro group was replaced with a nonreducible electron-withdrawing group (i.e., a cyano group), which gave the most potent and efficacious N-arylpropionamide SARM with favorable pharmacokinetic properties. As evidenced from structure–activity relationship studies, minor differences in ligand structure can lead to either agonist or antagonist activity. Full or partial agonist binding to AR is influenced by stereoisomeric conformation as well as by steric and electronic effects of the substituents. Molecular modeling of N-arylpropionamide AR ligands was used in conjunction with pharmacology, pharmacodynamics, pharmacokinetics, and metabolism to examine and optimize structural properties.

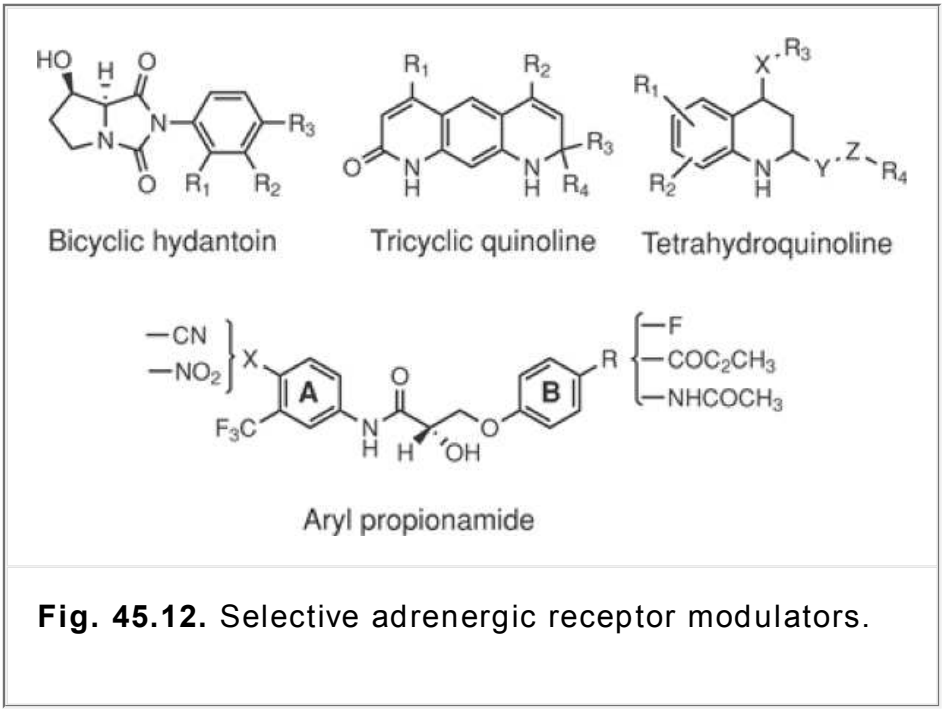

Fig. 45.12. Selective adrenergic receptor modulators.

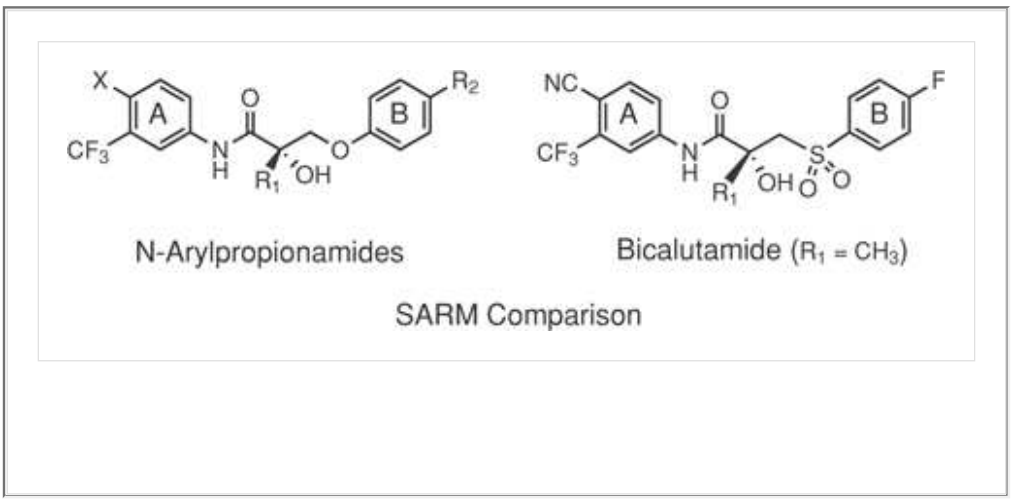

SARM Comparison

Results from in vitro and in vivo animal studies suggest that the therapeutic promise of SARMs as treatment for muscle wasting, osteoporosis, hormonal male contraception, BPH, or other conditions associated with aging or androgen deficiency—without unwanted side effects associated with testosterone—may be soon realized (2,79). The AR specificity and lack of steroidal-related side effects clearly distinguish these drugs from their steroidal predecessors and open the door for expanded clinical use of androgens. As the molecular mechanisms of action of SARMs on target tissues become more fully understood, the discovery of novel SARMs and expansion into broader therapeutic applications will be more feasible. Currently, research concerning SARMs is in preclinical discovery and the early phase of clinical development with the expectations that SARMs with the beneficial pharmacological activity of androgens without the unwanted side effects will provide individual patients who have various androgen-dependent disorders with a significantly improved quality of life.

Treatment of Prostatic Diseases

Diseases of the prostate represent some of the greatest threats to men's health. Incidence rates for BPH escalate rapidly with age, from approximately 50% of men at age 50 years to approximately 90% at age 90 years in the United States. Drugs that inhibit the metabolism of testosterone to DHT (i.e., 5α-reductase inhibitors) (90) or block urethral constriction (α_1-adrenergic receptor antagonists) (91) are used as front-line treatment for urinary obstruction associated with BPH. Surgery also commonly is performed as treatment for early-stage prostate cancer (i.e., prostatectomy) and transurethral resection of the prostate, making these some of the most common surgeries performed on men.

Prostate cancer is the most common noncutaneous cancer and remains the second leading cause of death from cancer in American men (92). Androgen receptor antagonists (i.e., antiandrogens) and LHRH (or gonadotropin-releasing hormone) analogs are routinely used for medical management of patients with early stage prostate cancer, whereas patients with advanced prostate cancer are treated with anticancer chemotherapy.

Benign Prostatic Hyperplasia

Benign prostatic hyperplasia is the noncancerous proliferation of the prostate gland. The major problem associated with BPH is lower urinary tract symptoms. Approximately 80% of men will develop BPH within their lifetime. Although the cause of BPH is not well understood, it occurs mainly in older men, and it does not develop in men whose testes were removed before puberty. As men age, the amount of active testosterone in the blood decreases, leaving a higher proportion of estrogen. Animal studies have suggested that BPH may result from the increased concentration of estrogen or DHT within the gland, which promotes cell growth (93). Men who do not produce DHT do not develop BPH (94).

The symptoms of BPH stem from obstruction of the urethra by an enlarged prostate and the gradual

loss of bladder function, which results in incomplete emptying of the bladder. The symptoms of BPH vary, but the most common symptoms involve changes or problems with urination. The typical symptoms of BPH are obstructive (e.g., poor urine stream, dribbling, and large residual urine volume) and irritative (e.g., hesitancy, increased frequency of urination, and nocturia), which can significantly

compromise the quality of life for men. The enlarging prostate increases the adrenergic tone of the prostate in patients with BPH, which results in further tightening of the urethra. When partial obstruction is present, urinary retention also can be brought on by alcohol, cold temperatures, a long period of immobility, or the ingestion of over-the-counter cold or allergy medicines that contain a sympathomimetic decongestant drug or anticholinergics.

Severe BPH can cause serious problems over time, including urinary retention and strain on the bladder, which can lead to urinary tract infections, bladder or kidney damage, bladder stones, and incontinence.

Before and during adulthood, DHT plays a critical role in determining prostate size, and multiple lines of evidence suggest the importance of DHT in the development of BPH (95,96). For instance, BPH does not develop in males with certain type 2 5α-reductase mutations or in males with very low levels of androgen because of prepubertal castration or hypopituitarism-related hypogonadism. Moreover, clinical treatment of BPH either by chemical or surgical castration or by type 2 5α-reductase inhibitor (e.g., finasteride) induces apoptosis of epithelial cells, which in turn significantly decreases the volume of the prostate (96). Recently, the role of age-dependent changes in the intraprostatic hormonal environment in the development of BPH was evaluated (90). Despite the aging-related decrease in testosterone and intraprostatic DHT production, an increased estradiol/DHT ratio was observed in the aging human prostate, which can be relevant to the development of BPH. Furthermore, estradiol is capable of inducing precancerous lesions and prostate cancer in aging dogs (97). Therefore, TRT in older men raises concern regarding acceleration of BPH and/or prostate cancer.

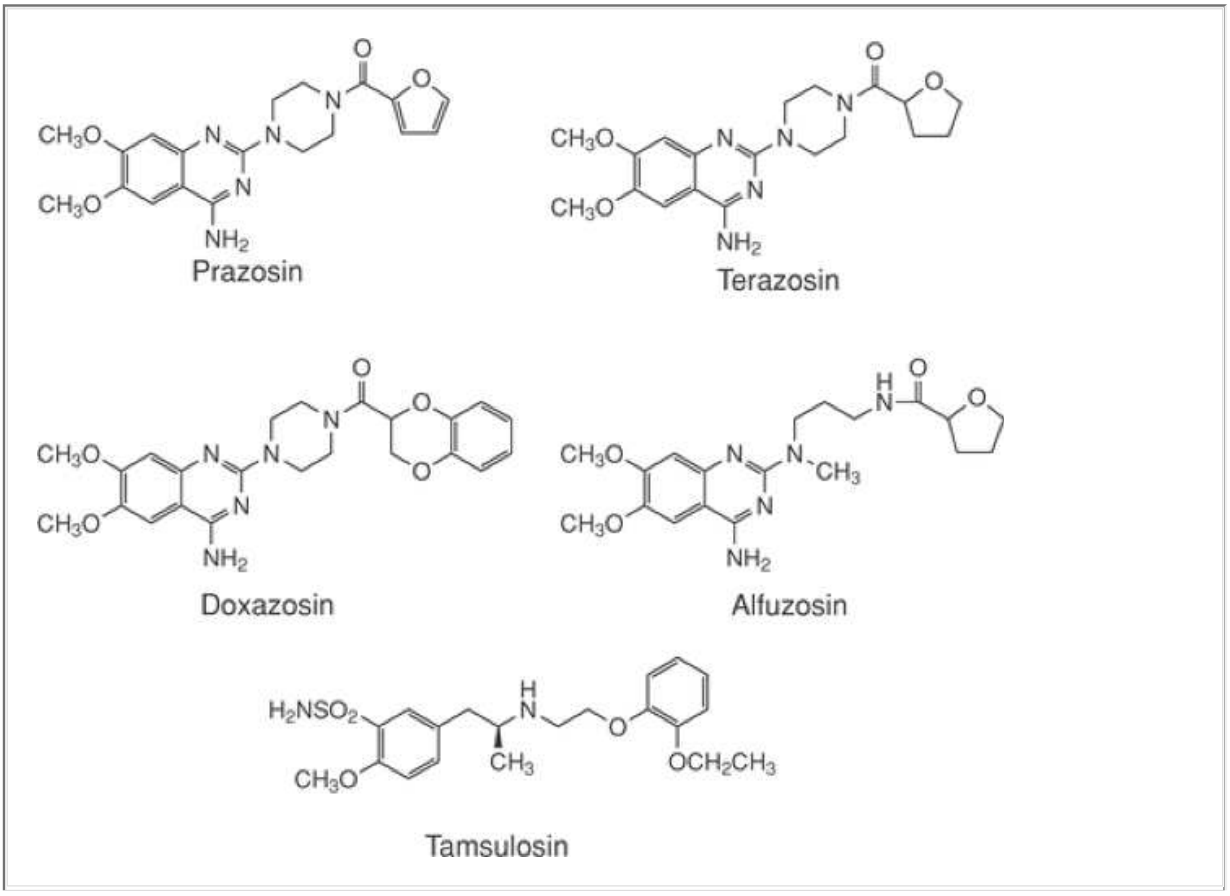

Fig. 45.13. α_1-Adrenergic antagonists for treatment of benign prostatic hyperplasia.

Surgical procedures often are used to reduce a large prostate mass, but there are early pharmacological treatments of BPH with an α_1-adrenergic blocker, a 5α-reductase inhibitor, and phytotherapy.

The α_1-adrenergic antagonists treat the increased adrenergic tone of the sympathetic nervous system by relaxing the muscles at the neck of the bladder and in the prostate, thereby reducing the pressure on the urethra and increasing the flow of urine (91). They do not cure BPH but, rather, help to alleviate some of the symptoms. Approximately 60% of men find that symptoms improve significantly within the first 2 to 3 weeks of treatment with an α_1-antagonist. In addition to alfuzosin and tamsulosin, which are the first-line α_1-adrenergic antagonists, other α_1-antagonists include doxazosin and terazosin, which also have been used to treat high blood pressure. Tamsulosin and alfuzosin are uroseletive α_1-adrenergic antagonists developed specifically to treat BPH.

The 5α-reductase inhibitors work by suppressing the production of intraprostatic DHT, thereby reducing the size of the prostate (90). Finasteride and dutasteride are the most commonly used drugs for this purpose. Unlike α_1-antagonists, 5α-reductase inhibitors are able to reverse BPH to some extent and so may delay the need for surgery. Several months of treatment may be needed before the benefit is noticed.

α_1-Adrenergic Antagonists

Mechanism of action

α_1-Adrenoceptors are widely distributed in the human body and play important

physiological roles (see Chapter 13). Of the three α_1-adrenoceptor subtypes (α_{1A}, α_{1B}, and α_{1D}), α_{1A}-adrenoceptors are expressed in prostate and urethral tissue and mediate smooth muscle contraction. The fact that a single α_{1A}-adrenoceptor subtype is found in the prostatic and urethral smooth muscle cells led to the design of drugs with uroselectivity for this receptor subtype. Thus, alfuzosin (an aminoquinazoline) and tamsulosin (an N-substituted, catecholamine-related sulfonamide) were designed for the treatment of BPH, as shown in Figure 45.13 (96). Doxazosin and terazosin, along with prazosin, originally were used as antihypertensives but also were found to be effective for the treatment of BPH based on their common mechanism of action. A comparison of the affinities (K_i, nM) of the α_{1A}-adrenoceptor antagonists (Table 45.3) did not show substantial differences for the quinazoline α_{1A}-antagonists (alfuzosin, doxazosin, and terazosin) but some uroselectivity for tamsulosin (91). Although in vitro studies showed subtype uroselectivity, in vivo studies showed that those α_{1A}-adrenoceptor antagonists without adrenoceptor subtype selectivity, such as alfuzosin and doxazosin, showed uroselectivity (terazosin was not uroselective), whereas tamsulosin, which exhibited in vitro selectivity for the α_{1A}-adrenoceptor, did not show the expected in vivo uroselectivity (99). These differences between in vitro and in vivo studies suggest that these drugs modify urethral pressures in a manner that is not correlated with their selectivity for the cloned α_{1A}-adrenoceptor subtypes. It is apparent that the existing α_{1A}-adrenoceptor antagonists have different in vivo pharmacological profiles that are not yet predictable from their receptor based on the current state of knowledge regarding the α_{1A}-adrenoceptor classification (99).

Thus, tamsulosin and alfuzosin are first-line drugs for the treatment of BPH and have no utility in treating hypertension, because they have fewer cardiovascular effects than terazosin and doxazosin. Their clinical profiles are related to their pharmacokinetic differences (Table 45.3). Improvements in urine flow occur 4 to 8 hours after the first dose and in BPH symptoms after 1 week.

Table 45.3. Some Properties and Pharmacokinetics of the α-Adrenergic Antagonists

Drug	Alfuzosin	Doxazosin	Tamsulosin	Terazosin
Trade Name	Uroxatral	Cardura	Flomax	Hytrin

Adverse reactions

In patients with BPH, the most common adverse effects for α_1-adrenergic antagonists are related to vasodilation, including dizziness, orthostatic hypotension, headache, and tachycardia, which occurred during the first 2 weeks of treatment (46). Therefore, a dose titration usually is required, especially in patients older than 60 years. These cardiovascular side effects are attributed to a nonselective blockade of α_1-adrenoceptors present in vascular smooth muscle in addition to the required blockade of α_1-adrenoceptors in prostate. No first-dose effect and fewer vasodilatory adverse events have been reported with the sustained-release formulations, which occur more frequently with the immediate-release formulation At higher doses, orthostatic hypotension occurs more frequently. The first-dose phenomenon of orthostatic hypotension and syncope has been reported occasionally in elderly patients and in those concurrently receiving calcium antagonists, diuretics, and β-blockers.

Quinazolines

Prazosin was the first selective quinazoline α_1-blocker to be discovered in the late 1960s as an antihypertensive. Alfuzosin, doxazosin, and terazosin are structurally similar (a 4-amino-6,7-dimethoxyquinazoline ring system) but differ in the attached side chain as a piperazine ring or open-chain analogue as shown in Figure 45.13. The other structural differences are the acyl groups attached to the second nitrogen of the piperazine or the aminopropyl chain. The differences in these groups afford

dramatic differences in some of the pharmacokinetic properties for these agents (see Table 45.5). Perhaps most significant are the long half-lives and durations of action for these drugs that permit once-a-day dosing and, generally, lead to increased patient compliance.

Alfuzosin is a first-line uroselective drug for the treatment of BPH, but with no utility in treating hypertension, because it has fewer cardiovascular effects than terazosin and doxazosin. Alfuzosin is hepatically metabolized by 7-O-demethylation and N-dealkylation, primarily by CYP3A4 to inactive metabolites. In patients with moderate or severe hepatic insufficiency, a reduction in clearance

resulted in a three to four times increase in its plasma concentrations, which may require a reduction in dose.

Doxazosin is primarily metabolized by 7-O-demethylation, hydroxylation of the benzdioxan ring, and oxidation of the piperazine ring to inactive metabolites. In patients with renal insufficiency, the elimination half-life was not significantly different from healthy volunteers.

Terazosin is similarly metabolized via 7-O-demethylation and N-dealkylation to four metabolites: 6- and 7-O-demethyl terazosin, the piperazine derivative of terazosin, and the diamine metabolite of the piperazine compound.

Catecholamine-Sulfonamide

Tamsulosin exhibits uroselectivity and is a first-line drug for the treatment of BPH, with no utility for treating hypertension, because of its fewer cardiovascular effects. Tamulson is O-deethylated by CYP3A4 to phenolic metabolites that are conjugated to glucuronide or sulfate before renal excretion and by O-demethylation and 3′-hydroxylation to catechol metabolites that also are conjugated with glucuronide and sulfate.

5α-Reductase Inhibitors

The development of BPH requires a combination of intraprostatic DHT and the aging process. Although not elevated in BPH, levels of DHT in the prostate remain at a physiological levels with aging despite a decrease in plasma testosterone. Adult males with genetically inherited, type 2 5α-reductase deficiency also have decreased DHT levels. These 5α-reductase–deficient males have a small prostate gland throughout life and do not develop BPH. Except for the associated urogenital defects that are present at birth, no other clinical abnormalities related to 5α-reductase deficiency have been observed in these individuals.

Mechanism of action

Inhibitors of DHT biosynthesis can result in a decrease in both circulating target-tissue DHT concentrations, thus blocking its androgenic action in these tissues. The critical enzyme targeted for DHT inhibition is 5α-reductase, which converts testosterone to DHT. The first agent to demonstrate 5α-reductase inhibition was a progestin analogue, medrogesterone (100) (Fig. 45.14). Two azasteroid-17-amide derivatives of medrogesterone have been developed as potent irreversible inhibitors of 5α-reductase and approved for the treatment of BPH: finasteride, a selective inhibitor of type 2 5α-reductase (101,102), and dutasteride, a nonselective inhibitor of type 1 and type 2 5α-reductase (103) (Fig. 45.14). Thus, the inhibition of type 2 5α-reductase suppresses the metabolism of testosterone to DHT, resulting in significant decreases in plasma and intraprostatic DHT concentrations (102,103,104).

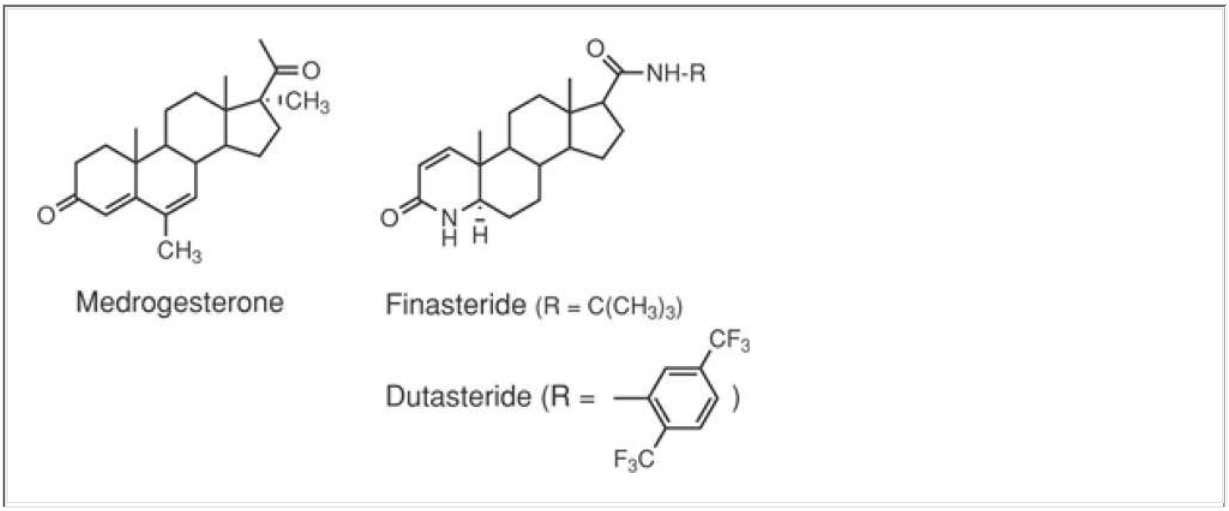

Fig. 45.14. 5α-Reductase inhibitors for the treatment of benign prostatic hyperplasia.

Finasteride and dutasteride are both mechanism-based inhibitors of type 1 and type 2 5α-reductase isoenzymes that inactivate 5α-reductase by an apparent irreversible modification of 5α-reductase (105,106). The inhibition constants (median inhibitory concentrations [IC_{50s}]) in Table 45.5 suggest that finasteride is 30 times more selective for type 2 5α-reductase, whereas dutasteride appears to be approximately 10 times more potent as an inhibitor of type 2 5α-reductase than as a inhibitor of type 1 5α-reductase. The reduction of finasteride to dihydrofinasteride proceeds through an enzyme-bound, NADP-dihydrofinasteride adduct (see Chapter 5) (105). The mechanism- based inhibition explains the exceptional potency and specificity of finasteride and dutasteride in the treatment of BPH. This concept of mechanism-based inhibition may have application to the development of other inhibitors of pyridine nucleotide–linked enzymes.

Drug interactions

Because finasteride and dutasteride are metabolized primarily by CYP3A4, the CYP3A4 inhibitors, such as ritonavir, ketoconazole, verapamil, diltiazem, cimetidine, and ciprofloxacin, may increase the drugs' blood levels and, possibly, cause drug–drug interactions. Clinical drug interaction studies have shown no pharmacokinetic or pharmacodynamic interactions between dutasteride and tamsulosin or terazosin, warfarin, digoxin, and cholestyramine.

Finasteride

The selective inhibition of the type 2 5α-reductase isozyme produces a rapid reduction in plasma DHT concentration, reaching 65% suppression within 24 hours of administering a 1-mg oral tablet (106). At steady state, finasteride suppresses DHT levels by approximately 70% in plasma and by as much as 85 to 90% in the prostate. The remaining DHT in the prostate likely is the result of type 1 5α-reductase. The mean circulating levels

of testosterone and estradiol remained within their physiological concentration range. Long-term therapy with finasteride can reduce clinical significant end points of BPH, such as acute urinary retention or surgery. Finasteride is most effective in men with large prostates. Finasteride has no affinity for the AR and no androgenic, antiandrogenic, estrogenic, antiestrogenic, or progestational effects.

Pharmacokinetics

The mean oral bioavailability of finasteride is 65%, as shown in Table 45.4, and is not affected by food (99). Approximately 90% of circulating finasteride is bound to plasma proteins. Finasteride has been found to cross the blood-brain barrier, but levels in semen were undetectable (<0.2 ng/mL). Finasteride is extensively metabolized in the liver, primarily via CYP3A4 to two major metabolites: monohydroxylation of the t-butyl side chain, which is further metabolized via an aldehyde intermediate to the second metabolite, a monocarboxylic acid (Fig. 45.15). The metabolites show approximately 20% the inhibition of finasteride for 5α-reductase. The mean terminal half-life is approximately 5 to 6 hours in men between 18 and 60 years of age and 8 hours in men older than 70 years of age. Following an oral dose of finasteride, approximately 40% of the dose was excreted in the urine as metabolites and approximately 57% in the feces. Even though the elimination rate of finasteride is decreased in the elderly, no dosage adjustment is necessary. No dosage adjustment is necessary in patients with renal insufficiency. A decrease in the urinary excretion of metabolites was observed in patients with renal impairment, but this was compensated for by

an increase in fecal excretion of metabolites. Caution should be used during administration to patients with liver function abnormalities, because finasteride is metabolized extensively in the liver.

Table 45.4. Some Properties and Pharmacokinetics of the 5α-Reductases

Drugs	Finasteride	Dutasteride
Trade Name	Proscar	Avodart
cLogPa	3.2 ± 0.4	5.6 ± 0.6

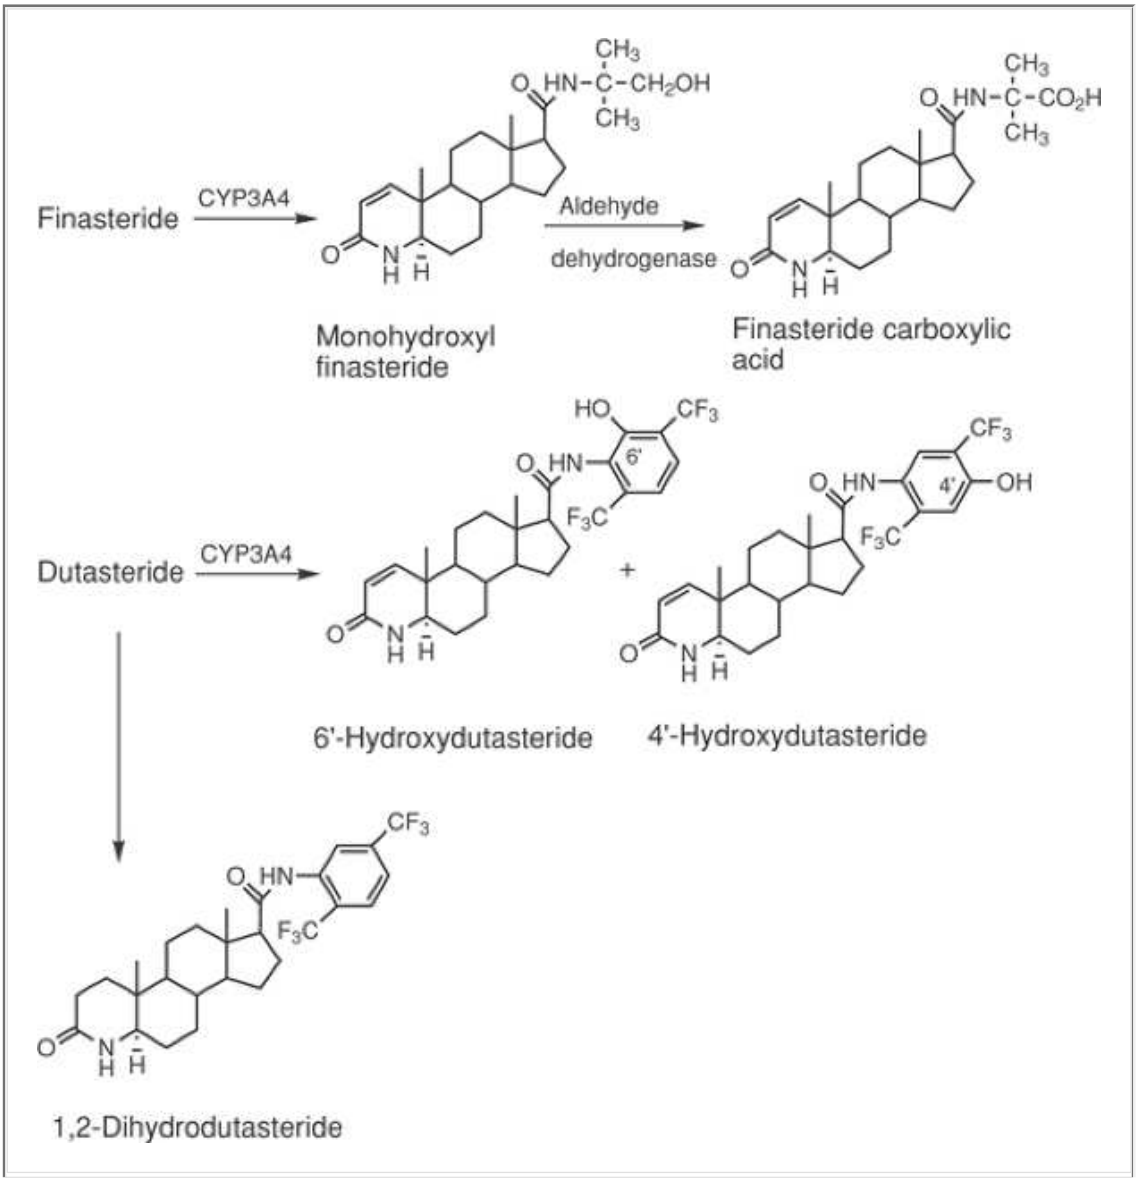

Fig. 45.15. Metabolites of finasteride and dutasteride.

Dutasteride

Similar to finasteride, dutasteride is a competitive and mechanism-based inhibitor not only of type 2 but also of type 1 5α-reductase isoenzymes, with which stable enzyme-NADP adduct complexes are formed, inhibiting the conversion of testosterone to DHT (106). The suppression of both type 1 and type 2 isoforms results in greater and more consistent reduction of plasma DHT than that observed for finasteride (107,108,109). The more effective dual inhibition of type 1 and type 2 5α-reductase isoforms lowers circulating DHT to a greater extent than with finasteride and shows advantages in treating BPH and other disease states (e.g., prostate cancer) that are DHT-dependent.

The maximum effect of 0.5 mg daily doses of dutasteride on the suppression of DHT is dose-dependent and is observed within 1 to 2 weeks. After 2 weeks of 0.5 mg daily dosing, median plasma DHT concentrations were reduced by 90%, and after 1 year, the median decrease in plasma DHT was 94% (108,109). The median increase in plasma testosterone was 19% but remained within the physiological range. The drug also reduced serum prostatic specific antigen by approximately 50% at 6 months and total prostate volume by 25% at 2 years. Dutasteride produced improvements in quality of life and peak urinary flow rate and reduction of acute urinary retention without the need for surgery. The main side effects are ED, decreased libido, gynecomastia, and ejaculation disorders. Long-term use (>4 years), however, did not reveal increased onset of sexual side effects. In addition, the combination of dutasteride and tamsulosin is well-tolerated and has the added advantage of rapid symptomatic relief.

Pharmacokinetics

Following oral administration, peak plasma concentrations of dutasteride occurs in approximately 2 to 3 hours, with a bioavailability of approximately 60% (Table 45.4), and no meaningful reduction in absorption with occurs with food (107). Dutasteride is highly bound to plasma proteins 99%. The concentrations of dutasteride in semen averaged approximately 3 ng/mL, with no significant effects of on DHT plasma levels of sex partners. Dutasteride is extensively metabolized in humans by CYP3A4 to three major metabolites: 4′-hydroxydutasteride and 1,2-dihydrodutasteride, which are less potent than parent drug, and 6′-hydroxydutasteride, which is comparable to the parent drug as an inhibitor of both Type 1 and Type 2 5α-reductases. Dutasteride and its metabolites were excreted mainly (40%) in feces as dutasteride-related metabolites. The terminal elimination half-life of dutasteride is approximately 5 weeks. Because of its long half-life, plasma concentrations remain detectable for up to 4 to 6 months after discontinuation of treatment. No dose adjustment is necessary in elderly patients, even though its half-life increased with age from approximately 170 hours in men between 20 and 49 years to 300 hours in men older than 70 years (102). No adjustment in dosage is necessary for patients with renal impairment.

Phytotherapy

A number of plant extracts are popularly used to alleviate BPH, although formal evidence that they are effective is often scanty (110). Extracts of the saw palmetto berry (*Serenoa repens*) are widely used for the treatment of BPH, often as an alternative to pharmaceutical agents. In a national survey conducted in 2002, 1.1% of the adult male population in the United States, or approximately 2.5 million males, reported using saw palmetto. The herb is widely used in Europe, where half of the German urologists prefer prescribing plant-based extracts rather than synthetic drugs. The most common nonstandardized preparation used is either the hexane-extract (Permixon®) or the ethanol or carbon dioxide extraction of the dried ripe fruit from the American dwarf saw palmetto plant (*Serenoa repens*), which is rich in fatty acids and plant sterols. The plant sterols appear to be the primary

active constituents. The U.S. Pharmacopeia states that the liposterolic extract product should contain 70 to 95% fatty acids and 0.2 to 0.5% sterols. Other substances in the extracts include polyprenic compounds and flavonoids. The usual therapeutic dose of the extracts is 320 mg daily.

Serenoa repens had been popular in the United States during the 19th century as a treatment for a variety of urogenital disorders and had been mentioned as a treatment for prostate problems as early as 1899. Research into the effects of *S. repens* in many European countries appeared to confirm a positive action on BPH. The mechanism of action for the saw palmetto is not clearly established, but the sterols may have, as one mechanism of action, the inhibition of 5α-reductase and a decrease in DHT production. Therapeutic results should be expected in 6 to 8 weeks, but clinical efficacy is observed with BPH for 6 months or longer. The liposterolic extract is largely devoid of the side effects noted for prescription BPH drugs.

Although most previous randomized trials of saw palmetto have reported small improvements in the symptoms of BPH or in urinary flow rates, these studies were limited by the small numbers of subjects enrolled, their short duration, failure to use standardized products, their failure to use standard outcome measures, and the lack of information from participants concerning how effectively the placebo was blinded. Using widely accepted outcome measures from the American Urological Association (AUA) and a matched placebo capsule, a randomized, 1-year, double-blind saw palmetto trial (funded by the National Institutes of Health National Institute on Complementary and Alternative Medicine) was performed to determine the efficacy of saw palmetto for the treatment of BPH (111) A total of 225 men aged

50 years and older with documented disease received 160 mg of a standardized saw palmetto extract twice a day or a matching-placebo capsule. Over the course of a year, the men made eight office visits and were evaluated for assessment of AUA standardized changes which induced maximal urine flow, postvoid residual urine volume, prostate size, and other health-related outcomes. In contrast to most previous studies, this study reported no significant benefit of saw palmetto on urinary symptoms in terms of objective measures of BPH over a 1-year period.

Despite the differences between these studies, the weight of evidence suggests that saw palmetto may induce mild to moderate improvements in urinary symptoms and flow measures.

Other Western herbs that have been investigated for the treatment of BPH include pumpkin seeds (*Cucurbita pepo*), nettle root (*Urtica dioica* or *Urtica urens*), bee pollen (particularly that from the rye plant), African potato (tubers of *Hypoxis rooperi*), and the African tree *Pygeum africanum*, also known as *Prunus africanum*. In most cases, but particularly with pumpkin seeds and African potato, the main active components are sterols, such as β-sitosterol, which also has been used for BPH. Triterpenoids in *Pygeum* sp. also have been proposed to be active components, potentially having the action of reducing prostate swelling. Among the Chinese herbs recommended for BPH, the iridoid glycosides may be the active components from plantago seed, catalpol from rehmannia, and morroniside from cornus (an ingredient in the rehmannia formulas). Iridoids have not been found in the Western herbal therapies for BPH and represent a potential new area for future investigation. Iridoids are the recognized active constituents of the Western herb chaste tree berry (*Vitex agnus costus*), which has been shown to reduce prolactin levels in women; elevated prolactin may be a risk factor for prostate enlargement in men. Triterpenoids found in vaccaria and alisma (an ingredient in rehmannia formulas) could contribute to their therapeutic effects in a manner similar to that suggested for pygeum.

Prostatic Cancer

Prostate cancer is the second leading cause of death in the United States and is the most commonly diagnosed cancer in American males (92). Prostate cancer is more common in African-American males, in whom it tends to be more aggressive and progressive, leading to advanced disease. The incidence of prostate cancer increases with age. Traditional treatments for prostate cancer include surgery (radical prostatectomy), radiotherapy, hormonal therapy, chemotherapy, cryosurgery (tissue

is frozen to kill cancer cells), or watchful waiting.

Ever since Huggins and Hodges won the 1966 Nobel Prize for describing the relationship between testosterone and prostate cancer, androgen deprivation has become an important component in the treatment of prostate cancer by providing what amounts to chemical castration, reducing the need for testicular surgery. Testicular surgery (bilateral orchiectomy) to prevent testosterone production was once the standard treatment for advanced prostate cancer. Although this surgery is not a cure, it may delay the advance of the disease. Refinements in the therapy have occurred since this time, including androgen deprivation with antiandrogens, 5α-reductase inhibitor combinations, intravenous bisphosphonate infusions, and chemotherapy for advanced cases. If the cancer is no longer responding to hormonal treatment, chemotherapy may be tried for advanced disease.

Because prostate cancer typically grows slowly and causes no symptoms, the prostate-specific antigen (PSA) test is most often used as a screening test for prostate cancer, although it also may be used to evaluate and manage other prostate problems. Screening tests are able to detect prostate cancer at an early stage, but it is not clear whether this earlier detection and consequent earlier treatment leads to any change in the natural history and outcome of prostate cancer. The PSA screening test cannot tell the difference between prostate cancer and other prostate problems. The PSA is a protein made by the prostate tissue. Men with prostate cancer often have elevated PSA levels, because the cancer cells make excessive amounts of this protein.

Antiandrogens (Androgen Antagonists)

Treatment for advanced prostate cancer involves the use of hormone-blocking drugs called antiandrogens. The goal of antiandrogen therapy is to block the effects of testosterone and DHT on ARs. Antiandrogens, however, are not a cure for prostate cancer. Nonsteroidal antiandrogens (Fig. 45.16), such as flutamide, nilutamide, and bicalutamide, are referred to as pure antiandrogens, because they bind exclusively to AR and, thus, are devoid of antigonadotropic, antiestrogenic, and progestational effects (112). These agents have advantages over steroidal antiandrogens, such as megesterol acetate or cyproterone acetate (Fig. 45.17), in terms of specificity, selectivity, and pharmacokinetic properties.

Antiandrogens block the binding of DHT at the AR and, when administered with an androgen, blocks or diminishes the effectiveness of androgens in androgen-sensitive tissues. Such compounds have shown potential therapeutic use in the treatment of acne, virilization in women, and hyperplasia and neoplasia of the prostate (113). Several steroidal and nonsteroidal agents have demonstrated antiandrogenic activity. Cyproterone acetate suppresses gonadotropin release and binds with high affinity to the AR (114,115). Oxendolone also acts by competing for the receptor binding sites (116). A novel AR antagonist, WIN 49,596, has been described (117) which contains a fused pyrazole ring at carbons 2 and 3 of the steroid nucleus. A potent nonsteroidal antiandrogen, flutamide, has been shown to compete with DHT for the AR (118). Its hydroxylated metabolite is a more powerful antiandrogen in vivo, and it has a higher affinity for the receptor than the parent compound (119).

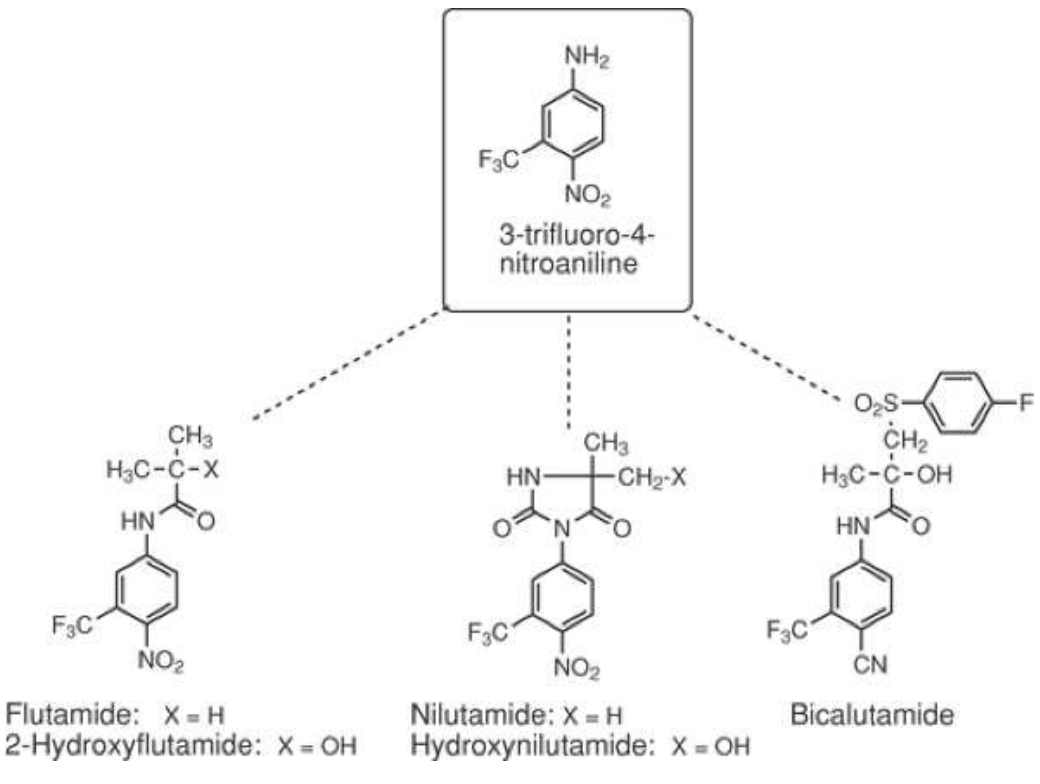

Fig. 45.16. Nonsteroidal antiandrogens.

Antiandrogens are particularly useful for the treatment of prostate cancer during its early stages. Often, however, prostate cancer advances to a "hormone-refractory" state, in which the disease progresses in the presence of continued androgen ablation or antiandrogen therapy, suggesting the development of androgen-independent prostate cancer cells or the ability of adrenal androgens to support tumor growth (as discussed above). Instances of antiandrogen withdrawal syndrome also have been reported after prolonged treatment with antiandrogens. Antiandrogen withdrawal syndrome is commonly observed clinically and is defined in terms of the tumor regression or symptomatic relief observed on cessation of antiandrogen therapy. The AR mutations that result in receptor promiscuity and the ability of these antiandrogens to exhibit agonist activity may account, at least in part, for this phenomenon. For example, hydroxyflutamide and bicalutamide act as AR agonists in AR mutants with an alanine residue at position 877 or leucine residue at position 741 (as opposed to threonine or tryptophan residues, respectively, that are present at these positions in the wild-type AR) (120,121).

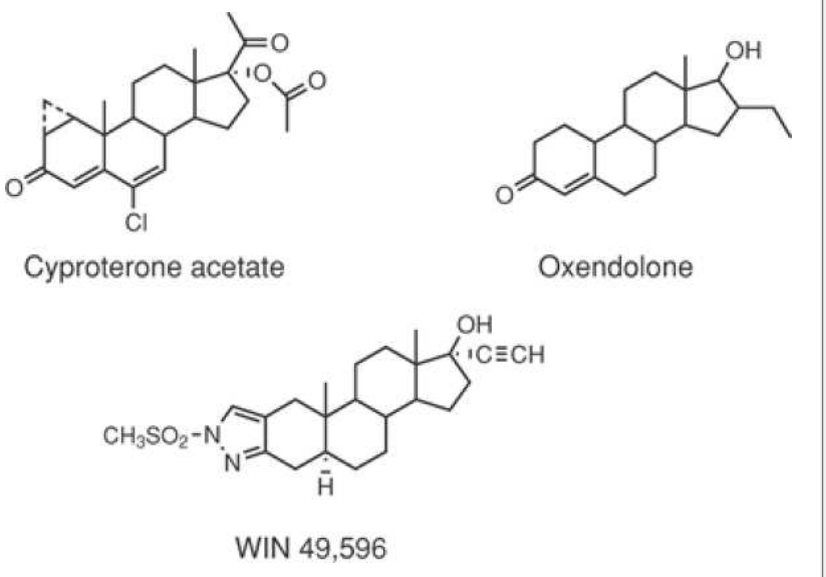

Fig. 45.17. Steroidal antiandrogens.

The search for nonsteroidal antiandrogens lead to the development of the substituted toluidides, flutamide and bicalutamide, and nilutamide, a hydantoin that is structurally related to the toluidides (Fig. 45.16). These compounds are pure antiandrogens and compete with DHT for the human prostate AR. They are used in combination with other drugs in the treatment of metastatic prostate cancer. Although these compounds possess no intrinsic hormonal activity, their antiandrogenic mechanism of action is via competitive blockade of ARs for DHT in the hormone-sensitive tumor cells of the prostate (122). As a result of this antagonism, androgen-dependent DNA and protein synthesis is inhibited, causing arrest or regression of the prostatic tumor. Because these nonsteroidal antiandrogens are metabolized extensively in the liver, they should be used with caution in patients who have liver function abnormalities.

Specific drugs

Bicalutamide

Bicalutamide is a nonsteroidal pure antiandrogen given at a dosage of 150 mg once daily as monotherapy for the treatment of early (localized or locally advanced) nonmetastatic prostate cancer (123). It also can be used at a lower dosage in combination with a LHRH analogue or surgical castration for the treatment of advanced prostate cancer. Bicalutamide is a racemate and its antiandrogenic activity resides almost exclusively in the (*R*)-enantiomer, which has an approximately fourfold higher affinity for the prostate AR than hydroxyflutamide does. The (*S*)-enantiomer has no antiandrogenic activity. (*R*)-Bicalutamide is slowly absorbed, but absorption is unaffected by food (124). It has a long plasma elimination half-life of 1 week and accumulates approximately 10 times in plasma during daily administration

(Table 45.5). (*S*)-Bicalutamide is much more rapidly absorbed and cleared from plasma. At steady state, the plasma levels of (*R*)-bicalutamide are 100 times higher than those of (*S*)-bicalutamide. Although mild to moderate hepatic impairment does not affect pharmacokinetics, evidence suggests slower elimination of (*R*)-bicalutamide in subjects with severe hepatic impairment (124). Bicalutamide metabolites are excreted almost equally in urine and feces, with little or no unchanged drug excreted in urine. Unmetabolized drug predominates in the plasma. Following oral administration, the racemate

displays stereoselective oxidative metabolism of its (*R*)-enantiomer, with an elimination half-life of approximately 6 days. (*R*)-Bicalutamide is cleared almost exclusively by CYP3A4-mediated metabolism, but glucuronidation is the predominant metabolic route for (*S*)-bicalutamide. No evidence indicates CYP3A4 induction in humans.

Table 45.5. Some Properties and Pharmacokinetics of the Antiandrogens

Drugs	Bicalutamide	Flutamide	Nilutamide
Trade Name	Casodex	Eulexin	Nilandron
cLogPa	4.9 ± 0.7	3.7 ± 0.4	3.3 ± 0.6
log D (pH 7)	4.9	3.7	3.3
Oral Bioavailability (%)	80–90	—	—
Onset of Action (weeks)b	8–12	2–4	1–2
Duration of Action	8 days	3 months to 2.5 years	1–3 months

Flutamide

Following oral administration, flutamide is completely absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism by CYP1A2 to its major metabolite, 2-hydroxyflutamide, and its hydrolysis product, 3-trifluoromethyl-4-nitroaniline (Fig. 45.16) (119). 2-Hydroxyflutamide is a more powerful antiandrogen in vivo, with higher affinity for the receptor than that of flutamide (123). 2-Hydroxyflutamide has an elimination half-life of approximately 8 hours. These studies show the principal role of CYP1A2 in the metabolism of flutamide to 2-hydroxyflutamide, with minor contribution from CYP3A4. 2-Hydroxyflutamide inhibits the metabolism of flutamide and both 2- and 4-hydroxylation of estradiol. Flutamide is a pure antagonist, whereas 2-hydroxyflutamide is a more potent AR antagonist but also can activate the androgenic receptor at higher concentrations (125). These findings raise the possibility that increased conversion of flutamide to 2-hydroxyflutamide or accumulation of 2-hydroxyflutamide in cells may contribute to the anomalous responses to flutamide that are observed in some advanced prostate cancers.

Nilutamide

Nilutamide is a hepatotoxic nitroaromatic antiandrogen used for the treatment of metastatic prostate carcinoma in men (114). It is a competitive antagonist of the AR. Nilutamide is a nitroaromatic hydantoin analog of flutamide, as shown in Figure 45.16, that is completely absorbed after oral administration, with a mean elimination half-life of approximately 50 hours (Table 45.5) (124). One of the methyl groups attached to the hydantoin ring is stereoselectively hydroxylated to a chiral metabolite, which subsequently is oxidized to its carboxylic acid metabolite. Less than 2% of nilutamide is excreted unchanged in the urine. In vitro, the nitro group of nilutamide was reduced to the amine and hydroxylamine moieties by nitric oxide (NO) synthases, a flavin monooxygenase (FMO) system (126). The therapeutic effects of nilutamide are overshadowed, however, by the occurrence of several adverse reactions mediated by toxic mechanisms, which are poorly investigated. The reduction of nilutamide is catalyzed by NO synthases via the formation of either or both a nitro anion free radical or its reduction to its hydroxylamino derivative could explain some of the toxic effects of this drug (127). Nitric oxide synthases also are involved in the formation of reactive NO and oxygen

species and in the interactions with some xenobiotic compounds.

Inhibitors of Androgen Biosynthesis

The association between lifetime exposure to testosterone and DHT and the risk of developing prostate cancer suggests chemoprevention with specific inhibitors of key enzymes associated with androgen biosynthesis (127). Two key enzymes considered for inhibition are

5α-reductase, which inhibits the formation of DHT and 17α-hydroxylase/17,20-lyase, which inhibits testosterone biosynthesis (Fig. 45.3).

5α-Reductase inhibitors

The 5α-reductase inhibitors have been discussed previously (see Benign Prostatic Hyperplasia). The results of the Prostate Cancer Prevention Trial (128) for finasteride showed a 25% relative risk reduction in prostate cancer in men aged 55 years or older, albeit at an increased risk of invasive tumors (129). The risk of invasive tumors may outweigh the benefit of these agents. The 5α-reductase inhibitors have not been proven to be effective as chemoprevention against clinically significant prostate cancer.

17α-Hydroxylase/17,20-lyase inhibitors

A second enzyme system targeted for androgen inhibition is 17α-hydroxylase/17,20-lyase, which is the key enzyme that converts pregnenolone to DHA and, subsequently, to testosterone (Fig. 45.3). Because testosterone has androgenic activity, inhibition of its biosynthesis would be useful in treating androgen-dependent diseases, such as prostate cancer (130). Inhibitors of 17α-hydroxylase/17,20-lyase inhibitors could prevent androgen biosynthesis from both testes and adrenals and may provide effective treatment of patients with prostate cancer.

The antifungal agent ketoconazole (Fig. 45.18) is an effective inhibitor of 17α-hydroxylase (IC_{50}, 76 nM), which has demonstrated the promise of 17α-hydroxylase inhibitors for the treatment of metastatic prostate cancer patients (131). The nonsteroidal imidazole agent R 75251(Liarozole) (Fig. 45.18) (132), is under development as a potentially more selective inhibitor of 17α-hydroxylase/17,20-lyase. The steroidal compounds MDL 27302 (133) as well as abiraterone (CB7598) and Sa 40 (134) (Fig. 45.18), were designed as mechanism-based inhibitors of 17α-hydroxylase/17,20-lyase. For MDL 27302, inhibition is specific to the cyclopropylamino compound, because the isopropylamino- or the cyclobutylamino-analogs were not inhibitory. Enzymatic specificity of MDL 27,302 of 17α-hydroxylase/17,20-lyase was demonstrated by its failure to inhibit steroid 21-hydroxylase and the cholesterol side-chain cleavage enzyme (CYP450scc). Both the 17α-hydroxylase and 17/20-lyase activities of human testicular microsomes were inhibited by MDL 27,302. Abiraterone and Sa 40 are heterocyclic analogues of MDL 27,302 and potent irreversible inhibitors of 17α-hydroxylase (IC50s, 4 and 24 nM, respectively) (134). Inhibition studies show that the 16,17-double bond is necessary for irreversible binding of these 17-pyridyl and 17-pyrimidyl steroids to 17α-hydroxylase. Oxidation to an epoxide probably is not involved, however, because the epoxide was a weak inhibitor (IC50, 260 nM).

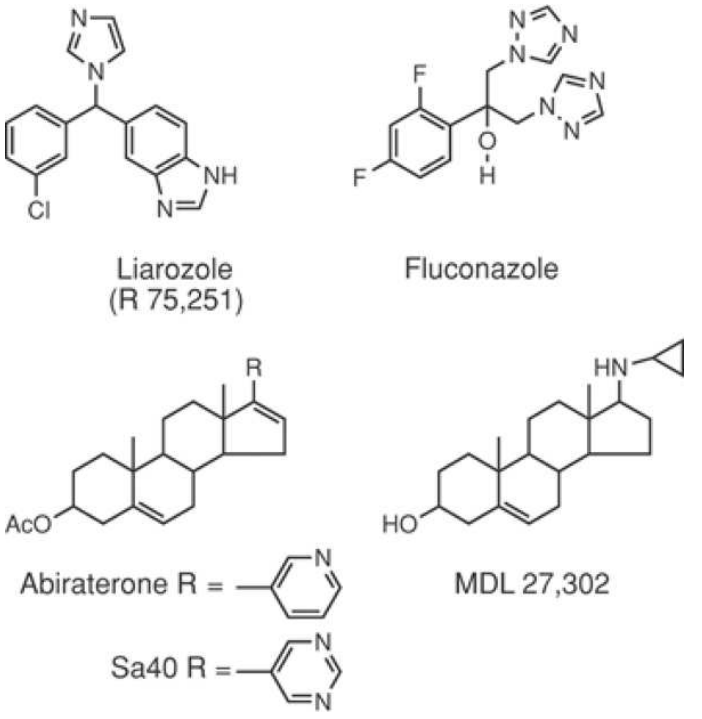

Fig. 45.18. 17-Hydroxylase/lyase inhibitors for prostate cancer.

Luteinizing hormone–releasing hormone agonists

The goal of LHRH therapy for prostate cancer is to suppress the production of testosterone in the testis and/or block its effects at its tissue receptors. Androgen deprivation using LHRH agonists (Fig. 45.19), such as leuprolide acetate (Lupron Depot), goserelin (Zoladex), and buserelin (Suprefact), suppresses the secretion of LH and, consequently, testosterone synthesis to castration levels (i.e., chemical castration) (135). The LHRH agonists significantly suppress the synthesis of intraprostatic DHT from testosterone and the size of the prostate (see the hypothalamus-pituitary-testis axis in Fig. 45.2). This effect is not immediate, however, and occurs 2 to 4 weeks after initiation of therapy. LHRH therapy slows the spread of cancerous cells and helps to alleviate or ease the symptoms associated with advanced prostate cancer. However, LHRH agonists are not cures for prostate cancer. The most common side effects associated with LHRH therapy are hot flashes, but impotence and loss of libido may also occur. Long-term use of LHRH therapy is associated with osteoporosis, decreased cognitive abilities, fatigue, and vascular stiffness. Symptoms may worsen over the first few weeks of treatment. Periodic monitoring of PSA and plasma testosterone levels is recommended. Tumor flare reactions may occur transiently but can be prevented by antiandrogens or by short-term estrogens at low dose for several weeks.

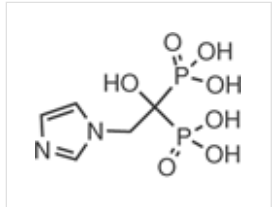
P.1292

Chemotherapy

Chemotherapy usually is reserved for patients whose prostate cancer has spread outside of the prostate gland and are no longer responsive to hormonal therapy. Chemotherapeutic drugs that can be used for prostate cancer include a combination regimen of mitoxantrone/corticosteroids or estramustane/docetaxel (Taxotere) (see Chapter 42).

Bone-Protecting Treatments

The most common site for the spread of prostate cancer is bone. Most symptoms of advanced prostate cancer are caused by the presence of disease in the bone. These symptoms can be mitigated with a drug called zoledronic acid (Zometa), a bisphosphonic acid administered by intravenous infusion that inhibits osteoclastic bone resorption, which can slow the spread of disease, reducing the development of bone pain and inhibiting bone fractures. Zoledronic acid is most commonly given to patients whose cancer is no longer responding to hormones, but it also may be given to prevent the bone thinning and weakening that results from hormonal treatments.



Treatment of Prostatitis

Prostatitis is a broad term used to identify inflammation of the prostate gland associated with lower urinary tract symptoms in men (136). Prostatitis rarely occurs in males younger than 30 years; however, it is a common problem in older males, being described as acute bacterial prostatitis, chronic bacterial prostatitis, or nonbacterial prostatitis. Because antimicrobial drug penetration generally is poor into the prostate gland, with poor efficacy of the antimicrobial agents and long duration of treatment; a 30 to 40% failure rate occurs with common treatment modalities. Three major factors determine the diffusion and concentration of antimicrobial agents in prostatic fluid and tissue: the lipid solubility of the antimicrobial agent, its dissociation constant (pK_a), and the percentage plasma protein binding. The physiological pH of human prostatic fluid is 6.5 to 6.7, but it increases in chronic prostatitis, ranging from 7.0 to 8.3 (136). A greater concentration of antimicrobial agents in the prostatic fluid occurs in the presence of a pH gradient across the membrane separating plasma from prostatic fluid. Of the available antimicrobial agents, β-lactam drugs have a low pK_a and poor lipid solubility and, thus, penetrate poorly into prostatic fluid, except for some cephalosporins. Good to excellent penetration into prostatic fluid and tissue has been demonstrated with many antimicrobial agents, including tobramycin, tetracyclines, macrolides, fluoroquinolones, sulfonamides, and nitrofurantoin. The diagnosis and therapy of prostatitis remains a challenge. Because prostatitis usually requires prolonged therapy, patients must understand the importance of compliance, and physicians should screen for drug interactions that may decrease compliance and efficacy.

Acute bacterial prostatitis is the least common of the prostate infections and, usually, is accompanied by a urinary tract infection with positive cultures. The symptoms include sudden onset of fever, chills, and low back pain, as well as complaints of urinary obstruction (e.g., dysuria, nocturia, urgency, frequency, and burning) and urinary irritation (e.g., hesitancy, straining, dribbling, weak stream, and incomplete emptying). The most commonly prescribed antimicrobials for acute bacterial prostatitis are trimethoprim–sulfamethoxazole, doxycline, and the fluoroquinolones, ciprofloxacin, ofloxacin, and norfloxacin (see Chapter 38). The concentrations of these antimicrobial agents in the prostatic fluid are two to three times that in plasma, thus achieving adequate concentrations in prostatic tissues to eradicate the most common causative pathogens. The recommended duration of treatment for acute bacterial prostatitis is 4 to 6 weeks. A short-course therapy is not recommended because of the risk of relapse or progression to chronic bacterial prostatitis.

Chronic bacterial prostatitis occurs when acute bacterial prostatitis has been inadequately treated because of pathogen resistance, relapse, or short-course therapy or because of blocked drainage of secretions from the prostate. Most men with chronic prostatitis will have had a previous bout of acute prostatitis. The most common clinical feature of chronic prostatitis is recurrent urinary tract infections and the symptoms and complaints of acute bacterial prostatitis. Fluoroquinolones, trimethoprim–sulfamethoxazole, doxycycline, and nitrofurantoin are used in the management of chronic prostatitis. Chronic prostatitis warrants at least 10 to 12 weeks of therapy. Poor clinical outcomes, however, have been observed because of poor diffusion of antimicrobials into the prostate.

Nonbacterial prostatitis is the most common type of prostatitis. It occurs more frequently than bacterial prostatitis, with the same signs and symptoms as bacterial prostatitis except that prostatic fluid cultures are negative for presence of bacteria. Inflammation is evident on prostate gland examination. Treatment includes minocycline, doxycycline, or erythromycin. Treatment duration is approximately 2 to 4 weeks.

Drugs used for Erectile Dysfunction

Phosphodiesterase Inhibitors

The currently available first- and second-generation oral PDE5 inhibitors, sildenafil, tadalafil, and vardenafil, have emerged as the first-line treatment for ED because of patient convenience, safety,

and clinical efficacy and have markedly improved the quality of life in men with ED of various etiologies. As defined by the National Institutes of Health Consensus Development Panel on Impotence in

1993, ED is the inability to achieve or maintain an erection sufficient for satisfactory sexual performance. It is estimated that 10 to 30 million men in the United States, and more than 100 million men worldwide, experience some form of ED. This condition is strongly associated with age, and according to the community-based Massachusetts Male Aging Study, the prevalence of ED in men between 40 and 70 years of age is 52%. The general classification of ED includes psychogenic ED (e.g., depression, psychological stress, relationship problems, and performance anxiety), organic ED (e.g., diabetes, hypertension, spinal cord injuries, and some medications), and mixed psychogenic and organic ED.

Treatment options for men with ED have changed significantly over the past three decades and have progressed from psychosexual therapy and penile prostheses (1970s) through revascularization, vacuum constriction devices, and intracavernosal injection therapy (1980s) to transurethral and oral drug delivery (1990s). The introduction of the first PDE5 inhibitor, sildenafil citrate (Viagra), in 1998 has revolutionized the treatment of men with ED of a broad-spectrum of etiologies and acknowledged the need for pharmacological agents in the treatment of ED (137). With the recognition of the prevalence of ED by the public and the effectiveness of agents like Viagra, there was an increase effort in the search for new agents with fewer side effects that led to the development of the second-generation PDE5 inhibitors, vardenafil and tadalafil, which have since been introduced into the world market at differing potencies and pharmacokinetics.

Mechanism of Action

The physiological mechanism to achieve penile erection is mediated via an NO/cyclic guanosine monophosphate (cGMP) pathway. During sexual stimulation, parasympathetic neurons and vascular endothelial cells release NO, which activates soluble guanylate cyclase, thereby increasing the level of cGMP in the corpus cavernosum and relaxation (vasodilation) of vascular smooth muscle. Phosphodiesterase-5 is a cGMP-specific hydrolyzing enzyme (see Chapter 17) and is present at high concentrations in the smooth muscle of the penile corpus cavernosum (138,139). One of the more effective methods for elevating cGMP levels in this tissue is to use PDE5 inhibitors. Other PDE isoenzymes also found in the human cavernous smooth muscle include PDE3 (cGMP-inhibited PDE) and PDE4 (cAMP-specific PDE). Thus, inhibitors of PDE, especially PDE5, have been shown to be an effective means for treating ED by enhancing and maintaining erections during sexual stimulation through sustaining sufficient cellular levels of cGMP in both the corpus cavernosum and the blood vessels supplying it. The increased vasodilation of the corporeal sinusoids allows more blood flow into the penis, thereby enhancing an erection.

Structure–Activity Relationships

The chemical similarities and distinct differences between sildenafil, vardenafil, and tadalafil in regarding their selectivity for the inhibition of PDE5 and other PDE isoforms and their pharmacokinetic disparities largely affect the efficacy profile of these compounds. The obvious difference for the three drugs is the heterocyclic ring systems used to mimic the purine ring of cGMP. Although the heterocyclic ring systems and the N-substituent (ethyl versus methyl) attached to the piperazine side chain (Fig. 45.20) are the only two structural differences between sildenafil and vardenafil, these differences do not explain why vardenafil has a more than 20 times greater potency than sildenafil for inhibiting PDE5. A structure–activity relationship analysis for the difference in potency between sildenafil and vardenafil revealed that the methyl/ethyl group on the piperazine moiety plays very little role in the potency difference for inhibiting PDE5, whereas the differences in the heterocyclic ring systems play a critical role in higher potency for vardenafil (140).

A comparison of the in vitro inhibition values (IC_{50s}) reveals that vardenafil is approximately 10 times more selective as an inhibitor of PDE5 than sildenafil and tadalafil (Table 45.6) (140). Furthermore,

vardenafil also was approximately four times more selective than sildenafil for the inhibition of PDE1 and PDE6, as shown by its IC_{50} selectivity ratios: a PDE5/PDE1 of 257 for valdenafil and 60 for sildenafil, and a PDE5/PDE6 of 16 for valdenafil

and 7.4 for sildenafil (Table 45.6). The low PDE5/PDE6 selectivity ratio suggests that at therapeutic doses, sildenafil is only approximately 10 times as potent for PDE5 as for PDE6, which is a retinal enzyme found in the photoreceptors of the human retina. This lower PDE5/PDE6 selectivity ratio toward PDE6 for sildenafil indicates it is more likely to inhibit PDE6, which is presumed to be the cause for color vision abnormalities observed with high doses or plasma levels of sildenafil.

Pharmacokinetics

Sildenafil, vardenafil and tadalafil have only limited oral bioavailability because of extensive presystemic metabolism in the intestine and hepatic first-pass metabolism via CYP3A isoform family (Table 45.6) (141). The three drugs are rapidly absorbed after oral administration and reach peak plasma concentrations within 30 to 60 minutes. Rapid absorption and lipophilicity are considered to be a prerequisite for their rapid onset of efficacy and sexual satisfaction. Sildenafil and vardenafil are both rapidly absorbed, but with a significant difference in their mean bioavailability of approximately 15% for vadenafil and 40% for sildenafil. The administration of a high-fat meal had no significant effect on the rate and extent of absorption of tadalafil but did decrease the rate of absorption for sildenafil and vardenafil, which is consistent with their calculated lipophilicity (Table 45.6). It remains unclear whether food has any effect on their absorption and therapeutic efficacy. They are all highly protein bound, with free plasma concentration fractions of only 4 to 6%. Although the bioavailability for tadalafil has not been reported, pharmacokinetic studies and its long duration of action suggest that it is predominately metabolized by hepatic CYP3A4 to catechol metabolites, with minimal presystemic metabolism.

The major route of elimination for the three PDE5 inhibitors is hepatic metabolism, with renal excretion of unmetabolized drug accounting for 1% or less of the elimination pathways (141). CYP3A is the major drug-metabolizing enzymes for the three PDE5 inhibitors. CYP2C9, CYP2C19, and CYP2D6, however, also contribute to the metabolism of sildenafil, and CYP2C9 contributes to the metabolism of vardenafil. Both sildenafil and vardenafil have active metabolites that reach plasma concentrations high enough to contribute to the overall efficacy and safety profile of their parent-drug molecules. Grapefruit juice increases the bioavailability of sildenafil and vardenafil as well as delays their absorption. The pharmacokinetics of sildenafil and vardenafil may become less predictable in patients who also drink grapefruit juice. Although patients usually will not be endangered by concomitant use of grapefruit juice, it seems advisable to avoid this combination, which can cause systemic vasodilatation.

The larger differences in their volumes of distribution, together with the substantial differences in their systemic clearance, result in distinct differences in their elimination half-lives: 3 to 5 hours for sildenafil and vardenafil, compared with approximately 18 hours for tadalafil.

Hepatic CYP3A and CYP2C activity has been described as being age-dependent, with reduced activity being exhibited in elderly compared to young individuals. This decrease in metabolic activity is reflected by a corresponding increase in plasma concentrations of all three PDE5 inhibitors, warranting dose reductions for sildenafil and

vardenafil in elderly patients. Similarly, ethnicity-dependent differences in the pharmacokinetics of all three PDE5 inhibitors may be expected based on known ethnic differences in CYP3A4/5 activity. Gender differences in pharmacokinetics have not been described for any of the three PDE5 inhibitors, which seems to be in agreement with the literature. Severe renal impairment resulted in an increase in plasma concentrations for all the drugs, and this warrants dose reductions for sildenafil and tadalafil in the affected patient population.

Drug Interactions

None of the three PDE5 inhibitors has been identified as CYP inhibitors, including CYP3A or CYP2C substrates. Because metabolism via CYP3A is the major elimination pathway for all three drugs (sildenafil, vardenafil, and tadalafil), all inducers and inhibitors of CYP3A activity have the potential to interfere with the elimination of these drugs. This interaction potential has been verified clinically for inducers of CYP3A activity only for rifampicin and tadalafil (141). The strong inhibitors of CYP3A4 (ritonavir, indinavir, saquinavir, erythromycin, and ketoconazole) increased the plasma levels for sildenafil, vardenafil, and tadalafil. Grapefruit juice, a selective inhibitor of CYP3A intestinal metabolism, also increased the plasma concentrations of sildenafil and vardenafil but not of tadalafil. Ritonavir, as an inhibitor of CYP3A4 and CYP2C9, increased the plasma levels for vardenafil by 50 to 300 times, most likely as a consequence of the simultaneous inhibition of both CYP3A4 and CYP2C9, the major metabolism pathways for vardenafil. The effect of ritonavir on sildenafil was much less pronounced (11 times), because other compensatory CYP-mediated metabolism pathways were still available. Ritonavir increased the plasma levels for tadalafil (CYP3A4) by approximately three times.

Adverse Effects

A number of side effects have been reported with these drugs, including nausea, cutaneous flushing, headache, and retinal effects, including a bluish haze and increased light sensitivity, and indigestion. It has been suggested that some of these side effects result from the inhibition of other PDEs, including the isoform PDE6 (141,142). The search is on for even more selective ED agents to see if additional side effects can be eliminated. If one is taking α-adrenergic blockers for high blood pressure, one should consult a physician before using the agents together (141). Other vasodilators associated with regulating the intracellular levels of cGMP, such as nitroglycerin, should not be used in combination with the PDE5 inhibitors.

Therapeutic Effects

The first line of treatment of ED is PDE5 inhibition, because the three drugs can be given orally. If the PDE5 inhibitors are not effective, then the cause may be low libido, and men should have their testosterone blood levels checked (in some instances, TRT may help to resolve ED). Other alternative drugs currently available for the treatment of ED include prostaglandin E_1, which is given by injection at the base of the penis or by suppository into the tip of the penis, as well as the α_1-adrenergic blocker and the nonselective PDE inhibitor papaverine. Apomorphine is a dopamine agonist that can be used for treating ED but, in humans, has the undesirable emetic side effect. Some selective dopamine D_4 agents are now being investigated for treatment of ED. Vacuum devices and penile implants are also available.

Specific Drugs for Erectile Dysfunction

Sildenafil

In 1998, sildenafil was the first selective PDE inhibitor to be approved and found to be effective in treating ED (137). Sildenafil has approximately one-tenth the selectivity for PDE5 as for PDE6, which is found in the photoreceptors of the human retina. In vitro metabolism studies for sildenafil have shown that the primary metabolite, N-desmethylsildenafil, and the minor metabolite, oxidative opening of the piperazine ring, are mediated by CYP3A4, CYP2C9, CYP2C19, and CYP2D6. The estimated relative contributions to clearance were 79% for CYP3A4, 20% for CYP2C9, and less than 2% for CYP2C19 and CYP2D6. These results demonstrate that CYP3A4 is the primary cytochrome mediating N-demethylation and that drugs inhibiting CYP3A4 likely impair sildenafil biotransformation and clearance. The pharmacokinetics of radiolabeled sildenafil were consistent with rapid absorption, first-pass metabolism, and primarily fecal elimination of N-demethylated metabolites. The absorption of sildenafil following oral administration was rapid (~92%), whereas the oral bioavailability was approximately 38% as a result of first-pass metabolism.

Vardenafil

Vardenafil was the second agent to be marketed and had the advantage that its onset time was not reduced by taking the medication on a full stomach (Table 45.6) (141,143). It is 30 times more potent as an inhibitor of PDE5 (mean IC_{50}, 3.9 nM) than sildenafil and 10 times more potent than tadalafil, with a greater selectivity (>1,000 times) for human PDE5 than for human PDE2, PDE3, and PDE4 and moderate selectivity (>80 times) for PDE1 (140,144) (Table 45.6). The PDE inhibitory selectivity and both the in vitro and in vivo potency of the new PDE5 inhibitor vardenafil. Vardenafil specifically inhibited the hydrolysis of cGMP by PDE5, with an IC50 of 0.7 nM (sildenafil 6.6 nM). The IC_{50} of vardenafil for PDE1 was 180 nM, for PDE6 11 nM, and for PDE2, PDE3 and PDE4 more than 1,000 nM.

Tadalafil

Tadalafil was the last agent to be released and can be taken on a full stomach without slowing the onset (Table 45.6) (141). It has a much longer duration of action, lasting up to 48 hours, compared with sildenafil and vardenafil, which last for approximately 4 hours. The

longer half-life of tadalafil results in a lengthened period of responsiveness as compared to sildenafil and vardenafil. This longer therapeutic window requires fewer time constraints for the effectiveness of tadalafil and has been interpreted as being advantageous through providing the option for more spontaneous sexual activity. Because of its long half-life, however, tadalafil, has been detected in plasma even 5 days after oral administration. This suggests the possibility of accumulation if taken regularly and in short intervals, which may result in an increased risk of side effects with the excessive use of this PDE5 inhibitor. The 3,4-methylenedioxy substitution on the phenyl ring was significant for increasing its potency as PDE5 inhibitor. Optimization of the chain on the piperazinedione ring resulted in no significant change in IC50s. Tadalafil is a highly potent PDE5 inhibitor (IC50, 5 nM), with high selectivity for PDE5 versus PDE1 through PDE4 (145). The PDE5/PDE6 selectivity ratio is 85.

Prostaglandin E_1

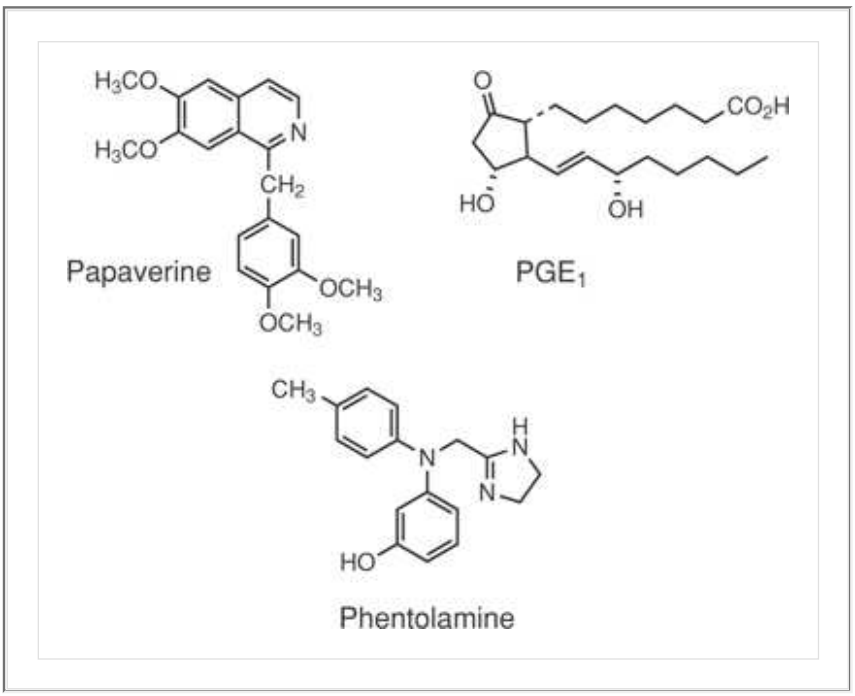
Prostaglandin E_1 (PGE1; Alprostadil) is approved for the intracavernosal (Caverject, Edex)or intraurethral suppository (Muse) treatment of ED. A three-drug combination of PGE1, papaverine, and phentolamine sometimes is used as an intracavernosal injection to achieve a synergistic action. Erectile dysfunction that is medication-induced or caused by endocrine problems, such as hypogonadism or hyper- or hypothyroidism, should be evaluated and appropriately treated before PGE1 treatment is considered. Prostaglandin E_1 is produced endogenously to relax vascular smooth

muscle and cause vasodilation by activating the adenylate cyclase/cAMP pathway. Recent studies show that the cAMP is important in the PGE1 relaxation of penile erectile tissue and vasodilation of penile resistance arteries (146). Moreover, agents that stimulate the release of cAMP also cross-activate the NO/cGMP cascade.

When administered by intracavernosal injection or as an intraurethral suppository, PGE1 acts locally to relax the smooth muscle of the corpora cavernosa and the cavernosal arteries. Swelling, elongation, and rigidity of the penis result when arterial blood rapidly flows into the corpus cavernosum to expand the lacunar spaces. The entrapped blood reduces the venous blood outflow as sinusoids compress against the tunica albuginea. Adding papaverine and phentolamine to the PGE1 regimen synergistically increases arterial blood flow via separate mechanisms. Papaverine relaxes the sinusoid and the smooth muscle of the helicine arteries, whereas phentolamine relaxes arterial smooth muscle and blocks both of the α-adrenergic receptors that inhibit an erection. Prostaglandin E_1 is rapidly metabolized within the urethra, prostate, and corpus cavernosum to 7α-hydroxy-5,11-diketotetranorprosta-1,16- dioic acid and 5α,7α-dihydroxy-11-ketotetranor-prostane-1,16-dioic acid (147). The major route of excretion of PGE1 metabolites is via the kidney. Its elimination half-life is 5 to 10 minutes. If any alprostadil is systemically absorbed, it is metabolized by a single pass through the lungs. The onset of action is within 10 minutes, and the time to peak effect is less than 20 minutes. The duration of action is 1 to 3 hours for the intracavernosal injection and 30 to 60 minutes for the intraurethral suppository.

Papaverine (intracavernosal)

Papaverine is used, sometimes in combination with phentolamine, by intracavernosal injection to facilitate erections in men with ED. In general, papaverine is most useful in patients with organic ED (neurogenic and, to a lesser extent, vascular). It is less useful in patients with ED resulting from endocrine problems (hypogonadism or hyper- or hypothyroidism) or medications. When administered by intracavernosal injection, papaverine, a weak and nonspecific PDE inhibitor, is thought to cause relaxation of the cavernous smooth muscles and vasodilation of the penile arteries by inhibition of PDE (148). These effects result in increased arterial blood flow into the corpus cavernosa and in swelling and elongation of the penis. Venous outflow also is reduced, possibly as a result of increased venous resistance. Adding phentolamine and PGE1 to the papaverine regimen synergistically increases arterial blood flow via their separate mechanisms. Papaverine is slowly released into the venous circulation with minimal systemic effects. The time to peak effect usually is within 10 minutes, and the duration of action is 1 to 6 hours with concurrent administration with phentolamine



Phentolamine (intracavernosal; Rogitine)

Phentolamine is used in combination with papaverine, by intracavernosal injection, to facilitate erections in men with impotence (see Papaverine above). Its mechanism of action is as an α-adrenergic antagonist (see Chapter 13) of both α_1- and α_2-receptors, causing vasodilation and reduction in peripheral resistance. When administered by intracavernosal injection, it is thought to cause relaxation of the cavernous smooth muscles and vasodilation of the penile arteries. This results in increased arterial

blood flow into the corpus cavernosa as well as swelling and elongation of the penis. Venous outflow also is reduced, possibly as a result of increased venous resistance. Phentolamine is slowly released into venous circulation with minimal, if any, systemic effects. Time to peak effect is within 10 minutes, and duration of action when used with papaverine is 1 to 6 hours.

Testicular Cancer

Testicular cancer develops in the testicles and, according to the National Cancer Institute (NCI), accounts only for approximately 1% of all cancers in men. Compared with prostate cancer, testicular cancer is relatively rare. It is most common among males between 15 and 40 years of age and is approximately fourfold more common in white men than in black men.

Nearly all testicular tumors originate from germ cells, the specialized sperm-forming cells within the testicles. These tumors fall into one of two types, seminomas or nonseminomas (149). Seminomas account for approximately 40 percent of all testicular cancer and are made up of immature germ cells. Seminomas are slow-growing and tend to stay localized in the testicle for long periods. Nonseminomas arise from more mature, specialized germ cells and tend to be more aggressive than seminomas. According to the American Cancer Society, 60 to 70% of patients with nonseminomas have cancer that has spread to the lymph nodes. α-Fetoprotein is a tumor-associated marker in blood for testicular cancer. Its measurement can help to show how well the chemotherapeutic drugs are working. Because seminomas are slow-growing, they tend to stay localized and usually are diagnosed at stage 1 (confined to testicle) or stage 2 (spread to lymph nodes). Treatment might be a combination of testicle removal, radiation, or chemotherapy. Most nonseminomas are not diagnosed at stage 1. Advanced testicular cancer (stage 3, metastasized to other tissues) seminomas as well as stage 2 and stage 3 nonseminomas usually are treated with multidrug chemotherapy. The majority of

cases are stage 1 when first identified; stage 3 cases are relatively rare.

Chemotherapy is the standard treatment, with or without radiation, when the cancer has spread to other parts of the body. The drugs approved to treat testicular cancer, including ifosfamide, etoposide, vinblastine, bleomycin, and cisplatin. Cisplatin usually is given in combination with bleomycin and etoposide or other chemotherapy drugs following surgery or radiation therapy. Testicular cancer has one of the highest cure rates of all cancers, essentially 100% at stage 1. Approximately 90% of men with advanced testicular cancer can be cured, according to the NCI. Because testicular cancer is curable when detected early, the NCI recommends regular monthly testicular self-examination after a hot shower, when the scrotum is looser, feeling for lumps or enlargement.

Male Osteoporosis

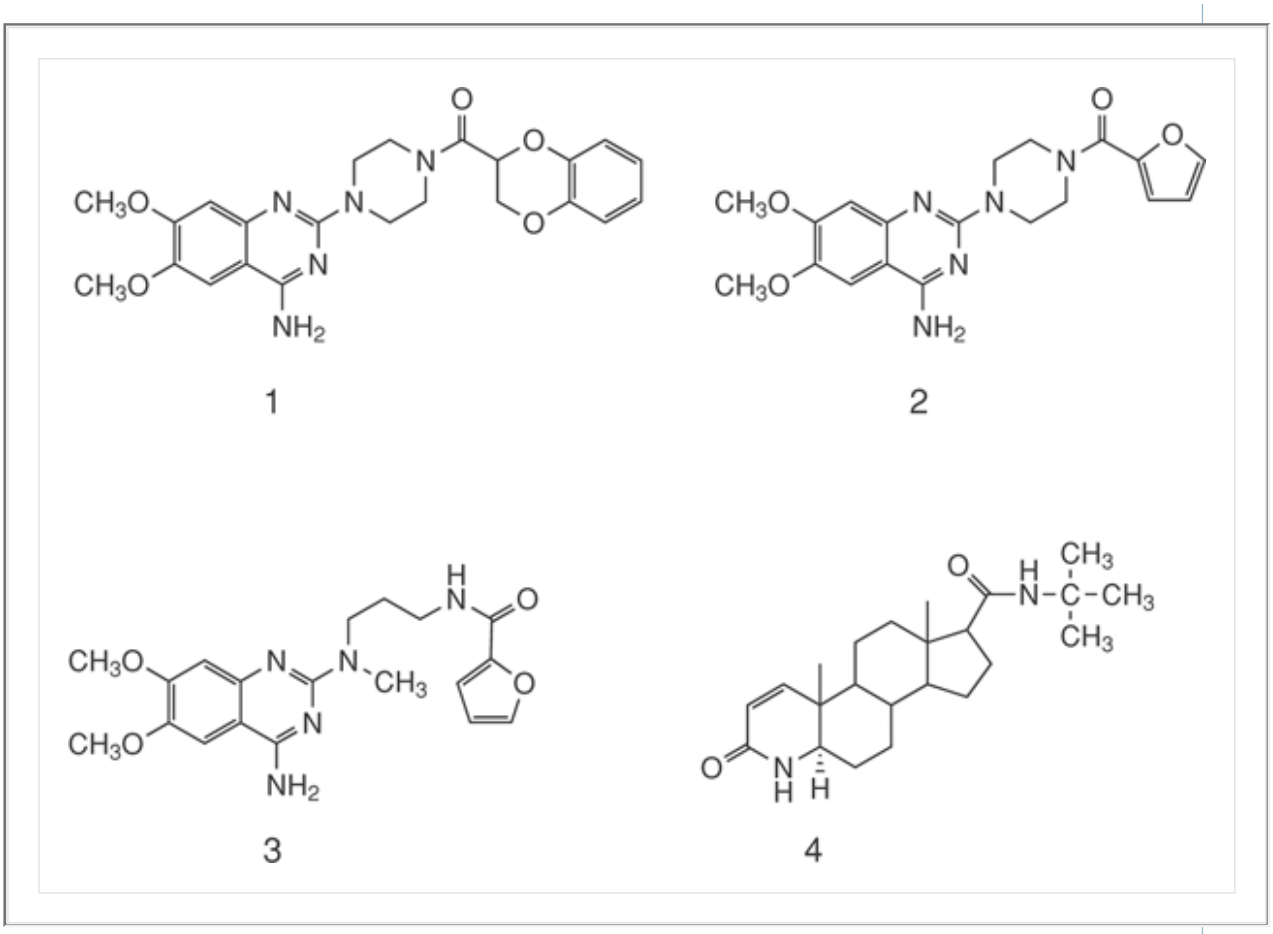
Osteoporosis is a common condition in men that usually develops after the age of 70 years and affects approximately 2 million men in the United States (150). Osteoporosis occurs less frequently in men because of greater skeletal bone mass during growth (i.e., greater bone size). Approximately 20 to 25% of all hip fractures occur in men, however, and the age-adjusted prevalence of vertebral deformities appears to be similar in men and in women. Currently, bisphosphonates (alendronate and risedronate) (see Chapter 35) are the therapy of choice for increasing bone mineral density to decrease the risk of fracture in the treatment of male osteoporosis, and a short course of parathyroid hormone (1-34; teriparatide) may be indicated for men with very low bone mineral density or for those in whom bisphosphonate therapy is unsuccessful. Antiandrogen therapy for the treatment of prostate cancer, hypogonadism, and diabetes are some of the risk factors for osteoporosis and fracture. Vitamin D and calcium have been shown to help improve bone mineral density. Testosterone replacement therapy is controversial except in men who clearly have hypogonadism and low levels of testosterone; in those men, treatment with testosterone appears to increase bone density.

Case Study

Victoria F. Roche

S. William Zito

BD is a 84-year-old white man who is spry for his age and lives with his 72-year-old wife in a small house in the rural countryside of New York State. They have several cats, and BD is allergic to cat dander and takes Dytan (diphenhydramine tannate; 50 mg every 12 hours) to control his symptoms. He reports to the ambulatory care clinic that he has had a recent onset of urinary hesitancy, a weak stream, intermittent flow, and postmicturation dribble. In addition, he complains that he has to urinate more frequently, especially during the night. BD reports that when he has to get up to urinate at night, he feels dizzy and wobbly in his rush to get to the bathroom. On further questioning, BD states that he gets dizzy every time he rises quickly from a sitting position. After examination and elimination of other conditions that could cause his symptoms (urinary tract infections, bladder cancer, or bladder stones), a diagnosis of benign prostatic hyperplasia (BPH) is made, and the physician wants to treat BD with medication. Evaluate the following choices for use in this case:



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 46

Women's Health

Robin M. Zavod

Drugs covered in this chapter:

Steroidal estrogens

- Conjugated Estrogens
- Estradiol
- Ethynyl estradiol
- Mestranol

Progestins

- Desogestrel
- Dienogest
- Drospirenone
- Elcomdetrine
- Ethisterone
- Gestodene
- Medroxyprogesterone acetate
- Megestrol acetate
- Nomogestrel acetate
- Norethindrone
- Norgestimate
- Norgestrel/Levonorgestrel
- Trimegestone

Mifepristone

Infertility drugs

- Clomiphene citrate
- Follicle Stimulating Hormone
- Gonadotropin Releasing Hormone
- Lutropin alfa

Selective estrogen receptor Modulators

- Tamoxifen
- Toremifene

Aromatase inhibitors

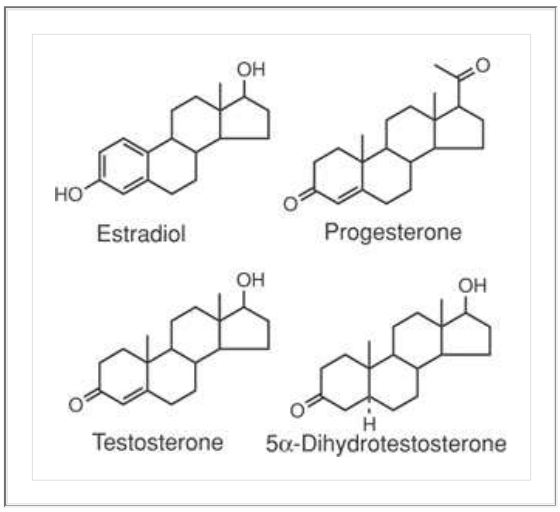
- Anastrozole
- Exemastane
- Letrozole

Fulvestrant

Introduction

The sex hormones are specific steroids necessary for reproduction as well as for the development of secondary sex characteristics in both sexes. The sex steroids are comprised of three classes—estrogens, progestins, and androgens. In this chapter, the two principal classes of female sex hormones, estrogens and progestins, will be discussed. The naturally occurring estrogens are C_{18} steroids and contain an aromatic A ring with a hydroxyl group at the 3 position. The most potent endogenous estrogen is estradiol. The naturally occurring progestins are C_{21} steroids and contain a 3-keto-4-ene structure in the A ring and a ketone at the C_{21} position. The most potent endogenous progestin is progesterone. The class of steroids that contains the male sex hormones is the androgen class. The naturally occurring androgens are C_{19} steroids and contain either a hydroxyl or ketone functional group at

both the C_3 and C_{17} positions. The primary androgen found in the blood is testosterone, with the active metabolite 5α-dihydrotestosterone formed in certain target tissues. All three classes of endogenous steroids are present in both sexes, but the production and circulating plasma levels of estrogens and progestins are substantially higher in females.



Sex Hormones: Reproductive Cycle

The female reproductive cycle is controlled by an integrated system involving the hypothalamus, anterior pituitary gland, ovary, and reproductive tract (Fig. 46.1). The hypothalamus exerts its action on the pituitary gland via the hormone signal gonadotropin-releasing hormone (GnRH). This hormone is released by the hypothalamus in a pulsatile fashion and stimulates the release of the gonadotropins, follicle stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary.

The two main gonadotropins, FSH and LH, regulate production of the sex hormones estrogen and progesterone. As the name implies, FSH promotes the initial development and growth of immature ovarian follicles, and as these follicles mature, they secrete estradiol. During the follicular phase, when estrogen levels are elevated, the endometrium undergoes proliferation as a direct result of estrogenic stimulation. As estradiol levels increase, the production of FSH decreases via feedback inhibition, and LH release is stimulated. The level of LH rises to a sharp peak (LH surge) at the midpoint of the menstrual cycle. This serves to cause the dominant follicle to rupture and release its egg (ovulation). The luteal phase follows ovulation and ends at menses. During this phase, the endometrium

shows secretory activity, and cell proliferation declines. Once ovulation has occurred, LH induces luteinization of the tissue that remains from the ruptured follicle, which leads to formation of the corpus luteum. The corpus luteum is responsible for the biosynthesis and secretion of progesterone during the luteal phase of the menstrual cycle, when endometrial preparation for pregnancy occurs, as well as during the early weeks of a pregnancy.

Clinical Significance

Women's health issues encompass a variety of disease states and range from contraception to infertility, menopause, osteoporosis, and oncology. Pharmacological agents treating these disease states are numerous and wide-ranging with regards to their use. Recent developments of drugs dealing with women's health issues not only have focused on producing better oral contraceptives but also have expanded to designing drugs for the treatment of osteoporosis, infertility, and breast cancer.

With so many medications to choose from, the clinician must be knowledgeable about the drug's pharmacodynamic, pharmacokinetic, and medicinal chemistry properties to optimize therapy. For example, with so many oral contraceptives (OCs) on the market, the clinician must apply his or her knowledge about the drug to tailor the therapy. For patients with acne, OCs with low androgenic characteristics would be appropriate. Postpartum mothers who are breastfeeding and want to start on OCs will need to use a product containing progestin only. In addition to OCs, drugs used to treat infertility must be customized to fit the patient's clinical picture. A variety of medications are used to treat infertility, ranging from clomiphene citrate, an antiestrogen, to products containing follicle-stimulating hormone.

Advancement in the treatment of bone disorders and cancer in women have resulted from the increased knowledge of estrogen receptors and the development of selective estrogen receptor modulators (SERMs). Modifications in the structure–activity relationships of SERMs produce drugs with favorable side effect profiles that are effective for osteoporosis and breast cancer. Many ongoing research investigations continue to develop drugs for treating the assortment of health care issues facing women. An essential component in both the development and the clinical applications of these drugs is the utilization of knowledge regarding the drugs' medicinal chemistry properties.

Nancy Ordonez Pharm.D.
Clinical Assistant Professor, University of Houston, College of Pharmacy

If the egg remains unfertilized, the corpus luteum degrades, and the levels of progesterone and estrogen decline. This leads to sloughing off of the endometrial lining, known as menstruation. At this point in the menstrual cycle, estrogen and progesterone levels are low, and hormonal feedback to the hypothalamus ceases. Without the influence of these hormonal signals, the hypothalamus releases additional GnRH, and the cycle begins again. A single menstrual cycle starts with the onset of menses (day 1) and ends with the start of the next menstrual period. This interval varies from 20 to 35 days, with an average length of 28 days. The major events of the ovarian cycle are summarized in Figure 46.2.

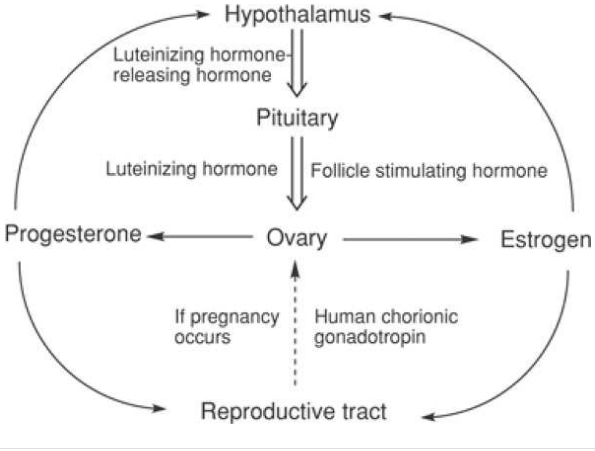


Fig. 46.1. Hypothalamic, ovarian, and reproductive tract interrelationships.

If the egg is fertilized successfully, then the menstrual cycle is interrupted because of the release of gonadotropin synthesized in the placenta, human chorionic gonadotropin (hCG). The role of this glycoprotein is to maintain the corpus luteum. Fourteen days after egg fertilization, the level of urinary hCG reaches a concentration that can be detected by a home pregnancy test. Levels of this gonadotropin peak around the seventh week of pregnancy and then decrease to a level that is maintained throughout pregnancy.

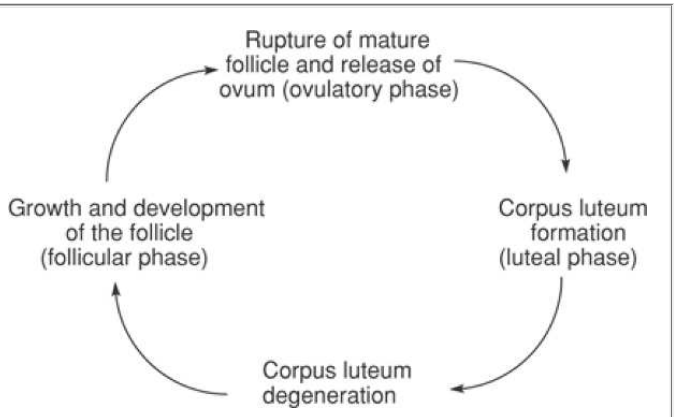

Fig. 46.2. Ovarian cycle.

Home Pregnancy Tests

With the increased availability of a variety of home diagnostic tests, the sale of home pregnancy, ovulation, and fertility tests alone was a $330 million dollar business in 2005. Home pregnancy tests have been utilized since 1976, with approximately 26 devices currently available in the United States. These tests claim that they can be utilized on the first day of a missed menstrual period (or, for certain devices, even earlier) with more than 99% diagnostic accuracy for pregnancy. Despite these claims, accurate results are obtained only a fraction of the time (Table 46.1) (1).

Home pregnancy tests are qualitative tests and simply detect the presence of the α and β subunits of hCG in a small sample of urine collected early in the day (Table 46.2) (2,3). Their detection limits range from 6.3 to 50 IU/L, and all are calibrated using regular hCG. A positive response indicates that the anti-hCG monoclonal or polyclonal antibodies found within the tests have successfully bound to a specific site along hCG. A second antibody linked to an enzyme that reacts with this anti-hCG complex causes a color change (3). What is not clear is if it is the regular hCG or the hyperglycosylated

hCG (hCG) that is the source for the immunoreactivity observed during the weeks immediately following implantation. Compelling evidence suggests that hyperglycosylated hCG may be the principle source of hCG immunoreactivity, yet the detection limits for this glycoprotein are poorer than those reported for regular hCG. Only 6 of 15 home pregnancy tests evaluated were equally capable of detecting hyperglycosylated hCG and regular hCG (2).

Table 46.1. Clinical Sensitivity Evaluation of Home Pregnancy Tests (1)

Name of Device	Confidence in Positive Results (%)	Clinical Sensitivity (%)
EPT	45	16
Clear Blue Easy	100	80
Earliest Results		
First Response	100	>95
Early Result		
Fact Plus Select	24	<16
Accu-Clear	22	<16

False-positive results can stem from recent birth, miscarriage, or the use of menotropins or hCG injections in women experiencing infertility, in whom hCG levels may still be elevated (4). Although unlikely because of the use of monoclonal antibody technology, there also may be false-positive results from pharmacological sources, including methadone, promethazine, or chlorodiazepoxide (3). False-negative results generally are a consequence of errors in using the device or in handling the urine sample.

Table 46.2. Evaluation of Home Pregnancy Tests with Regular Human Chorionic Gonadotropin (hCG) and Hyperglycosylated hCG (H-hCG) Standards (2)

	Regular hCG (IU/L)				H-hCG (IU/L)				hCG limit
Name of Device	6.3	13	25	50	6.3	13	25	50	(IU/L)

Answer	–	–	+	++	–	–	±	+	100

(–), negative result observed; (±), exceptionally faint positive result observed; (+), clear positive result observed; (++), strongly positive result observed.

For the first 9 weeks of pregnancy, the corpus luteum produces an adequate level of estrogen and progesterone to maintain the pregnancy. After this period, the placenta assumes these responsibilities. Both estrogen and progesterone levels increase during pregnancy, finally reaching their maximal concentrations a few days before labor and delivery.

Over the course of a woman's lifetime, her hormonal status and ability to reproduce vary considerably. Sexual maturation and the onset of the reproductive period are correlated with the start of cyclic menstrual bleeding. This typically occurs between the ages of 8 and 17 years (average age, 11 years). Later in life, reproductive capacity begins to wane, and women gradually lose ovarian

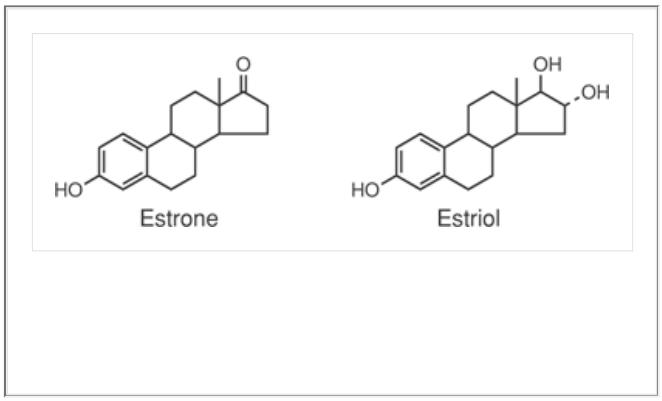
function, which causes intermittent maturation of follicles and, therefore, irregular production of the corpus luteum. This is referred to as perimenopause. Eventually, cessation of menses occurs, resulting in menopause and the loss of reproductive capacity. This typically occurs between the ages of 45 and 55 years. Throughout a woman's reproductive life cycle, various types of hormone therapy play key roles in regulating the hormone cycle. This chapter will focus primarily on hormonal therapies for the treatment and/or management of contraception, endometriosis, infertility, menopause, and breast cancer.

Steroid Hormones

Estrogens

Three endogenous estrogens are present in women. Estradiol, the most potent of the three, represents 10 to 20% of the circulating estrogen. Estrone is 10-fold less potent than estradiol and accounts for 60 to 80% of the circulating estrogen. The remaining 10 to 20% is in the

form of estriol, a very weak estrogen. Estrone was the first estrogen to be isolated in crystalline form from the urine of pregnant women. The two other C_{18} estrogen steroids, 17β-estradiol and estriol, were isolated and characterized later.



Biosynthesis

Estrogens are biosynthesized in the maturing dominant follicle and in the corpus luteum in premenopausal women. During pregnancy, the placenta becomes the primary location of estrogen biosynthesis (5,6). Approximately 50% of estrone production occurs in the ovaries. The remaining estrone is biosynthesized from estradiol as well as from the conversion of estrone sulfate to estrone in the adrenal gland and the aromatization of androstenedione. In contrast to premenopausal women, in whom the natural estrone to estradiol ratio is 1:2, postmenopausal women have an estrone to estradiol ratio of 2:1, which reflects the loss of ovarian function.

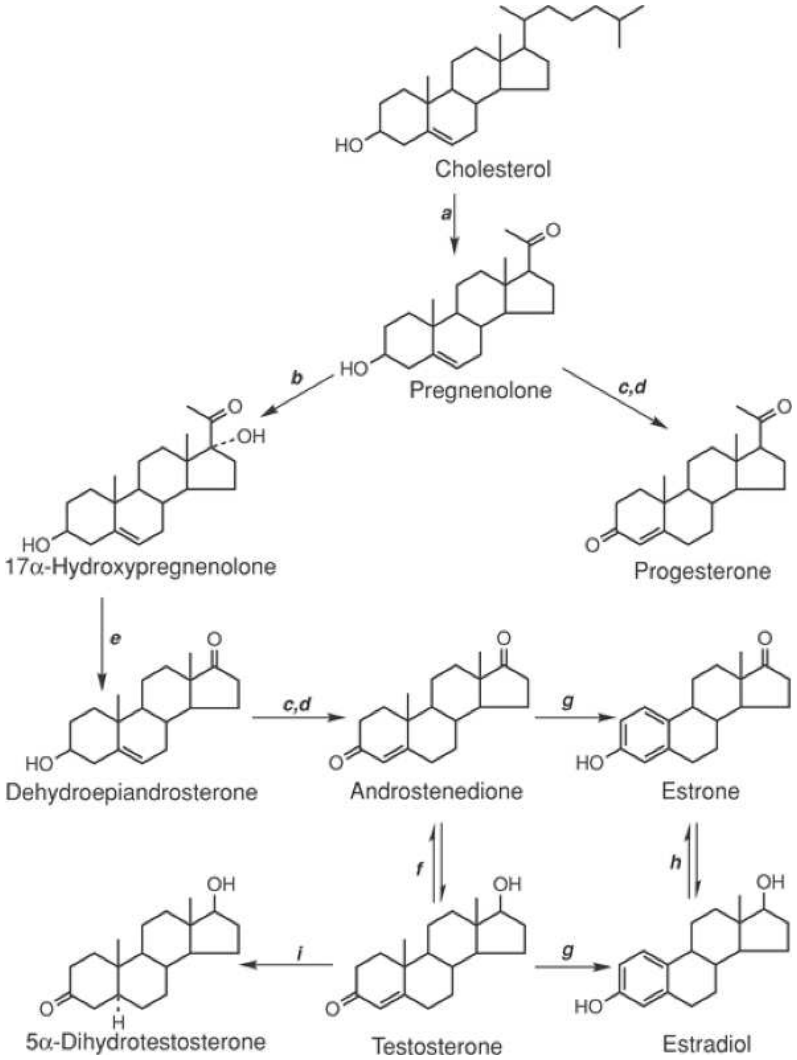


Fig. 46.3. Biosynthesis of sex steroid hormones. The enzymes involved in this biosynthesis are (a) side-chain cleavage, (b) 17α-hydroxylase, (c) 5-ene-3β-hydroxysteroid dehydrogenase, (d) 3-oxosteroid-4,5-isomerase, (e) 17,20-lyase, (f) 17β-hydroxysteroid dehydrogenase, (g) aromatase, (h) estradiol dehydrogenase, and (i) 5α-reductase.

In endocrine tissues, cholesterol is the steroid that is stored and converted to estrogen, progesterone, or androgen when the tissue is stimulated by a gonadotropic hormone. The major pathways for the biosynthesis of sex steroid hormones are summarized in Figure 46.3. In the ovary, FSH acts on the preovulatory follicle to stimulate the biosynthesis of estrogens. The thecal cells of the preovulatory follicle convert cholesterol into androgens, whereas the granulosa cells convert androgens to estrogens.

Cleavage of the side chain of cholesterol produces pregnenolone (step a in Fig. 46.3), which can then be transformed into progesterone or, via several biosynthetic

steps, to the aromatic A ring system found in estrogens (7). Pregnenolone is converted by 17α-hydroxylase to 17α-hydroxypregnenolone (step b), which then proceeds on to the intermediate dehydroepiandrosterone (DHEA) via 17,20-lyase reaction (step e) (8). DHEA is converted by 5-ene-3β-hydroxysteroid dehydrogenase and 3-oxosteroid-4,5-isomerase to the 17-ketosteroid, androstenedione (steps c and d), which is interconvertible with testosterone via 17β-hydroxysteroid dehydrogenase (step f). The final step in the biosynthesis is the conversion of the C_{19} androgens to the C_{18} estrogens via the loss of the C_{19} angular methyl group and aromatization of ring A to form 17β-estradiol or estrone (step g) catalyzed by aromatase. The interconversion of 17β-estradiol and estrone is catalyzed by estradiol dehydrogenase (step h), a member of the 17β-hydroxysteroid dehydrogenase family.

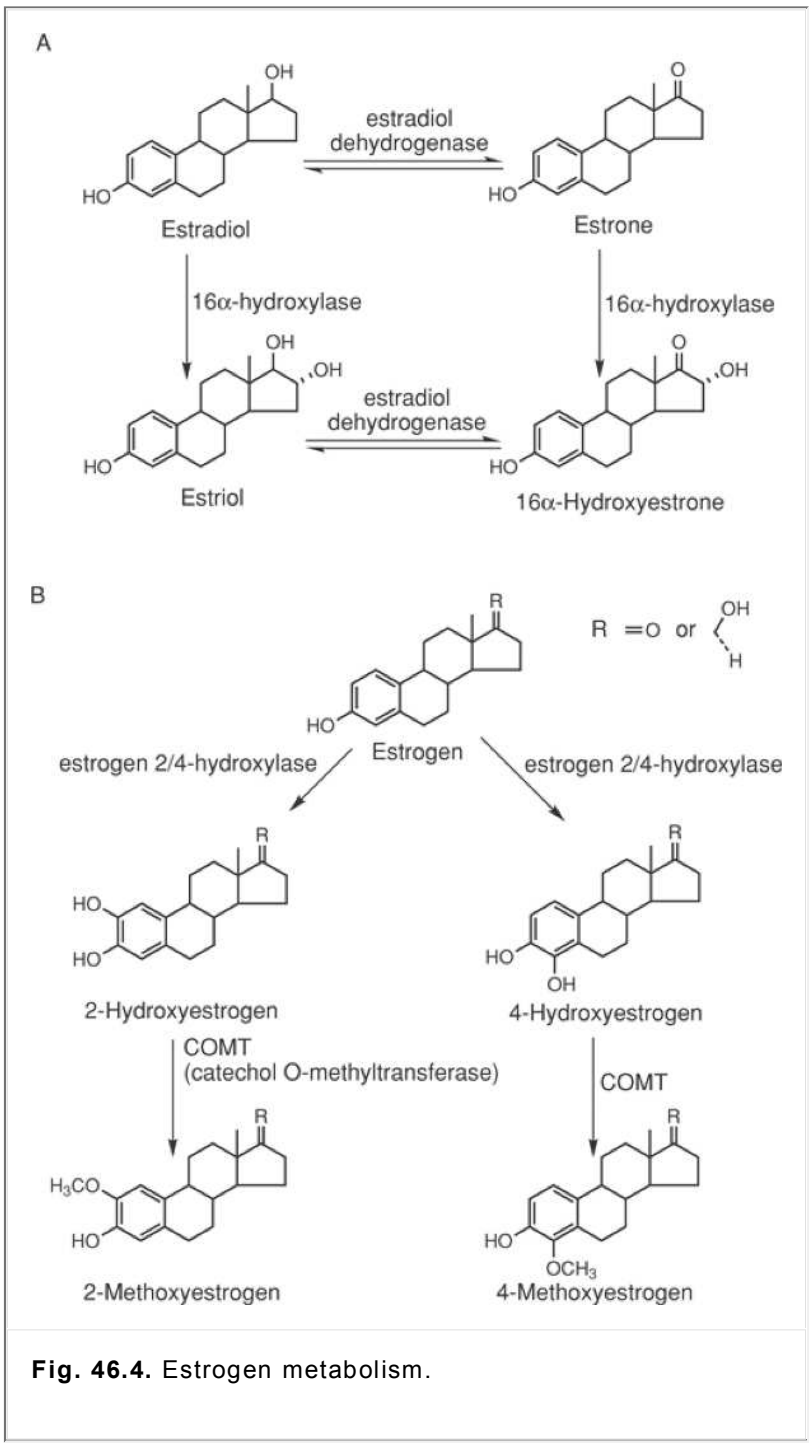

Fig. 46.4. Estrogen metabolism.

Metabolism

Metabolism of the estrogens to their water-soluble glucuronide and sulfate conjugates occurs mainly in the liver. Creation of a reservoir of estrogen occurs as a result of enterohepatic recycling, a process by which estrogens undergo desulfation followed by resulfation.

Approximately 50% of an exogenous dose of 17β-estradiol undergoes hepatic first-pass metabolism to metabolites that are readily excreted via the kidney, and the remaining 50% is found in bile fluid (9). Much of the material found in bile subsequently enters the intestine, where it is reabsorbed and returned to the liver. Only 10% of an administered dose is found in the feces (5). Both 17β-estradiol and estrone are converted by 16α-hydroxylase to yield estriol (Fig. 46.4A), which is found in the urine as the glucuronide conjugate.

Table 46.3. Estrogenic Affinity for Binding Proteins and Metabolic Clearance Rate (11,12)

Estrogen	RBA to SHBG	% Bound to SHBG	% Bound to Albumin	Metabolic Clearance Rate (litter/day/m^2)
17β Estradiol	50	37	61	580
Estrone	12	16	80	1050
Estriol	0.3	1	91	1100
Estrone sulfate	0	0	99	80
Equilin sulfate	0			175

RBA, relative binding affinity (testosterone, 100%)
SHBG, Sex hormone binding glovulin

Estrogens are metabolized by estrogen 2/4-hydroxylase (CYP3A4) at positions ortho to the 3-phenolic group to form the 2-hydroxyestrogens and the 4-hydroxyestrogens (Fig. 46.4B). The resulting catechol estrogens bind to estrogen receptors (ERs) and produce weak to moderate estrogenic effects. These metabolites are unstable in vivo, however, and are rapidly converted to their 2-methoxy and 4-methoxyestrogen metabolites as well as to their glucuronide, sulfate, and glutathione conjugates. These metabolites are found in comparatively large amounts in the urine (9,10).

Estradiol is 37% bound to sex hormone binding globulin (SHBG) and 61% bound to albumin, leaving only 2% free in circulation (Table 46.3) (11,12). The affinity of estrone and of the sulfated esters of estrone and estradiol for SHBG is less than that that of estradiol; however, they are more tightly bound to albumin than estradiol is. These proteins are vital to the transport, distribution, and metabolic clearance rate of estrogens (13). In addition, estradiol is capable of inducing the synthesis of SHBG.

Mechanism of Estrogenic Action

Molecular interactions

Estradiol plays a key role in several physiological processes, including the development of secondary sex characteristics during puberty, stimulation of the mammary glands during pregnancy, and thermoregulatory capacity. Estradiol facilitates these processes via its biological target, the ER, of which there are two subtypes (ER-α and ER-β). The two receptors differ in size: ER-α is composed of 595 amino acids, and ER-β is composed of 485 amino acids. The expression and distribution of these subtypes is inconsistent between the various tissues and organs, which may explain the wide response that is observed (11). The predominant ER in the female reproductive tract and mammary glands is ER-α, whereas ER-β is found primarily in vascular endothelial cells, bone, and male prostate tissues. Expression of both ER-α and ER-β can be regulated hormonally via estradiol. Estradiol has similar affinities for both ER-α and ER-β (Table 46.4), which is not the case for certain non-steroidal estrogenic compounds and antiestrogens (14).

Within each target cell are two receptor locations, one within the nucleus, where a genomic mechanism predominates, and a second within the cell membrane, where a nongenomic mechanism prevails. Unlike the nuclear receptors, the cell membrane receptors are coupled to G proteins that are linked to a cascade of intracellular signals. Nuclear ER-α and ER-β are virtually identical in their DNA binding sites but are only ~60% homologous in the C-terminal ligand binding domain (11,13).

When estradiol binds either ER-α or ER-β, the receptor protein is phosphorylated and undergoes a conformational change to produce either homo- or heterodimers (ER-α/ER-α, ER-β/ER-β, or ER-α/ER-β) (15). The dimeric ER complex then migrates from the cytosol to the cell nucleus, where it teams up with specific estrogen-response elements (ERE) found within an adaptor protein, typically a promoter, which aids in binding of the complex to estrogen activated genes (11,13). This complex also enlists a coactivator (CoA) complex to this promoter, which regulates DNA transcription (Fig. 46.5). Because the ER can interact with other nuclear receptors as well as with transcription factors, it is not easy to tease out all the factors that control estrogen-mediated biological responses.

Physiological effects

One of the principal actions of the estrogens is to promote the development of female secondary sex characteristics. These feminizing attributes include hair growth, skin softening, breast growth, and accumulation of fat in the thighs, hips, and buttocks. Estrogen also stimulates the growth and development of the female reproductive tract, including the uterine oviduct, cervix, and vagina.

Estrogens play a significant role in breast tissue as well. Considerable research has focused on understanding

breast cancer and the factors that influence its growth. Estrogens serve as “fuel” for hormone-dependent mammary carcinoma and cause proliferation of breast cells. They also stimulate gene expression and, therefore, the production of several proteins, including those intracellular proteins important for breast cell function and growth as well as those proteins that influence tumor growth and metastasis. Some of these intracellular proteins include the enzymes needed for DNA synthesis, such as DNA polymerase, thymidine kinase, thymidylate synthetase, and dihydrofolate reductase (16,17).

Table 46.4. Relative Binding Affinities of Endogenous and Exogenous Estrogens (14)

Estrogen	ER-α Binding Affinity	ER-β Binding Affinity
17β-estradiol	100	100
Estrone	60	37
Estrone sulfate	<1	<1
Estriol	14	21
Coumestrol	94	185
Genistein	5	36
Tamoxifen	7	6
Clomiphene	25	12
Diethylstilbestrol	468	295

ER, estrogen receptor.

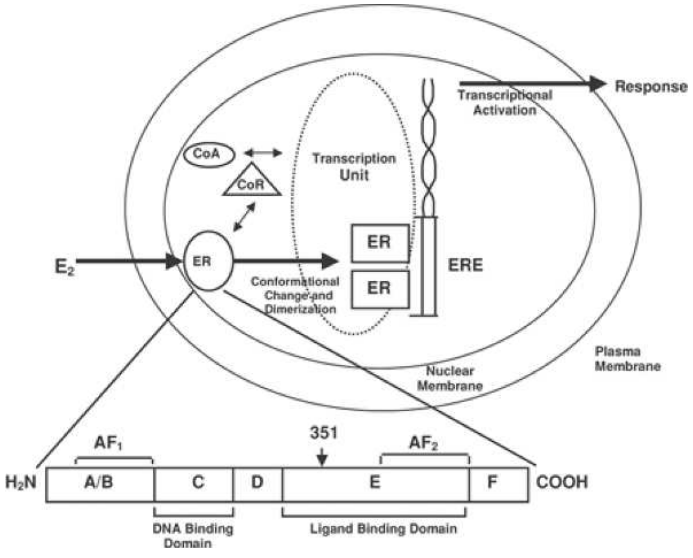

Fig. 46.5. A subcellular model of estradiol (E_2) action in a target tissue. The abbreviations used are as described in the text.

Steroidal Estrogens

Estradiol

Estradiol is the most potent endogenous estrogen, exhibiting high affinity for the ER and high potency when administered parenterally. When administered orally, estradiol is promptly conjugated in the intestine and oxidatively metabolized by the liver, resulting in its low oral bioavailability and therapeutic effectiveness.

Ethynyl estradiol and mestranol

One method to increase the oral bioavailability of estradiol is to prevent metabolic oxidation of the estradiol C_{17} hydroxyl group to estrone. This is readily accomplished via alkylation of the C_{17} position with a chemically inert alkyne group (e.g., ethynyl estradiol [EE]) (Fig. 46.6). This synthetic analogue is several hundred-fold more potent than estradiol, with doses in the microgram rather than the milligram range (Table 46.5) (18). Following oral administration, EE is rapidly and almost completely absorbed, with an oral bioavailability of approximately 40% and an elimination half-life of 26 hours (Table 46.6). Ethynyl estradiol undergoes extensive first-pass metabolism to its 3-O-glucuronide and 3-O-sulfate metabolites and, via aromatic hydroxylation, to 2–hydroxyethynylestradiol and its O-methyl metabolites. Ethynyl estradiol undergoes extensive enterohepatic recycling. The bacteria in the GI tract hydrolyze the glucuronide and sulfate conjugates, thereby permitting reabsorption of EE. It is for this reason that a number of antibacterial agents have an adverse effect on oral contraceptive (OC) efficacy.

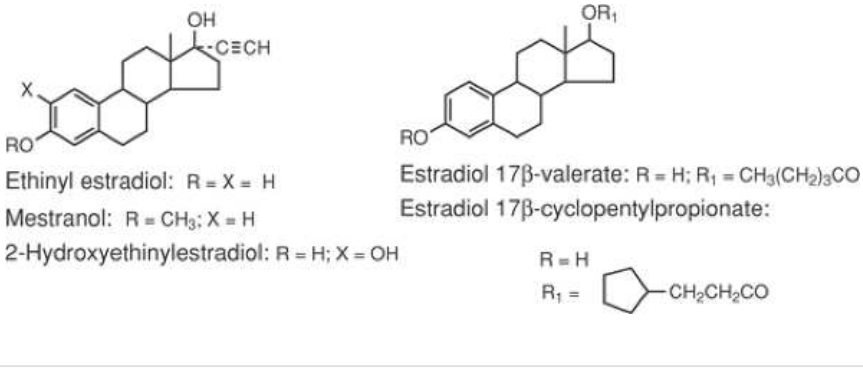

Fig. 46.6. 17α-Ethynyl estrogens and estradiol esters.

Another semisynthetic estrogen, mestranol, is the 3-O-methyl ether of EE (Fig. 46.6). Mestranol is a prodrug and, following oral administration, is rapidly metabolized to EE via hepatic O-demethylation. Mestranol and EE are used primarily in OC formulations (19).

Esters of estradiol

To deliver estrogens with a longer duration of action, 17β-estradiol must be derivatized into an ester prodrug. In contrast to the ethynyl derivatives delivered orally, these estrogen analogues usually are administered intramuscularly. Slow hydrolysis of the ester releases free estradiol over a prolonged period of time. The therapeutically useful esters of estradiol include 17β-valerate and 17β-cyclopentylpropionate (cypionate) (Fig. 46.6). Estradiol cypionate is available as a sterile solution of the drug in oil (e.g., cottonseed oil), with a duration of action of 14 to 28 days. Estradiol valerate is available as a sterile solution in a vegetable oil (e.g., sesame oil or castor oil), with a duration of action of 14 to 21 days.

Conjugated estrogens

Pregnant mares produce two unique estrogenic compounds, equilenin and equilin, that are excreted in the urine as sodium sulfate conjugates. These conjugated metabolites also are utilized as estrogen preparations (Fig. 46.7). Conjugated Estrogens USP is a mixture of the sodium salts of the sulfate esters of estradiol derived from equine urine or prepared synthetically from estrone and equilin. These preparations are composed of a mixture of sodium estrone sulfate (52.5–61.5%) and

sodium equilin sulfate (22.5–30.5%) as well as several lesser metabolites (e.g., 17α- and 17β-dihydroequilenin or 17α- and 17β-estradiol) as sodium sulfate conjugates. Esterified Estrogens USP is a blend of estrone sodium sulfate (75–85%) and sodium equilin sulfate (6–15%) (Fig. 46.7).

Table 46.5. Potencies of Orally Administered Estrogens (12,13)

Type of Estrogen	FSH suppression	Serum SHBG suppression

Piperazine estrone sulfate	1.1	1
Micronized estradiol	1.3	1
Conjugated estrogens	1.4	3.2
Ethynyl estradiol	80–200	614

FSH, follicle-stimulating hormone; SHBG, sex hormone binding globulin.

Table 46.6. Pharmacokinetic Properties for Some Estrogenic and Progestinal Agents

Drug	Proteinb binding	Oral Bioavailability	Biotransformation	Elimination half-life (hrs)	Time to peak conc. (hrs)	Peak s conc.(r

[a]USP Drug Information 2000.

[b]Sex hormone binding globulin (SHBG) synthesis is stimulated by estrogens and inhibited by androgens; as high in women as in men. cProgesterone binds strongly to cortisol binding globulin (CBG; 17.7%) and and weakly to albumin (79.3%). Absorption is the rate-limiting step for the elimination half-life of Levonorg 1.1–1.7%; SHBG, 92–62%; and albumin, 37.56%; but suppresses SHBG by 33%. Norethindrone: free, 3.5 35.5%; and albumin, 61%. Medroxyprogesterone does not bind SHBG. 3-Keto-desgestrel, 64%; albumin, Norgestimate >90% protein bound.
dA mean dose of 35 µg levonorgestrel is released daily.
ND, no data available.

Synthetic Conjugated Estrogens A is a mixture of conjugated estrogens prepared synthetically from plant sources (i.e., soy and yams) containing a mixture of 9 of the 10 known conjugated estrogenic substances present in Conjugated Estrogens USP. Synthetic Conjugated Estrogens A is a

mixture of the sodium salts of estrogen sulfates, including estrone sulfate and sodium equilin sulfate.

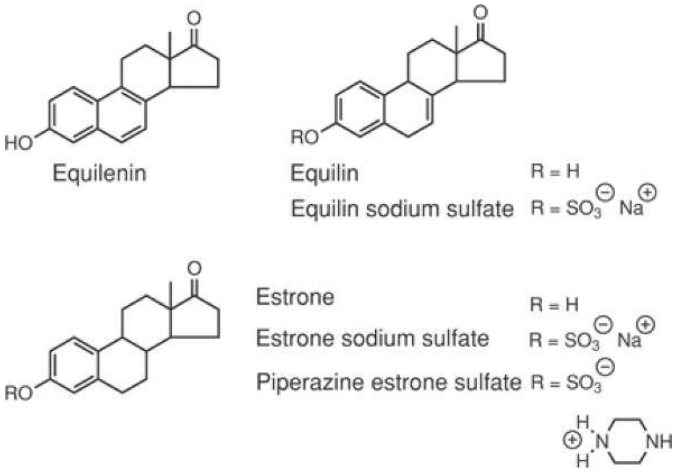

Fig. 46.7. Conjugated and esterified estrogens.

Another sulfate conjugate that is orally effective is estropipate (piperazine estrone sulfate). This derivative has the same actions and utility as the conjugated, naturally occurring estrogens.

Nonsteroidal Estrogens

Stilbene derivatives

The steroid nucleus is not required for estrogenic action. Several derivatives of stilbene (diphenylethylene) that were used therapeutically demonstrate potent estrogenic activity. Diethylstilbestrol (DES), prepared in 1939, was one of these stilbenes (Fig. 46.8). A *trans* stilbene, DES has 10-fold the estrogenic potency of its *cis* isomer, largely because the *trans* isomer more closely resembles estradiol (20). Unfortunately, when DES was administered to relieve pregnancy-related symptoms, it was correlated with abnormal growth in the offspring.

Structure–Activity Relationships

As a result of numerous studies, there is an extensive body of knowledge regarding structure–activity relationships for estrogens (21,22,23,24). The aromatic A ring and the C_3 hydroxyl group are structural features essential for estrogenic activity. The 17β-hydroxyl, the distance between the C_3 and C_{17} hydroxyl groups, and the presence of planar hydrophobic scaffolding also are important structural contributors and help to optimize estrogenic activity. Ideally, the distance between the oxygen atoms of the C_3 and C_{17} hydroxyl groups should range from 10.3 to 12.1 Å.

Substitution of the estrogen steroid nucleus can significantly modify estrogenic activity. Functionality at the C_1 position greatly reduces activity, and only small groups can be accommodated at the 2 and 4 positions. Addition of hydroxyl groups at positions 6, 7, and 11 reduces activity. Removal of the oxygen function from position 3 or 17, or epimerization of the 17β-hydroxyl group of estradiol to the α-configuration, results in an estrogenic analogue that is less active (25). The equine estrogens contain one or two additional double bonds in the steroidal B ring (equilin and equilenin, respectively) (Fig. 46.7). The presence of this unsaturation substantially boosts the estrogenic potency of these estrogens. Substituents at the 11β position are tolerated; for example, 11β-methoxy or 11β-ethyl has significantly greater affinity for the ER as compared to estradiol.

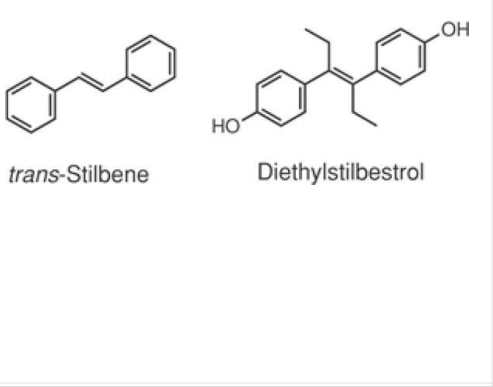

Fig. 46.8. Nonsteroidal estrogens.

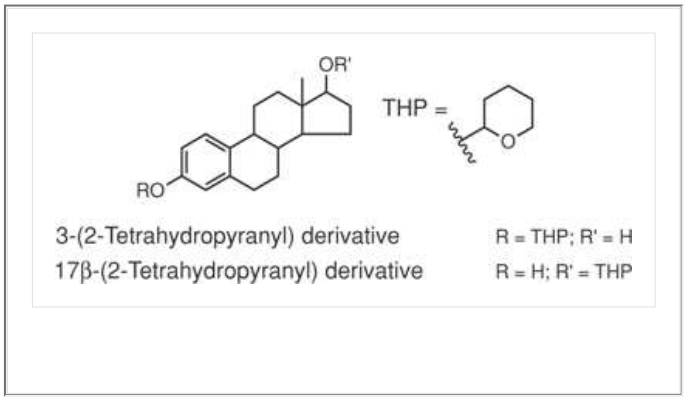
Certain modifications at the 17α and 16 positions can lead to enhanced activity. For example, the 17α-ethynyl or 17α-vinyl groups provide the greatest activity, whereas highly polar substituents at this position are poorly tolerated. At the 16 position, moderate size and polarity are tolerated. Enlargement of the D ring (i.e., D-homoestradiol) greatly reduces estrogenic activity.

Pharmacokinetics

The bioavailability observed varies with the route of estrogen administration. When administered subcutaneously, the order of bioavailability of the three naturally occurring steroids is estradiol > estrone > estriol. When administered orally, this order changes to estriol > estradiol > estrone (26). Although all three of these estrogens demonstrate at least minimal bioavailability when administered orally, chemical modifications have led to estrogen analogues with improved oral activity. For example, EE is a more effective oral estrogen because of its resistance to metabolism in the gastrointestinal tract and in the liver. Other types of highly active, orally bioavailable estrogen analogues include those with a labile ether (e.g., 3-(2-tetrahydropyranyl) and 17β-(2-tetrahydropyranyl) estradiol) (27). These drugs proved to be 12- and 15-fold as active, respectively, as estradiol.



Estrogen Antagonists

Agents that antagonize the actions of estrogens are of particular interest for their contraceptive utility and for the treatment of estrogen-dependent breast cancer. There are three classes of agents that either interfere with estrogen activation of its receptor (e.g., impeded estrogens or triphenylethylene antiestrogens) or limit estrogen biosynthesis (e.g., inhibitors of aromatase).

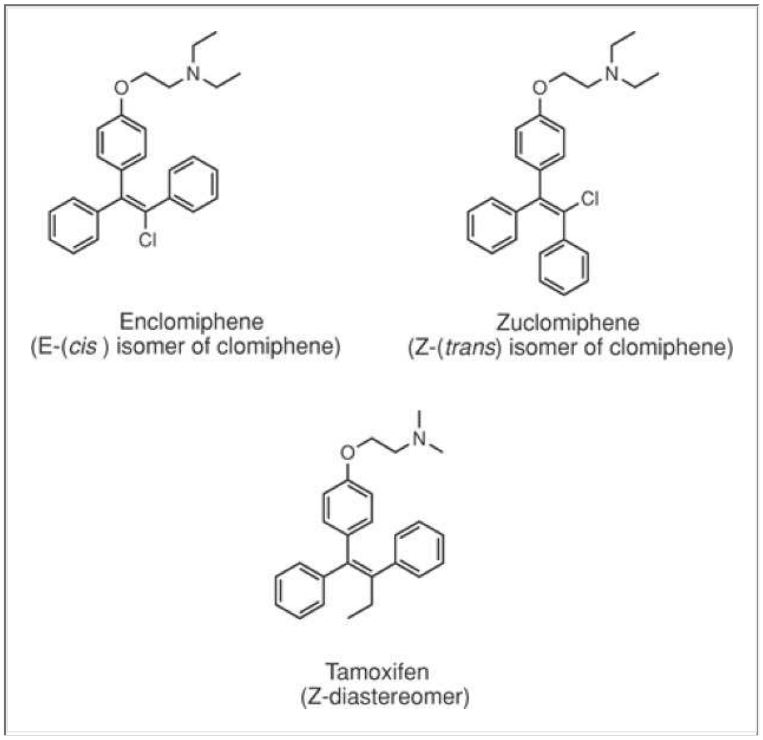


Fig. 46.9. Antiestrogens—triphenylethylene analogues.

Impeded estrogens

The impeded estrogens (e.g., estriol) interact with the ER in target tissues but dissociate from the receptor too rapidly to produce a significant estrogenic effect. If, however, the impeded estrogens are present in a high enough local concentration, they will compete with or impede estradiol access to its receptor site, thereby reducing the effect of estradiol on the cell (5,28).

Antiestrogens—triphenylethylene analogues

The triphenylethylene antiestrogens (Fig. 46.9) are structurally related to the stilbene family of estrogens and exhibit high affinity for the ER. They prevent translocation of the estrogen–receptor complex into the nucleus of target cells and interfere with the binding of the receptor–hormone complex to the acceptor site of the chromatin (29,30).

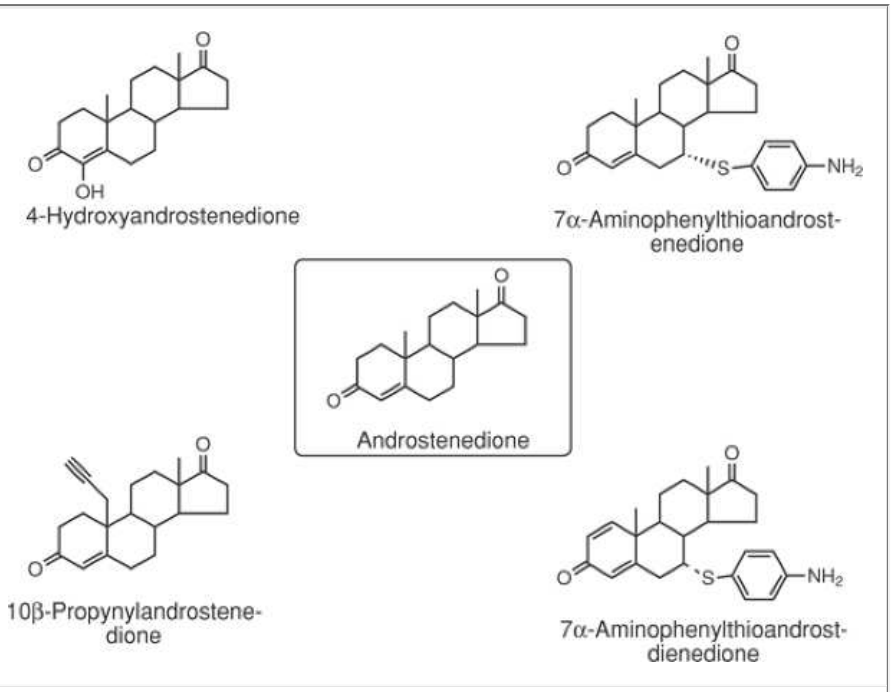

Fig. 46.10. Androstenedione aromatase inhibitors.

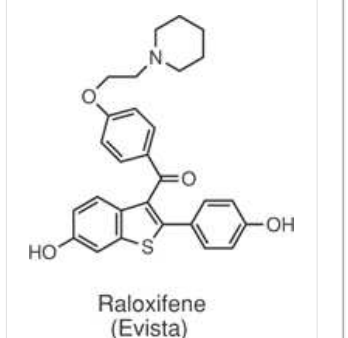
Advances in the molecular pharmacology of estrogen and ERs have led to the development of SERMs. These agents exhibit tissue-specific estrogen agonist or antagonist activity (31). The 3,4-dihydronaphthalene- and benzothiophene-containing SERMs are rigid analogues of the triphenylethylenes. The first SERM to be marketed for the treatment of osteoporosis was the benzothiophene raloxifene, an estrogen agonist at the bone (see Chapter 34). Discussion about the SERMs used in the treatment of breast cancer can be found later in this chapter.



Aromatase inhibitors

Androstenedione Derivatives

Inhibitors of aromatase block the conversion of androgens to estrogens and, therefore, have the therapeutic potential to control reproductive functions and aid in the treatment of estrogen-dependent cancers, such as breast cancer. These steroidal agents compete with androstenedione for the active site of the aromatase enzyme. The structure–activity relationships for steroidal aromatase inhibitors indicate that the best agents are substrate analogues, with only small structural changes to the A ring and at C_{19} permitted (Fig. 46.10). Analogues

that contain aryl functionalities at the 7α position have enhanced affinity for the enzyme. In addition, 4-hydroxy-androstenedione, several androsta-1,4-diene-3,17-diones, and 10β-propynylestr-4-ene-3,17-dione act as enzyme-activated irreversible inhibitors (suicide substrates) in vitro. Additional information about the use of aromatase inhibitors in the treatment of breast cancer can be found later in this chapter.

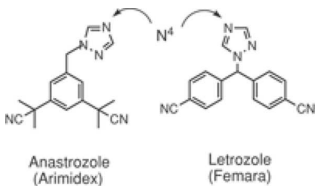


Fig. 46.11. Triazole aromatase inhibitors.

Triazole Derivatives

Triazole based aromatase inhibitors were developed based on the aromatase inhibitor aminoglutethimide (32,33) and include anastrozole (34) and letrozole (35) (Fig. 46.11). The triazoles inhibit aromatase as a result of the N-4 nitrogen of the triazole ring interaction with the heme iron atom of this CYP19 enzyme complex. Anastrozole and letrozole are competitive inhibitors of aromatase and selectively inhibit the conversion of testosterone to estrogens in all tissues and, thereby, reduce serum concentrations of circulating estrone, estradiol, and estrone sulfate. Because estrogen acts as a growth factor for hormone-dependent breast cancer cells, reduction of serum and tumor concentrations of estrogen inhibits tumor growth and delays disease progression. Ovarian production of estrogen declines in postmenopausal women, so the conversion of androstenedione and testosterone to estrone and estradiol in peripheral tissues becomes the primary source of estrogen. The structure–activity relationships of these inhibitors have been reviewed elsewhere (36,37,38). Additional information about the triazole derivatives as it relates to the treatment of breast cancer can be found later in this chapter.

Clinical Applications

Estrogens are utilized in the treatment of a wide variety of menstrual-related disturbances, including the management of menopausal symptoms (e.g., vulvar and vaginal atrophy); female hypoestrogenism resulting from hypogonadism, castration, or primary ovarian failure; as well as amenorrhea, dysmenorrhea, and oligomenorrhea. They also are effective in the management of ovarian development failure, acne, and senile vaginitis. After childbirth, estrogens have been used to suppress lactation in those women who elect not to participate in breastfeeding. More detailed discussions about the clinical application of estrogens in the treatment of several disease states can be found later in this chapter.

Administration of estrogens may promote sodium retention and, as a result, cause retention of water and, possibly, edema. This effect, however, is less pronounced than that observed with the glucocorticoids. More detailed information regarding the pharmacology and toxicology of estrogens can be found in published reviews (5,21,39).

Progestins

Fraenkel (40) first observed in 1903 that removal of the corpus luteum shortly after conception resulted in pregnancy termination. In 1929, Corner and Allen (41) developed an assay method for progestogenic activity, and by 1934, the hormone progesterone had been isolated by several research groups (26).

Biosynthesis

Progesterone biosynthesis is initiated when LH, secreted from the anterior pituitary, binds to the target cell surface LH receptor.

Activation of the LH receptor results in an increase of intracellular cyclic adenosine monophosphate (cAMP) levels via activation of a G protein and adenylate cyclase. In the presence of elevated concentrations of cAMP, cholesterol esterase activation occurs. This enzyme catalyzes the cleavage of cholesterol esters to free cholesterol, which is then converted in mitochondria to pregnenolone as described previously. The formation of progesterone from pregnenolone is catalyzed by 5-ene-3β-hydroxysteroid dehydrogenase and 3-oxosteroid-4,5-isomerase (steps c and d in Fig. 46.3).

Progesterone is secreted primarily from the ovaries (30 mg/day), particularly by the corpus luteum in reproductive-age women and by the placenta during pregnancy. Compared to the ovaries, the adrenal gland produces only a small fraction of progesterone (1 mg/day).

Metabolism

Progesterone is rapidly metabolized by the liver, regardless of the route of administration, and has a half-life of 5 to 10 minutes (Fig. 46.12). Progesterone is mainly excreted renally as the glucuronide and sulfate conjugates of 5β-pregnanediol. The glucuronide metabolite serves as an index of the corpus luteum activity, and a premature drop in its level may be a warning of possible miscarriage.

Other routes of metabolism include 6α-hydroxylation and reduction of the 20-ketone. These metabolites have no significant progestogenic activity. The formation of 5β-pregnanediol from progesterone is characterized by reduction of the 4,5-double bond to create a *cis* A/B ring juncture and reduction of the 3-ketone to a 3α-hydroxy group.

In the serum, progesterone is bound to either cortisol binding globulin or albumin, with only a small fraction being freely available. The metabolic clearance rate for progesterone is 2,100 to 2,500 L/day, for which protein binding has no role.

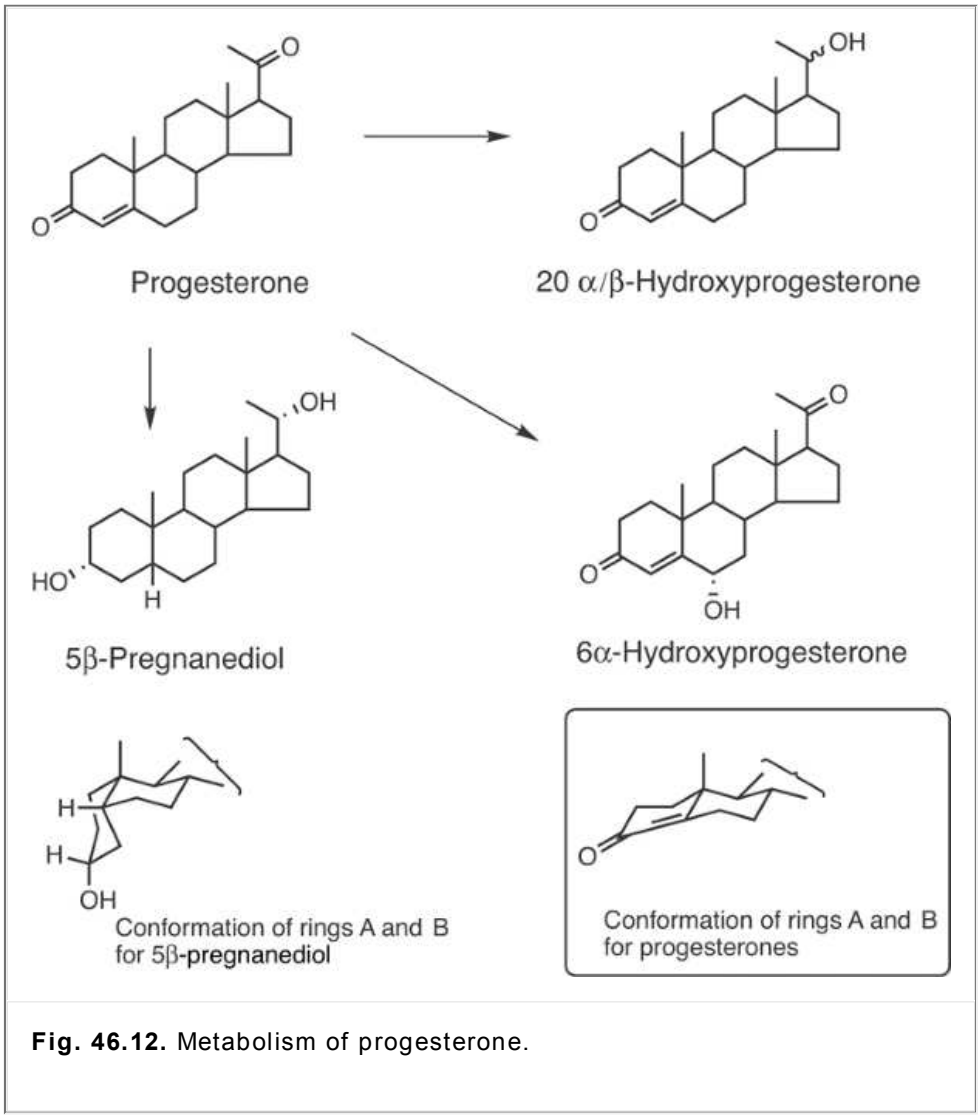

Fig. 46.12. Metabolism of progesterone.

Mechanism of Progestin Action—Molecular Interactions

The progesterone receptor is a ligand-activated transcription factor and a member of the nuclear receptor superfamily. All nuclear receptors have three conserved functional domains, including the DNA binding domain, the N-terminal domain, and the C-terminal

ligand binding domain (42). Very little is known about the structure of the N-terminal domain. The DNA binding domain contains two asymmetric zinc fingers with four cysteine residues coordinated to each zinc atom. Between the zinc fingers is an α helix, which has specific interactions with the DNA. The ligand binding domain is composed of 12 α helices and four β sheets that ultimately form a hydrophobic cavity in which the receptor agonist binds (42). When progesterone binds to its receptor, a conformational change in the receptor occurs, transforming it into an active transcriptional factor. Phosphorylation of the receptor occurs at this point, but it is unclear what biochemical role that plays. The receptor then undergoes dimerization to form PR-A and PR-B, which are not structurally identical. These isoforms have similar activities as it relates to steroid hormone and DNA binding, but their functional activities are unique. The dimer interacts with specific nuclear DNA sequences (hormone- response elements) within progesterone-responsive genes. The receptor agonist–receptor dimer complex combines with coactivators that link the complex to gene transcription (43). The rate of gene transcription is then either increased or decreased. Once gene transcription is initiated, proteins are biosynthesized, and physiological effects are observed in target cells and organs.

Physiological Effects

The primary physiological site of action of progesterone is the uterus. It acts on both the endometrium (inner mucous lining) and the myometrium (muscle mass) of the uterus. The effect of progesterone on the endometrium, already primed by estrogens, is to induce the secretory phase of the menstrual cycle. During this phase, the endometrial glands grow and secrete large amounts of carbohydrates that can be utilized by the fertilized ovum as an energy source. The primary function of progesterone with respect to the myometrium is to stop spontaneous rhythmic contractions of the uterus.

Progesterone often is referred to as the “hormone of pregnancy.” For the first trimester, the corpus luteum serves as the primary source of progesterone, at which point the developing placenta takes over as the major source of progesterone and estrogen. The high level of progesterone that is produced during pregnancy sends a signal to the hypothalamus via the negative feedback system to prevent release of the FSH and LH necessary for the development of new ova.

In general, the nonreproductive effects of progesterone are fairly insignificant. Progesterone is able to antagonize the actions of aldosterone, and as a result, there is an increase in sodium excretion. When sodium levels drop, aldosterone secretion is stimulated, and sodium is retained (44). It has been suggested that the temperature-raising effect of progesterone may be the result of a reduction in perspiration. This effect is not unique to progesterone, because other steroids in the pregnane and androstane series have a similar effect (45).

Ovarian biosynthesis and secretion of progesterone is controlled by the release of LH from the anterior pituitary during ovulation. The LH induces progesterone secretion from the corpus luteum during the second half of the menstrual cycle. If conception does not occur, the corpus luteum degenerates, and progesterone production decreases. As progesterone levels drop, endometrial sloughing occurs—otherwise known as menstruation.

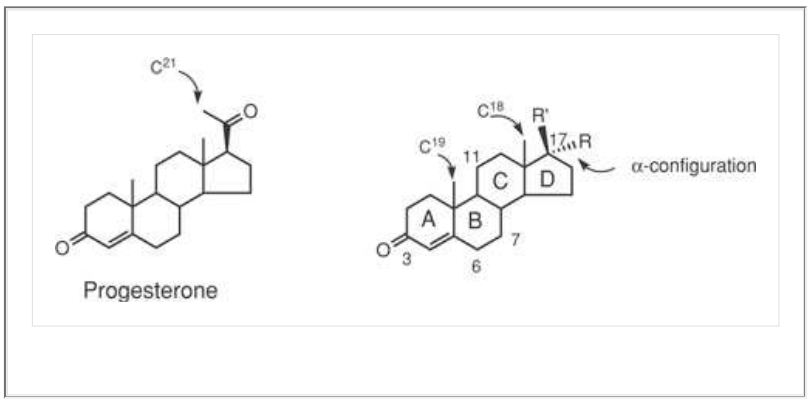
Side Effects

Characteristic progestin-related side effects include nausea and vomiting, drowsiness, as well as breakthrough and irregular bleeding. With prolonged therapy, a greater incidence of these effects may occur, along with edema and weight gain, breast pain, decreased libido, and masculinization of the female fetus.

Structure–Activity Relationships

Progestin activity is restricted to those molecules with a steroid nucleus. The synthetic progestins generally can be divided into two classes of compounds: the androgens (19-norandrostane or estrane derivatives), and the 17α-hydroxyprogesterones (46,47,48,49). In the androgen series, a 17α-substituent, such as ethynyl, methyl, ethyl, and variations of these, provides oral bioavailability. Ethisterone (17β-hydroxy-17α-ethynylprogesterone) (see Fig. 46.14),

the first androstane found to be effective, has only about one-third the activity of progesterone when delivered subcutaneously, but is 15-fold more active than progesterone when administered orally. Closely related to testosterone, this progestin has significant androgenic activity. Removal of the CH_3 group at position 19 leads to norethindrone (norethisterone) (Fig. 46.14), which has 5- to 10-fold more progestin activity. The activity of norethindrone is increased further by the addition of a chlorine substituent at position 21 (blocks metabolic hydroxylation) or by the addition of a methyl group at carbon 18 (norgestrel) (see Fig. 46.15). Ethynodiol acetate is an extremely potent oral progestin. It is more active when administered orally than parenterally and, when combined with an estrogen, is effective as an OC.



Further unsaturation of the B or C ring of 19-androstane derivatives usually enhances progestin activity. Introduction of a halogen or methyl substituent in the 6α or 7α positions generally increases hormonal activity. Acetylation of the 17β-OH of norethindrone increases the duration of action of the drug. Removal of the 3-keto function of norethindrone allows retention of potent progestin activity and no androgenic effects.

Activity of the 17α-hydroxyprogesterones is enhanced by unsaturation at C_6 and C_7 and by substitution of a methyl group or a halogen at C_6. This activity may be further increased by introducing a CH_3 group at C_{11}. These substitutions prevent metabolic reduction of the two carbonyl groups and metabolic oxidation at C_6. Substitution of a fluoro group at C_{21} prevents metabolic hydroxylation and enhances oral effectiveness.

Table 46.7. Hormonal Activities of Representative Progestins (11)

Progestogen	Antiestrogenic	Androgenic	Antiandrogenic	Glucocorticoid	Antimineralocorticoid
Progesterone	[check mark][check mark]	0	[check mark]	[check mark][check mark]	[check mark][check mark]
Medroxyprogesterone acetate	[check mark][check mark]	[check mark]	0	[check mark][check mark]	0
Norethisterone (1)	[check mark][check mark]	[check mark][check mark]	0	0	0
Levonorgestrel (2)	[check mark][check mark]	[check mark][check mark]	0	0	0
Etonogestrel (3)	[check mark][check mark]	[check mark][check mark]	0	[check mark]	0
Norgestimate (3)	[check mark][check mark]	[check mark][check mark]	0	?	?
Drospirenone (4)	[check mark][check mark]	0	[check mark][check mark]	0	[check mark][check mark]
Elcometrine (4)	[check mark][check mark]	0	0	0	?

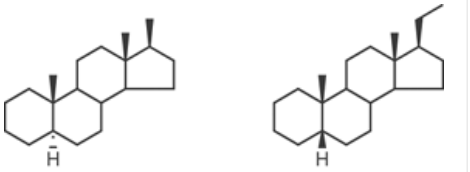
Nomegestrol acetate (4)	[check mark][check mark]	0	[check mark][check mark]	0	0
Trimegestone (4)	[check mark][check mark]	0	[check mark]	0	[check mark]
Dienogest (4)	[check mark][check mark]	0	[check mark][check mark]	0	0

The number in parentheses indicates the generation of progestogen. [check mark][check mark], effective; [check mark], weekly effective; 0, not effective;?, unknown.

Because glucocorticoid receptor activity is not desirable yet is innate to those derivatives that bind with high affinity to the progesterone receptor, structural alterations have been investigated to pare out this biological activity. Small B-ring substituents serve to decrease glucocorticoid action, as do substituents at the C_{17} position.

Synthetic Progestins

Early generations of the progestins were utilized primarily for contraceptive purposes, so antigonadotropic activity was considered to be desirable. Unfortunately, many of these agents were plagued by androgenic activity and the corresponding adverse effects (Table 46.7) (11). Development of newer progestins is now focused on analogues with improved progesterone receptor selectivity (Table 46.8) and little or no effect on the androgen, estrogen, or glucocorticoid receptors (43). From a structural perspective, these synthetic progestins contain either a pregnane or androstane steroid nucleus.



Not only can the progestins be classified structurally, they also can be organized by generation. The first-generation agents include 17-hydroxyprogesterone analogues (Fig. 46.13) as well as norethynodrel, norethindrone, and their derivatives (Fig. 46.14). Norgestrel and levonorgestrel are two of the predominant agents in the second-generation (Fig. 46.15). The levonorgestrel derivatives desogestrel, gestodene, and norgestimate compose the third generation (Fig. 46.16), and the new,

fourth-generation 19-norprogesterones include NES, nomegestrol acetate, and trimegestone (Fig. 46.17). In addition, there is one nonethynylated estrane, dienogest, and one spironolactone derivative, drospirenone, to round out the fourth generation (43). The antiandrogenic activity associated with several fourth-generation agents (e.g., trimegestone, drospirenone, and dienogest) makes this group of progestins unique (Table 46.7) (11). Trimegestone and elcometrine are the most potent progestins, with the third-generation levonorgestrel and etonogestrel (3-ketodesogestrel) being slightly less potent (Table 46.8).

Table 46.8. Steroid Receptor Binding Affinities (11,43)

Progestogen	Progesterone	Androgen	Glucocorticoid	Mineralo-corticoid
Progesterone	50	0	10	100
Medroxyprogesterone acetate (1)	115	5	29	160

Norethisterone (1)	75	15	0	0
Levonorgestrel (2)	150	45	1	75
Etonogestrel (3)	150	20	14	0
Norgestimate (3)	15	0	1	0
Gestodene (3)	90	85	27	290
Drospirenone (4)	35	65	6	230
Elcometrine (4)	136	0	38	?
Nomegestrol acetate (4)	125	42	6	0
Trimegestone (4)	330	1	9	120
Dienogest (4)	5	10	1	0

The number in parentheses indicates the generation of progestogen.

Progesterone and Its Derivatives

Progesterone has a significant role in priming the uterine endometrium for implantation of a potential blastocyst. It also is involved in formation of the placenta postimplantation, the development of mammary glands, and by preventing contraction of the uterine musculature, pregnancy maintenance. Progesterone also has inhibitory roles, including ovulation prevention via an antigonadotropic effect and inhibition of the conversion of testosterone to dihydrotestosterone, an active metabolite, by virtue of its ability to be a substrate for 5α-reductase (43). Interestingly, progesterone reduces nuclear estradiol receptor levels and induces 17-hydroxysteroid dehydrogenase, the enzyme that catalyzes the conversion of estradiol to the less potent estrone (50).

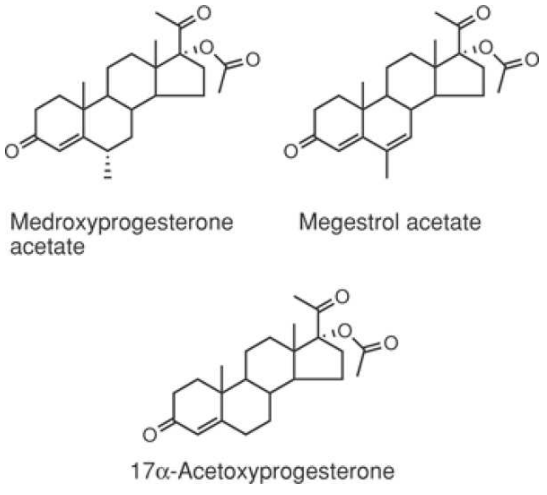


Fig. 46.13. Progesterone and its derivatives.

There are some limitations as to how progesterone can be administered, because it has relatively low bioavailability when administered orally. The pharmacokinetics for progesterone and its derivatives are listed in Table 46.6. To achieve consistent

therapeutic benefit, progesterone must be administered either by injection or intravaginally. Progesterone may need to be administered over a relatively long period of time to maintain a

pregnancy, so it is important to note that neither of the two routes just mentioned is without significant adverse effects. As a result, development of orally active derivatives has been a significant priority.

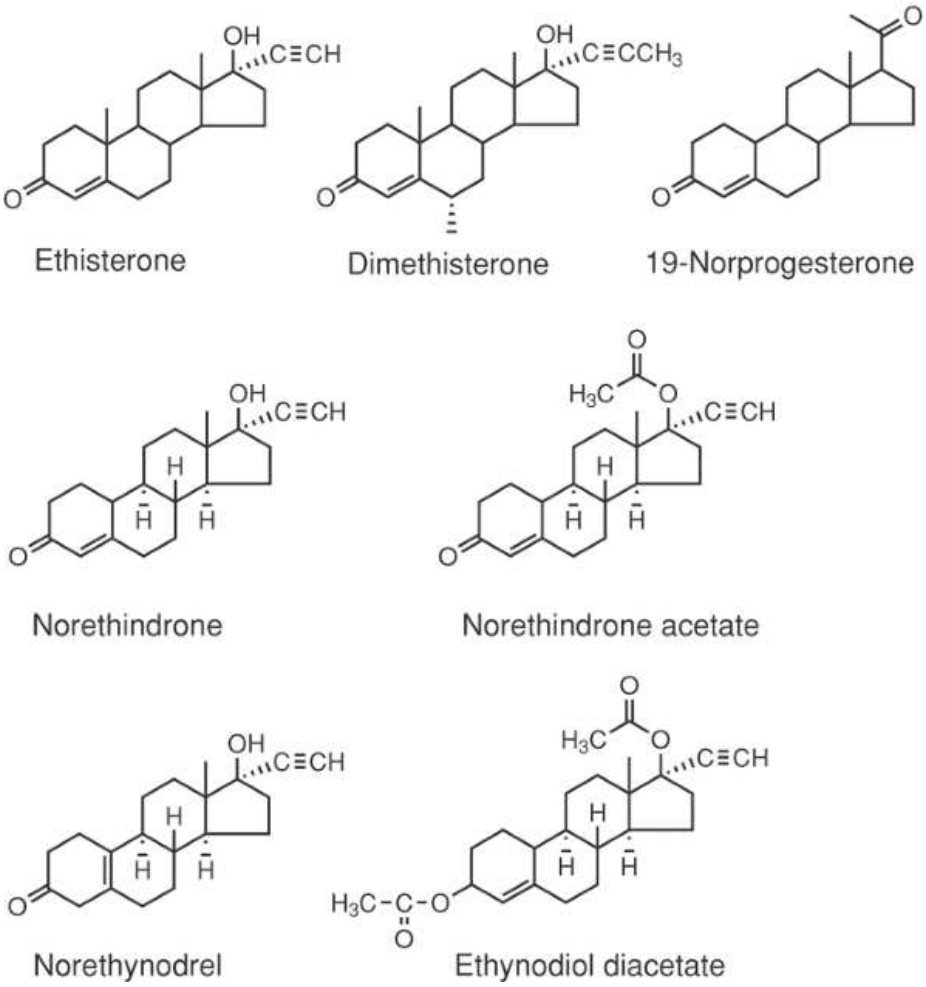

Fig. 46.14. Progestins and norethisterone/norethindrone-related, 19-nortestosterone androstanes.

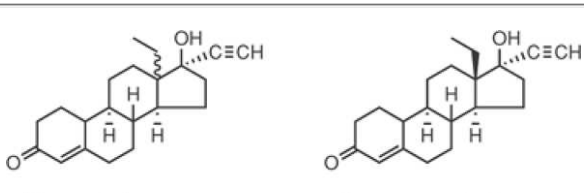

Fig. 46.15. Norgestrel and levonorgestrel.

Medroxyprogesterone acetate

The initial structural modifications made to progesterone led to only weakly active or inactive analogues. For example, 17α-acetoxyprogesterone had limited activity when administered orally (51). Further structural modification of 17α-acetoxyprogesterone was aimed at limiting metabolic hydroxylation at C_6. This was accomplished by the addition of a C_6 substituent, and the resulting analogue displayed improved biological activity (48).

Among the first of these substituted 17α-acetoxyprogesterone analogues to be utilized therapeutically was medroxyprogesterone acetate, a 6α-methyl progesterone analogue (Fig. 46.13) (52). This analogue is 25-fold more active than ethisterone. Following oral administration, medroxyprogesterone acetate is completely and rapidly deacetylated by first-pass metabolism to medroxyprogesterone. Medroxyprogesterone is extensively metabolized via pathways similar to those for progesterone, except for 6α-hydroxylation. Most medroxyprogesterone acetate metabolites are excreted in the urine, primarily as glucuronide conjugates. Plasma protein binding for medroxyprogesterone is approximately 86%, primarily to serum albumin, with no binding to SHBG.

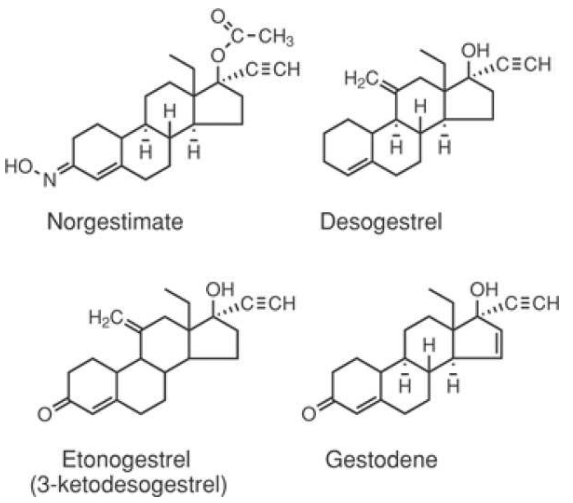

Fig. 46.16. Levonorgestrel-related, 19-nortesterone androstanes.

Megestrol acetate (megace)

Progestin activity is further enhanced when a double bond is introduced between positions 6 and 7, as is found in megestrol acetate (Fig. 46.13). Megestrol is used primarily in the treatment of breast and endometrial carcinomas and in postmenopausal women with advanced hormone-dependent carcinoma. Less than 10% of an oral dose undergoes metabolism. Several major metabolites appear in the urine (e.g., 2-hydroxy and 6-hydroxymethyl megestrol and their glucuronide conjugates).

Synthetic Progestins

Ethisterone and its analogues

Ethisterone (Fig. 46.14), a 17α-ethynyl derivative of testosterone, is one of the first synthetic progestins to be used therapeutically. In 1937, this agent was synthesized from male sex hormones (androstanes) in an attempt to find an orally active androgen (53). Ethisterone later proved to be an effective oral progestin and became useful in the treatment of menstrual dysfunctions (49). Several molecular modifications

of ethisterone have improved progestogenic action, including introduction of methyl groups in the $C_{6\alpha}$ and C_{21} positions (e.g., dimethisterone) (Fig. 46.14) (39).

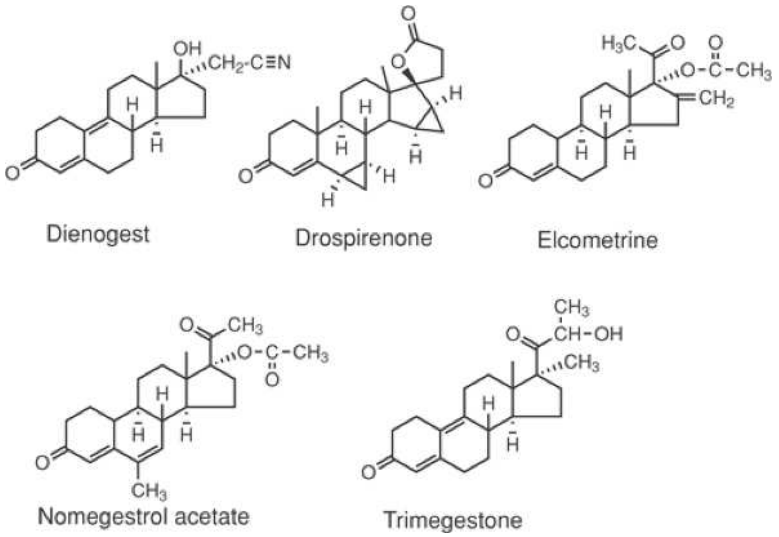

Fig. 46.17. 19-Norprogesterones (fourth-generation progestins).

A second breakthrough was made in 1944, when Ehrenstein (54) discovered that the C_{19} methyl group is not necessary for progestogenic activity. In fact, this work showed that loss of the C_{19} methyl results in analogues with activity equal to or greater than that of parenterally administered progesterone. In 1953, Djerassi et al. (55) synthesized 19-norprogesterone (Fig. 46.14). This drug differed from the natural hormone only in replacement of the C_{19} angular methyl group with a hydrogen atom. When administered parenterally, this analogue was eightfold more active than progesterone and, at the time, was the most potent progestin known.

Norethindrone (norethisterone) and norethynodrel

Research on 19-norsteroids as potential progestins culminated in the synthesis of two potent, orally active progestins, norethindrone and norethynodrel (Fig. 46.14) (46). These two substances were among the first 19-norsteroids to be used clinically for progesterone-related disorders. When combined with estrogens, such as EE or mestranol, these agents were effective contraceptives. Because the progestogenic action of norethynodrel is approximately one-tenth that of norethindrone, it is no longer utilized in OC formulations. Although norethindrone is a weak androgen, it does not exhibit any glucocorticoid or antimineralocorticoid activity (Table 46.7).

Following oral administration, norethindrone acetate is completely and rapidly deacetylated by hepatic and intestinal first-pass metabolism to norethindrone, with an oral bioavailability of approximately 64%. Subsequent metabolism of norethindrone includes reduction of the Δ^4 double bond to both the 5α- and 5β-dihydronorethindrone products as well as reduction of the ketone. The pharmacokinetics for norethindrone acetate are indistinguishable from that of orally administered norethindrone. Roughly 36% of norethindrone is bound to SHBG, and 61% is bound to albumin (11).

Norethindrone acetate also can be administered transdermally along with estradiol when formulated as a patch. This combination of hormones can be utilized as part of either a continuous or a cyclic hormone replacement regimen.

Norgestrel and levonorgestrel

Norgestrel is formulated as a racemic mixture despite the fact that only its levo isomer, levonorgestrel, is pharmacologically active (Fig. 46.15). Levonorgestrel exhibits some androgenic activity but no glucocorticoid or antimineralocorticoid action. Levonorgestrel can be administered orally, transdermally (combined with estradiol and formulated as a 7-day patch), and for prolonged, continuous use, via an intrauterine device (IUD). The oral bioavailability of levonorgestrel is approximately 95% (11). From a protein binding perspective, 48% of an oral dose is bound to SHBG, and 50% is bound to albumin. Levonorgestrel undergoes metabolic reduction of its ketone and is hydroxylated.

Norgestimate and desogestrel

Norgestimate (Fig. 46.16) is considered to be a pro-progestin (prodrug), because it rapidly undergoes a two-step metabolic transformation to form two active products, norelgestromine (levonorgestrel 3-oxime) and levonorgestrel (Fig. 46.15). Deacetylation occurs in the intestine and liver, whereas conversion of the 3-oxime to the corresponding ketone occurs primarily in the liver. Unlike the other progestins mentioned, norgestimate and its metabolites are not bound to SHBG.

Norgestimate exhibits high selectivity for the progesterone receptor and low androgenic activity as a result of a large drug-induced increase in the production of SHBG. As a component of both mono- and triphasic OC formulations, this progestin exhibits fewer androgenic side effects, including less of a detrimental effect on the patient's lipid profile and lack of significant weight gain (56). Rates of breakthrough bleeding were lower with a triphasic regimen including norgestimate compared to a monophasic regimen containing norethindrone acetate. Norgestimate is metabolized to norelgestromin, the primary active metabolite and the active progestin found in the contraceptive patch (Ortho Evra).

Desogestrel also is a prodrug and is rapidly metabolized in the intestinal mucosa and on first pass through the liver to its active metabolite, etonogestrel (3-ketodesogestrel) (Fig. 46.16). Following oral administration, the relative bioavailability for desogestrel is approximately 84%. Desogestrel also exhibits high selectivity for the progesterone receptor and low androgenic activity, and it does not diminish the beneficial effects of estrogen on the lipid profile. The rates of breakthrough bleeding are low with the monophasic desogestrel/EE formulation, which has improved therapy discontinuation percentages. Unfortunately, there is conflicting evidence regarding the risk of venous thromboembolism with these preparations, with some studies suggesting a twofold increase in risk (56).

Gestodene

Unlike the other members of the third generation of progestins, gestodene is not a prodrug (Fig. 46.16). It exhibits nearly 100% oral bioavailability and excellent receptor binding affinity for the progesterone receptor. Because the SHBG level is considered to be a surrogate marker for venous thromboembolism (VTE) risk, it is important to note that an increase in SHBG levels is evident both in monophasic combination OC preparations (200–300% increase) and in triphasic preparations (150% increase) that contain gestodene (57). Both the monophasic and triphasic preparations also cause an increase in triglyceride and total cholesterol levels, although the increase is smaller in magnitude than those associated with desogestrel and norgestimate. An increase in high-density lipoprotein (HDL) levels was not observed (58). The effectiveness of a gestodene/ethynyl estradiol combination transdermal patch is currently under investigation.

Dienogest, drospirenone, elcomdetrine, nomegestrol acetate, and trimegestone

Classified as a testosterone-like, norethindrone-related progestin, dienogest is structurally unique in that it contains an estrane skeleton, a C_{17} cyanomethyl group that replaces the C_{17} ethynyl group, and Δ^9 unsaturation (Fig. 46.17). An effective OC preparation results when dienogest is combined with EE. Similarly, correction of menopausal symptoms results when dienogest is combined with estradiol valerate. Limited evidence suggests that this combination has a positive impact on cognition, which is in direct opposition to the Women's Health Initiative (WHI) study data regarding the combination of medroxyprogesterone acetate and conjugated estrogens.

Table 46.9. Components of a Representative Set of Oral Contraceptives (64)

Trade Name	Estrogen	Progestin
Monophasic combination oral contraceptives		
Alesse	EE (20 µg)	Levonorgestrel (0.1 mg)
Loestrin-21/Loestrin Fe 1/20	EE (20 µg)	Norethindrone acetate (1 mg)
Yasminellea	EE (20 µg)	Drospirenone (3 mg)
Yasmin	EE (30 µg)	Drospirenone (3 mg)
YAZ	Estradiol (20 µg)	Drospirenone (3 mg)
Loestrin-21/Loestrin Fe 1.5/30	EE (30 µg)	Norethindrone acetate (1.5 mg)
Lo/Ovral	EE (30 µg)	Norgestrel (0.3 mg)
Desogen	EE (30 µg)	Desogestrel (0.15 mg)
Ortho-Cept	EE (30 µg)	Desogestrel (0.15 mg)
Levlen	EE (30 µg)	Levonorgestrel (0.15 mg)
Nordette	EE (30 µg)	Levonorgestrel (0.15 mg)
Seasonale	EE (30 µg)	Levonorgestrel (0.15 mg)
Seasonique	EE (30 µg) days 1–84	Levonorgestrel (0.15 mg) days 1–84
	EE (10 µg) days 85–91	Levonorgestrel (0.15 mg) days 85–91
Ortho-Novum 1/35	EE (35 µg)	Norethindrone (1 mg)
Modicon	EE (35 µg)	Norethindrone (0.5 mg)
Ovcon-35 (chewable)	EE (35 µg)	Norethindrone (0.4 mg)
Ortho-Cyclen	EE (35 µg)	Norgestimate (0.25 mg)

Demulen	EE (35 μg)	Ethynodiol diacetate (1 mg)
Ovcon-50	EE (50 μg)	Norethindrone (1 mg)
Demulen 1/50	EE (50 μg)	Ethynodiol diacetate (1 mg)
Ovral	EE (50 μg)	Norgestrel (0.5 mg)
Ortho-Novum 1/35	Mestranol (50 μg)	Norethindrone (1 mg)
Biphasic combination oral contraceptives		
Mircette	EE (20 μg) days 1–21	Desogestrel (0.15 mg)
	EE (10 μg) days 24–28	Desogestrel (0.0 mg)
Ortho-Novum 10/11	EE (35 μg)	10 tablets Norethindrone (0.5 mg)
	EE (35 μg)	11 tablets Norethindrone (1 mg)
Triphasic combination oral contraceptives		
Estrostep 21 and Estrostep Fe	EE 20/30/35 μg	Norethindrone acetate (1 mg)
Cyclessa	EE (25 μg)	Desogestrel (0.1/0.125/0.15 mg)
Ortho TriCyclen Lo	EE (25 μg)	Norgestimate (0.18/0.215/0.25 mg)
Triphasil	EE (30/40/30 μg)	Levonorgestrel (0.05/0.075/0.125 mg)
Ortho TriCyclen	EE (35 μg)	Norgestimate (0.18/0.215/0.25 mg)
Ortho Novum 7/7/7	EE (35 μg)	Norethindrone (0.5/0.75/1 mg)
Progestin-only agents		
Ortho Micronor		Norethindrone (0.35 mg)
Ovrette		Norgestrel (0.075 mg)

[a]Not yet approved by the U.S. Food and Drug Administration.
EE, ethynyl estradiol.

Derived from spironolactone, drospirenone (Fig. 46.17) is the only progestin with antimineralocorticoid activity. Its affinity for the mineralocorticoid receptor is fivefold greater than that of aldosterone. Drospirenone has progestogenic action, but only 10% that of levonorgestrel. Drospirenone also has antiandrogenic action, because it blocks testosterone from binding to androgenic receptors but does not exhibit estrogenic or glucocorticoid receptor

activity.

This androstane-based progestin has several distinctive functional groups: two cyclopropyl groups, one that

includes C_6 and C_7 and the other C_{15} and C_{16}, and a C_{17} lactone. When combined with EE, drospirenone is effective in a monophasic OC (Table 46.9). Additionally, drospirenone plus estradiol (Angeliq) is used in the treatment of various menopausal symptoms. The unique antimineralocorticoid activity of drospirenone effectively negates the side effects related to angiotensinogen production (causing an increase in sodium and water retention) associated with EE. Remarkably, within the first several cycles, women actually lost weight when utilizing this combination of hormones (43). Regrettably, this benefit was lost, and statistically significant weight gain occurred as the number of cycles approached 13 (56).

Elcometrine (Fig. 46.17) is a member of the 19-norprogesterone class of progestins. When administered subcutaneously (implant), intravaginally (vaginal ring), or transdermally, elcometrine is an exceptionally potent progestin. It is 100-fold more potent when administered subcutaneously than when delivered orally. Its oral bioavailability is only 10%, with a half life of just 1 to 2 hours because of rapid metabolism (11). The C_{16} methylene functionality substantially increases its affinity for the progesterone receptor. Elcometrine does not bind to the androgenic receptor and, therefore, does not possess either androgenic or antiandrogenic activity (11). Unfortunately, like medroxyprogesterone acetate, elcometrine has affinity for the glucocorticoid receptor, although adverse effects were noted only at exceptionally high doses. Because of its antiestrogenic action, elcometrine also can be administered transdermally along with estradiol as a treatment for menopausal symptoms (43). From a protein binding perspective, elcometrine does not bind to SHBG but, rather, to albumin (11).

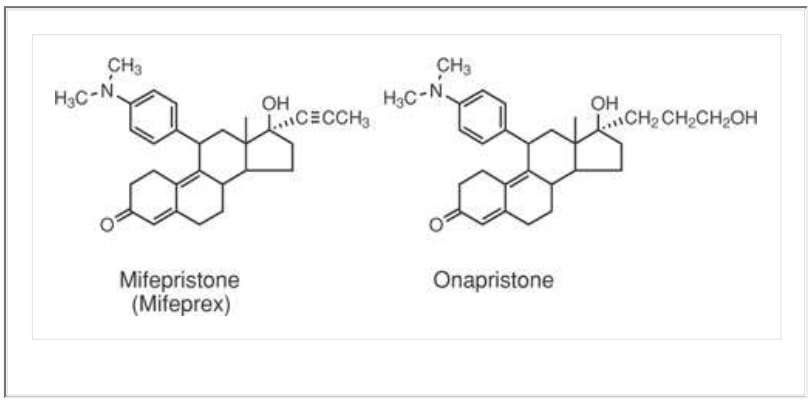
Nomogestrol acetate (Fig. 46.17) is structurally similar to megestrol acetate but lacks the angular C_{19} methyl group. It has substantially better selectivity for the progesterone receptor and higher potency than medroxyprogesterone acetate. Nomogestrol acetate has potent antigonadotropic action and, therefore, is an appropriate progestin to use in an OC preparation. It exhibits no glucocorticoid, antimineralocorticoid, or androgenic activity; however, it does demonstrate significant antiandrogenic action (11). Like NES, this progestin is bound primarily to albumin. Like desogestrel, it does not diminish the beneficial effects of estrogen on the lipid profile (11).

Trimegestone, the most potent of the 19-norprogesterones, contains an unusual C_{21} hydroxyl group (Fig. 46.17). It has very high affinity for the progesterone receptor but only weak affinity for the mineralocorticoid receptor. Trimegestone displays no glucocorticoid, androgenic, or antiandrogenic action. This progestin undergoes metabolic hydroxylation to produce metabolites with substantial progestogenic action. Either alone or in combination with estradiol, trimegestone has shown favorable results regarding bone loss and bone turnover (43). Given with estradiol, this hormone replacement therapy (HRT) combination is effective in the treatment of postmenopausal symptoms regardless of whether it is administered continuously or as part of cyclic therapy. Like desogestrel and nomogestrel acetate, this progestin does not diminish the beneficial effects of estrogen on the lipid profile (11).

Progestin Antagonists

Mifepristone

An antiprogestin is a substance that competes with progesterone for its receptor and, ultimately, prevents progesterone from binding to and activating its receptor. Because progesterone is integral to the continuation of an early pregnancy, it is expected that antipro-gestins will interfere with pregnancy maintenance. In 1982, the first antiprogestin, mifepristone (RU 486), was reported (59). Mifepristone was shown to interrupt early stages of implantation and pregnancy in humans (60). Following oral administration, mifepristone is rapidly absorbed, with a peak plasma concentration in approximately 90 minutes, an oral bioavailability of approximately 70%, and a terminal elimination half-life of 18 hours. It is 98% protein bound, primarily to albumin and α_1-acid glycoprotein. Mifepristone is metabolized primarily via CYP3A4 pathways involving mono- and di-N-demethylation and terminal hydroxylation of the 17-propynyl chain. The fact that approximately 83% of the drug is recovered in the feces and 9% in the urine suggests a biliary route of elimination. Mifepristone also demonstrates antiglucocorticoid activity (61).



Additional antiprogestin analogues, such as onapristone (ZK 98,299), exhibit less antiglucocorticoid activity (62). These antiprogestins also have demonstrated therapeutic potential for the treatment of hormone-dependent breast cancer (63).

Therapeutic Applications

A woman's reproductive life cycle spans nearly four decades. During this time her hormonal status and ability to reproduce vary considerably. The need for hormonal intervention during this time period varies from person to person and, typically, requires highly individualized medication regimens. The remainder of this chapter will focus on hormonal and selected nonhormonal therapies for the treatment and/or management of contraception, endometriosis, infertility, menopause, and breast cancer.

Contraceptive Methods

Despite the availability of a wide variety of contraceptive methods and technologies, nearly half of all pregnancies in the United States are unplanned, and one-fourth are

terminated. You might expect that cost, adverse effects, and inconvenience would be some of the hurdles to achieving contraceptive efficacy, but one of the greatest barriers is ineffective patient education (64). Despite ease of use, nearly 50% of those patients who have chosen an OC regimen discontinue their therapy within a year (65). If information regarding potential side effects, dosing requirements, and how the therapy is able to prevent pregnancy is provided in an accessible fashion, however, there may be many fewer patients who discontinue their contraceptive therapy (64,66,67).

Behavioral and Barrier Methods

Behavioral methods, such as natural family planning, fertility awareness, coitus interruptus, and lactation infertility, typically result in the highest pregnancy rates of all of the contraceptive methods. To be effective, these methods require disciplined effort on the part of the patient and her partner and somewhat detailed patient training. Barrier methods, such as male and female condoms, diaphragms, sponge (including nonoxynol-9 spermicide), and cervical caps, still require a very conscientious and often preplanned effort on the part of the patient as well as fairly detailed patient training. Unplanned pregnancy rates with these barrier methods are approximately 12 to 15%. Pharmacological contraception, including OCs, patches, vaginal rings, IUDs, and injectable medications, provides substantially lower pregnancy rates with diligent use, relatively limited patient effort, and patient education that is focused largely on adverse effects.

Combination Oral Contraceptives

Available since the early 1960s, most OC pills contain both an estrogen and a progestin component. The estrogen component, either EE or mestranol,

suppresses FSH release and, therefore, prevents the formation of a dominant follicle during the follicular phase of the menstrual cycle. The dominant follicle is responsible for producing estradiol, which sends a negative feedback signal to the hypothalamus to prevent the secretion of additional gonadotropins and, therefore, prevent maturation of additional follicles. The estrogen component also is responsible for maintaining the stability of the endometrial lining (68). The progestin component, of which there are many available, suppresses the LH surge and, therefore, blocks ovulation.

In the more than 40 year evolution of OCs, the estrogen dose has dropped to one-sixth, and the progestin dose to one-tenth, of the original levels. This makes the newer OC agents substantially safer but also subject to adverse effects, such as irregular and breakthrough bleeding. In addition to these dosage changes, the pro-gestin components have become progressively more selective in their binding to the progesterone receptor, thereby limiting the androgenic side effects that were characteristic of the older progestins (56).

OC agents are either monophasic or multiphasic in their hormone composition (Table 46.9). The multiphasic formulations more closely mimic the natural changes in both hormone concentrations that occur throughout the menstrual cycle. Most of the OC formulations are administered for 21 days, followed by 7 drug-free days to allow monthly withdrawal bleeding. Recently approved extended-cycle products, which allow the patient to experience only 7 drug-free days every 3 months, have efficacies similar to that of the standard 28 day regimen (Seasonale and Seasonique) (Table 46.9). Another nonstandard combination OC consists of estrogen plus progestin for 21 days, followed by 2 hormone-free days and then 5 days of EE (Mircette) (Table 46.9) (66). In Spring 2007 the FDA approved the first continuous regimen of low-dose EE and levonorgestrel (hybrel) that completely eliminates the menstrual cycle.

Two triphasic formulations that use a low dose of estradiol (25 µg) are currently under development. These formulations aim to minimize the side effect profile (e.g., breast tenderness, bloating, and nausea) and to maximize cycle control (e.g., minimal breakthrough bleeding). The formulation includes estradiol and a triphasic stair-step dose of either norgestimate or desogestrel.

A low-dose formulation was approved by the U.S. Food and Drug Administration (FDA) in early spring of 2006 (YAZ) (Table 46.9). This preparation is monophasic and is comprised of estradiol and drospirenone. The dosing regimen for this OC is comprised of 24 days of drug therapy, followed by 4 drug-free days to allow withdrawal bleeding. The 3-mg drospireneone component of this preparation is equivalent to 25 mg of spironolactone in terms of diuretic potential. Because of the diuretic action of drospirenone, the drug has the potential to cause hyperkalemia. Diminished fluid-related weight gain is an obvious advantage to this OC formulation, but caution is advised in patients with renal or adrenal insufficiency, with hepatic dysfunction, or who are receiving chronic pharmacotherapy that may increase serum potassium levels (e.g., angiotensin-converting enzyme inhibitors and potassium-sparing diuretics). This product joins a previous OC formulation that contains drospirenone (Yasmin) (Table 46.9). It should be noted that intracyclic bleeding (spotting) is more prevalent with EE doses of less than 30 µg, as is the case with these OCs. Studies have shown that the incidence of this adverse effect was greatest during the first cycle of OC use and diminished to very low incidence within three cycles (69).

Although the adverse effects of OC therapy include an increased risk of stroke, acute myocardial infarction, and venous thromboembolic disease, the incidence of cardiovascular disease in this patient population (age, <35 years) is already low (66). In women older than 35 years, the natural incidence of cardiovascular disease increases, so these adverse effects become more important to consider. From a metabolic perspective, the primary adverse effect of the estrogen component is an increase in hepatic production of proteins, including those that enhance venous and arterial thromboembolism (70). In addition, the progestin component has an adverse effect

on the lipid profile, including an elevation of serum triglyceride and a decrease in HDL levels. Generally speaking, the estrogen component of a combination OC balances out this negative impact on a patient's lipid profile. Neoplastic effects are associated with OCs as well, such as an increased risk of cervical cancer and a decreased risk of colorectal, endometrial, and ovarian cancers that persists long after the discontinuation of therapy.

Progestin-Only Oral Contraceptives

A few contraceptive formulations only contain progestins (Table 46.9). Their contraceptive effects are accomplished via several mechanisms. From a hormonal perspective, progestins are able to suppress ovulation by preventing midmenstrual-cycle LH and FSH peaks via negative feedback inhibition. They also thicken cervical mucus to prevent entry of sperm into the endometrial cavity as well as transform the endometrium into an unsuitable environment for embryo implantation. Although the progestins suppress ovulation, they only do so 60% of the time, which generally is not sufficient for young women. The progestin-only OCs are an appropriate choice, however, for older women in whom fertility is diminished, for those patients with contraindications to exogenous estrogen (e.g., smoking or high blood pressure), or for a lactating patient who is already experiencing prolactin-induced ovulation suppression (64). Unlike the combination oral agents, timing of administration is critical, because the effect of the progestin on the cervical mucus lasts for only 27 hours. If there is more than a 3-hour delay in the time of administration from the previous day, that dose is considered to be “missed,” and additional contraceptive methods are recommended.

The first progestin-only “mini-pills” contained either norethindrone or norgestrel. Their adverse effect profile is limited, because there is no estrogen component to increase the risk of venous thromboembolism or other cardiovascular related risks. Agents that induce metabolic enzymes (e.g., primidone, carbamazepine, topiramate, rifampin, ritonavir, and St. John's wort) may decrease the efficacy of the mini-pills by reducing the circulating levels of hormone (71). Antibiotics do not alter the enterohepatic recycling of progestins as they do with estrogens.

Table 46.10. Contraceptive Methods Using Nonoral Routes of Administration

Trade Name	Estrogen	Progestin	Route of Administration
Ortho Evra	EE (0.75 mg)	Norelgestromin (6 mg)	Patch
NuvaRing	EE (15 µg)	Etonogestrel (120 µg)	Vaginal ring
Lunellea	Estradiol cypionate (5 mg)	Medroxyprogesterone acetate (25 mg)	IM
Depo-Provera		Medroxyprogesterone acetate (150 mg/mL)	IM (400–1,000 mg weekly)
Norplanta		Levonorgestrel (36 mg/rod)	6 Subdermal rods (5 years)
Jadelle		Levonorgestrel	2 Subdermal rods (5 years)
Implanon		Etonogestrel	1 Subdermal rod (3 years)

Uniplant		Nomogestrel acetate	1 Subdermal rod
Nestorone		Elcometrine	1 Subdermal rod (2 years)
Mirena		Levonorgestrel (52 mg)	IUD (5 years)

[a]Not available in the United States.
EE, ethynyl estradiol; IM, intramuscular.

Transdermal Contraceptive Patch

Despite the ease of administration of the OCs, poor patient adherence rates have fueled the development of several long-acting contraceptive formulations. The contraceptive patch (Table 46.10), containing a combination of norelgestromin and EE, is applied to the upper arm, abdomen, or buttocks once per week on the same day of the week for 3 weeks, followed by a patch-free week to allow withdrawal bleeding. After several weeks of therapy (several patches applied), the mean and steady-state serum concentrations were in the range needed for contraceptive efficacy (72). Despite the absence of first-pass metabolism with this route of administration, the EE component undergoes hydroxylation and is conjugated to the corresponding glucuronide and sulfate derivatives. Contraceptive efficacy is compromised with coadministration of various metabolic enzyme inducers. If more than 48 hours elapse between patch removal and administration, it is recommended to start a new 4-week cycle with the newly administered patch, and an additional method of contraception should be used for one week (73). The patch provides equivalent efficacy to the OCs; however, it may not be as effective for women who weigh more than 90 kg (74). The adverse effects associated with the patch are headache, nausea, breast and abdominal pain, and application site irritation.

Contraceptive Vaginal Ring

The vaginal ring, another long-acting contraceptive, continually delivers a low dose of etonogestrel and EE directly into the vagina (Table 46.10). The ring is inserted into the vagina by the patient and remains in place for 3 weeks. Again, 1 drug-free week allows appropriate withdrawal bleeding. Unscheduled removal of the ring is allowed, but the ring must be reinserted within 3 hours to ensure continued therapeutic efficacy (67). This formulation has comparable efficacy with the OCs yet provides continuous hormone delivery, thereby minimizing the side effects caused by the pulsatile delivery associated with oral

dosing regimens (67,75). This formulation is not without adverse effects, including decreased libido, nausea, vaginitis, and breast tenderness.

Contraceptive Injectables

An intramuscular formulation that contains an aqueous suspension of medroxyprogesterone acetate and estradiol cypionate is available but is not currently marketed in the United States (Table 46.10). The 28- to 33-day dosing interval provides excellent contraceptive effectiveness. There are several advantages to this contraceptive method, including scheduled withdrawal bleeding and a quick return to a fertile state on discontinuation of therapy. The adverse effects are similar to those seen with other combination OC formulations, including headache, weight gain, decreased libido, and breast tenderness (67).

Progestin-Only Injectables

The issue regarding timing of administration all but disappears when a progestin injection is administered every 3 months. In this formulation, medroxyprogesterone acetate is an aqueous microcrystalline suspension (Table 46.10). The mechanisms by which this progestin accomplishes contraceptive efficacy are the same as those discussed previously for other progestins. Despite the ease of use, the continuation rate after a year of injections is less than 30%, largely because of the adverse effects, including irregular and heavy bleeding, amenorrhea, and infertility that lasts for 9 to 21 months after the last injection (64). Improved patient education concerning the potential side effects may be a simple solution to discontinuation of therapy.

Several subdermal implants are available that provide contraceptive efficacy for 1 to 5 years depending on the formulation (Table 46.10). These implants consist of progestins contained within individual rods that are surgically implanted into the upper arm. As indicated in Table 46.10, varying durations of action can be expected depending on the number of rods implanted. Currently, Norplant is not available in the United States, and Implanon has only received “approval” status by the U.S. FDA. These formulation is subject to the same adverse effects as other progestin-only methods.

Intrauterine Devices

There are two forms of IUDs: one that releases the progestin levonorgestrel (Table 46.10), and one that is copper-coated. Both devices are T-shaped and must be inserted into the uterus by a physician. These devices mechanically irritate the endometrium and create an inflammatory environment that is toxic to sperm and ova and is not conducive to embryo implantation (64), The copper coating further enhances this inflammatory response. The copper-based IUD can be used continuously for 10 years, whereas the progestin-containing device is only approved for 5 years of use (76). Although generally well tolerated, ectopic pregnancy and infection (related to device insertion or to the device itself) are two serious potential complications. Discontinuation of use often is a result of breakthrough and/or heavy withdrawal bleeding.

Emergency Contraception

Emergency contraception is defined as any method that prevents pregnancy after intercourse. This type of therapy is available in either combination or single-agent formulations. The progestin only pills contain either levonorgestrel (Plan B) or norgestrel (Fig. 46.14). The two combination regimens include EE along with each of these progestins. Typically, these agents are administered as one dose within 72 hours of intercourse, with another dose taken 12 hours later. Nausea and vomiting are common side effects. If the patient is hormone adverse, then insertion of a copper IUD within 5 days of ovulation (the earliest estimated date) will prevent implantation (77).

Mifepristone (Mifeprex) is a 19-nortestosterone–based antiprogestogen that competes with the endogenous agonist for the progesterone receptor (see previous discussion). If administered within 5 days of unprotected intercourse, it also will prevent pregnancy. Despite the presence of the bulky 11β-diethylamino phenyl group, mifepristone has higher receptor affinity than progesterone itself. It is not completely understood how mifepristone inactivates the progesterone receptor. Of note is that mifepristone and progesterone do not interact similarly with the ligand binding domain, such that in the presence of mifepristone, the conformational change that occurs in this domain is unique from that produced by the natural agonist (42).

Endometriosis

Endometriosis, a condition present in 1 of 10 menstruating women, is characterized by implantation of endometrial tissue outside the uterus, typically within the pelvic region (78,79). During a normal menstrual cycle, hormonal signals cause the endometrial tissues to thicken in anticipation of embryo implantation. If a pregnancy does not occur, then these tissues are shed, resulting in a monthly period. When endometrial tissues implant outside the uterus, they respond identically to those within the uterus, such that when hormones fall in response to a nonpregnant state, these tissues are shed—yet have no natural exit. This tissue may form cysts, which in turn may form scar tissue and/or adhesions. Typically, the presence of one or more of these elicits significant pain and discomfort, especially during menstruation. Because the resulting scars and/or adhesions can cause infertility (78), treatment should be sought if the patient wishes to have children.

The cause of endometriosis is not completely understood. Sampson's hypothesis in 1927 suggests that menstrual fluids flow back (retrograde) through the

fallopian tubes, where the endometrial cells can then implant and grow. Another theory proposes that the bloodstream is responsible for transporting the endometrial cells to

regions outside the uterus. A third hypothesis is that endometriosis is a genetically acquired disease and that environmental factors trigger disease initiation (78,79). One of the hypotheses currently gaining some strength involves the immune system. Abnormal B- and T-cell function is evident in endometrial lesions, as are abnormal levels of cytokines, growth factors, and interleukins (80). Regardless of the cause, the growth of these endometrial lesions are controlled by both estrogen and progesterone (81), which means that hormonal intervention is likely to be effective in the treatment of this condition.

Pharmacological Management

Treatment of endometriosis largely depends on the severity of the symptoms experienced by the patient. Characteristics of the pain experienced by patients include dysmenorrhea, pelvic and lower abdominal pain, and dyspareunia (81). The American Association of Reproductive Medicine has a four-tiered system to describe the severity of the endometriotic disease, ranging from stage I (mild) to stage IV (severe) (80). Pharmacological management looks to achieve two primary goals: pain management, and prevention/delay of disease progression. Nonsteroidal anti-inflammatory drugs (e.g., ibuprofen), which inhibit prostaglandin biosynthesis, may be sufficient to ease menstrual pain, but this pain may not be adequately managed even at the maximum dose. Endometriotic pain is directly related to the fluctuating levels of endogenous hormones. Clear evidence indicates that endometriosis-related symptoms improve substantially during pregnancy and after menopause. Because OCs chemically produce a “pregnant” state, one might expect this type of hormone therapy to be a viable treatment option.

Combination oral contraceptives

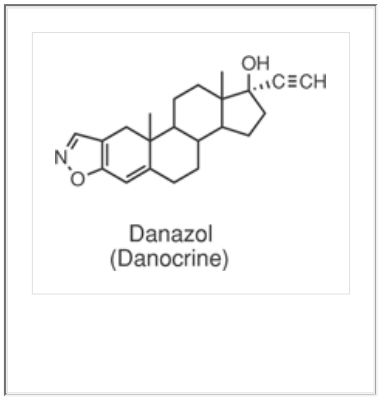
There are a number of hormone-based pharmacological options for the treatment of endometriosis. If a woman wishes to achieve complete cessation of endometriosis-related pain, a 3- to 4-month regimen using a combination OC is recommended. This forces the body into a chemically “pregnant” state, such that hormone fluctuations and ovulation cease. As a result, menstrual flow decreases, and the size of the endometrial implants diminish. No evidence suggests that one OC combination is more efficacious than another (80). After 3 to 4 months of continuous OC therapy, 1 drug-free week is required to allow withdrawal bleeding to occur. If daily administration is difficult for the patient to manage, then selection of one of several delivery systems that allow less frequent dosing (e.g., transdermal patch or vaginal ring) is appropriate. Cyclic dosing is more appropriate if the patient does not experience symptoms continually throughout the menstrual cycle. Adverse effects include nausea, headache, and breakthrough bleeding.

Gonadotropin-releasing hormone agonists

The GnRH agonists leuprolide, goserelin, and nafarelin down-regulate the hypothalamic-pituitary GnRH receptors, thereby limiting the secretion of FSH and LH and causing suppression of ovarian function (78,80). This creates an estrogen-deficient environment that prevents menstruation and reduces the size of wayward endometrial implants. These agents have enjoyed success in the treatment of endometriosis (85–100% success with 6 months of therapy), but they come with a price. The GnRH agonists generate a state of artificial menopause, which can cause classical vasomotor symptoms (e.g., urogenital atrophy and insomnia). Bone mineral density suffers substantially after prolonged use, so the duration of this type of therapy is limited to 6 months (82). One way to extend the duration of therapy is to coadminister agents that address these side effects. Suggested “add-back” therapies include a progestin alone (e.g., norethindrone), a progestin and a bisphosphonate (e.g., etidronate), or a progestin and an estrogen (e.g., conjugated equine estrogen [CEE]). The amount of estrogen that is added back is enough to counteract the side effects of the GnRH agonists but insufficient to cause endometrial tissue growth (80). A serious limitation to multidrug therapy is the considerable cost associated with these agents as compared to the OCs or progestin injectables.

Androgenic agents

Danazol, a synthetic analogue of 17α-ethynyl testosterone, induces amenorrhea, anovulation and endometrial atrophy via suppression of the hypothalamic-pituitary-ovary (HPO) axis (78,80). This causes an estrogen-deficient state, but it also causes an increase in androgen production. Danazol generally is not well tolerated because of its androgenic and anabolic side effects, including acne, decreased breast size, facial hair, weight gain, and oily skin (78,79). This type of therapy is not a viable option for women with liver disease or hyperlipidemia. Because danazol is teratogenic, it is recommended that effective contraception be utilized during treatment (78,80).



Progestins

Medroxyprogesterone acetate (Fig. 46.13), administered by injection (Depo-Provera), orally, or delivered via IUD, effectively suppresses the HPO axis, induces anovulation, and reduces serum estrogen levels (83). This prevents menstruation and endometrial implant growth. As a result, endometriosis-related pain is minimized in approximately 90% of the patients. Drug therapy selection should reflect the fact that pharmacological therapy is likely to be required on a chronic basis. The progestins are fairly well tolerated and relatively inexpensive, but they are not without adverse effects,

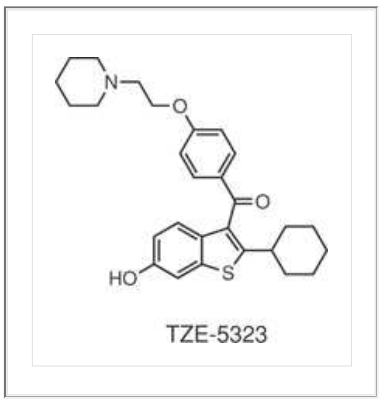
including nausea, breakthrough bleeding, weight gain, and mood swings, including depression.

Aromatase inhibitors

Normal endometrial tissues are devoid of aromatase activity. In patients with endometriosis, evidence suggests that high levels of aromatase are present in endometrial implants. Aromatase is the enzyme that catalyzes the conversion of androstenedione and testosterone to estrone and estradiol, respectively (Fig. 46.3). If an aromatase inhibitor, such as anastrozole (Fig. 46.11), is administered, then estrogen production will be decreased in the endometrial implants. A local state of estrogen deficiency will prevent growth of these implants (84). Unfortunately, one outcome of prolonged aromatase therapy is the development of osteoporosis. As a result, an OC typically is coadministered to provide baseline estrogen concentrations and limit the risk of osteoporosis.

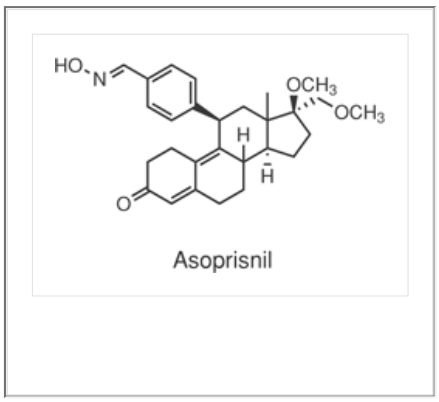
Selective estrogen receptor modulators

To be effective in the treatment of endometriosis without therapy-limiting side effects, a SERM must behave as an estrogen antagonist at the endometrium and as an agonist at the bone. An investigational agent, TZE-5323, has antiestrogenic action by virtue of its ability to inhibit binding of estrogen to ER-α and ER-β and then limit subsequent transcriptional activation (85). This agent may prove to be beneficial in the treatment of endometriosis.



Progesterone receptor modulators

Like the SERMs, the selective progesterone receptor modulators bind to the progesterone receptors and act as either an agonist or antagonist depending on the absence or presence of progesterone and the tissue that is being targeted. In the absence of progesterone, these agents demonstrate progestin activity. In the presence of progesterone, they exhibit antiprogestin activity in some target tissues, particularly the endometrium (81). Several investigational agents, including asoprisnil, have suppressed the growth of endometrial implants while estrogen concentrations remained at similar levels to those found during the follicular phase of the menstrual cycle (86). Asoprisnil undergoes metabolic O-dealkylation to an active metabolite.



Surgical intervention

Laparoscopic surgical intervention to remove the endometrial implants is recommended for those patients who do not wish to utilize pharmacological methods because of their immediate interest in having children. It should be noted that as many as 20% of patients do not respond to surgical intervention. This results, in part, from a failure to identify and excise all the errant endometrial tissues (80). Adjunct therapy is not routinely utilized, because study data fail to consistently show efficacy (87).

Infertility

Infertility is not a disease state of the "individual" but, rather, often is considered to be a disease state of the "couple." Defined as the inability to conceive a pregnancy after 12 months of unprotected intercourse, infertility affects 10 to 13% of couples. Identification of the cause of infertility requires thorough medical histories as well as several diagnostic tests (Table 46.11) (88,89). The causes of infertility include ovulatory disorders as well as situations in which tubal factors, uterine factors, cervical factors, and/or immunologic and thrombophilic factors play a substantial role (Table 46.12) (90).

In 1994, nearly one-third of all first births were by women older than 35 years of age, an interesting statistic that highlights the recent trend to delay having children (88,91). With this delay comes an age-related reduction in fertility and the need to employ one or more pharmacological therapies to achieve a live birth. There have been more than 1 million babies born as a result of in vitro fertilization (IVF), with nearly one in three embryo-transfer cycles resulting in a live birth (92). Many infertility treatment options and protocols are available, most of which are highly individualized (Table 46.13) (89).

Intrauterine Insemination and In Vitro Fertilization

Intrauterine insemination (IUI) involves induction of ovulation, followed by transfer of motile sperm directly into the uterine cavity. This type of procedure is indicated if erectile dysfunction or male infertility (low motility, count, and/or poor morphology) has been identified, if the cervical environment is not conducive for effective sperm motility and/or sustenance, and if there are any physiological dysfunctions (93).

In vitro fertilization involves hyperstimulation of the ovaries to produce multiple mature follicles. Once the follicles reach 18 to 21 mm in diameter, hCG is administered, and within 34 to 36 hours, all the mature follicles are aspirated and their eggs removed from the ovaries. Depending on the couple, fertilization of the oocyte by the sperm may or may not require assistance. The resulting fertilized oocytes or embryos are then sustained and

monitored for 3 to 5 days. Embryo characterization is performed daily to identify the most advanced embryos of good quality for subsequent transfer into the uterine cavity. Preimplantation genetic diagnosis can be performed with a single cell biopsied from each embryo that reaches the 6- to 8-cell stage by day 3. The genetic tests performed (only on 10 chromosomes) will help the physician and patient to identify those embryos with normal genetic makeup (including sex determination). Despite these advanced technologies and regardless of the age group the pregnancy rate does not exceed 50%, and the risk for multiple births is substantially higher than that observed in the general population.

Table 46.11. Infertility Medical Evaluation (88,89)

Male	Female
Fertility in other relationships	Previous pregnancies, fertility in other relationships; onset of menstrual cycle

Medication use	Medication use, including contraceptive use
Alcohol or recreational drug	Alcohol or recreational drug use, cigarette smoking use, cigarette smoking
Environmental exposure (e.g., sauna, hot tub), chemotherapy	Environmental exposure (e.g., DES), chemotherapy or radiation exposure or radiation exposure
Sexual dysfunction/frequency of	Frequency of intercourse intercourse
Semen analysis	Ovulation documentation Screening tests: pap smear, cervical cultures, mammogram, infectious disease screening Day 3 FSH levels (>10 mIU/mL = low rate of pregnancy) Thyroid panel, including TSH levels Fasting Prolactin levels Clomiphene citrate challenge test + FSH and estradiol levels (assess ovarian reserve) Hysterosalpingogram (assess tubal patency, shape of intrauterine cavity) Laparoscopy (assess endometriosis or if adhesions are present) Hysteroscopy (assess interuterine lesions or abnormalities)

DES, diethylstilbestrol; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone.

Table 46.12. Infertility Classification and Causes (90)

Ovulatory Disorders	Characteristics	Therapeutic Regimen
WHO Class I		
Hypogonadotropic, hypogonadal anovulation	Low or low normal FSH, low estradiol due to decreased Gn-RH or pituitary not responding to Gn-RH	Weight gain, reduce exercise, pulsatile Gn-RH
WHO Class II		
Normogonadotropic, normoestrogenic anovulation	Normal gonadotropins and estrogens, FSH secretion during follicular stage is subnormal, includes women with PCOS	Weight loss, clomiphene with or without metformin, aromatase inhibitors
WHO Class III		
Hypergonadotropic, hypoestrogenic anovulation	Premature ovarian failure, ovarian resistance	

Hyperprolactinemic anovulation therefore estrogen secretion	Elevated levels of prolactin inhibits gonadotropin and	Dopamine agonists (bromocriptine)
Tubal Factor Infertility		Hysterosalpinogram, IVF, tubal reconstruction, laparoscopic surgery (endometriosis)
Uterine Factor Infertility		Leiomyoma, polyp removal
Cervical Factor Infertility		IUI, IVF
Immunologic and Thrombophilic Factor Infertility		Low dose aspirin and heparin, anticoagulation therapy
Unexplained Infertility		Clomiphene with or without IUI, gonadotropins with IUI, ART

ART, assisted reproduction technology; FSH, follicle-stimulating hormone; nGnRH, gonadotropin-releasing hormone; IUI, intrauterine insemination; IVF, invitro fertilization; PCOS, polycystic ovarian syndrome, WHO, World Health Organization.

Clomiphene Citrate (Clomid)

Clomiphene citrate is by far the most frequently prescribed agent to stimulate ovulation. It is administered orally as a mixture of two geometric isomers. The Z (*cis*,

zuclomiphene)-diastereomer displays estrogenic activity, and the E (*trans*, enclomiphene)-diastereomer exhibits antiestrogenic activity (Fig. 46.9). Its ability to stimulate ovulation stems from its action at the hypothalamic ERs, where it serves to block these receptors and interfere with natural feedback inhibition. When an estrogen deficiency is perceived by the hypothalamus, it responds by secreting GnRH. This peptide hormone signals the pituitary to release the gonadotropins FSH and LH. Elevated FSH levels promote follicular development, which in turn causes the maturing follicles to secrete estradiol. Clomiphene is administered orally (50 or 100 mg) for 5 consecutive days, typically on days 5 to 9 of the menstrual cycle. Approximately 7 days after the last clomiphene tablet is taken, the hypothalamus finally is able to detect that estradiol levels are elevated, and it then signals the pituitary to secrete LH. This surge in LH causes the dominant follicle to rupture and release an egg, a process known as ovulation.

Table 46.13. Representative Infertility Treatment Options (89)

Treatment Option	Patient characteristics	Pharmacological Therapy
Intrauterine insemination	Mild endometriosis Unexplained infertility Mild male factors	Clomiphene citrate (days 5–9), monitor LH levels
Ovulation induction	Ovulatory disorder PCOS Hyperprolactinemia Hypothalamic amenorrhea Premature ovarian failure	Progestin challenge test; gonadotropin therapy (hMG and/or FSH)
In vitro fertilization (with or without donor oocytes)	Tubal factor Severe endometriosis Unexplained infertility	Ovarian hyperstimulation, hCG
Therapeutic donor	Women without	Sperm donor

insemination	partners Severe male factor	

FSH, follicle-stimulating hormone; hCG, human chorionic gonadotropin; hMG, human menopausal gonadotropin; LH, luteinizing hormone; PCOS, polycystic ovarian syndrome.

The clomiphene citrate challenge test is a diagnostic tool utilized to evaluate ovarian reserve in women older than 35 years of age. The protocol involves measurement of FSH and estradiol levels on day 3 of the cycle, followed by administration of 100 mg of clomiphene citrate on days 5 to 9 and measurement of FSH and estradiol on day 10 of the cycle. Elevated estrogen levels on day 3 are a good predictor of a poor pregnancy prognosis. Any FSH measurement that is high (>10 mIU/mL), even if other levels measured within the same cycle are within the normal range, is interpreted to mean a significantly limited reproductive potential because of poor ovarian reserve (88,91,94).

The adverse effects associated with clomiphene include thickening of the cervical mucus, which creates a substantial barrier for motile sperm. A postcoital test can be performed to determine if this, in fact, represents an insurmountable hurdle. If so, an IUI is warranted to bypass this cervical challenge. Another adverse effect is endometrial thinning, which is not conducive to embryo implantation; if this is the case, additional pharmacological therapies are recommended to thicken the endometrial lining. Other adverse effects include hot flashes and mood swings (95).

Women with low estrogen levels or hypothalamic disorders that result in irregular or absent ovulation are not candidates for clomiphene therapy. There is a 10% chance of having twins and a slightly higher risk of miscarriage in women stimulated with clomiphene (95). Clomiphene-based ovulatory stimulation should only be considered for a maximum of six cycles.

Clomiphene is readily absorbed from the GI tract following oral administration, with a half-life of approximately 5 days. It is metabolized in the liver, and its metabolites are excreted principally in the feces via enterohepatic recirculation.

Human Chorionic Gonadotropin (Pregnyl)

Human chorionic gonadotropin mimics LH both in structure and in function. It is produced by the placenta during pregnancy and is isolated from the urine of pregnant women. In the protocols for IUI or IVF, exogenous hCG must be administered to stimulate a scheduled ovulation. Between 36 and 72 hours after intramuscular administration, the dominant follicle ruptures and releases its egg. At that point, the scheduled IUI or IVF occurs. The hCG can be given in combination with clomiphene citrate to enhance ovulation (95). (For an in-depth discussion of hCG, see Chapter 7.)

Human Menopausal Gonadotropin (Reprondex)

Human menopausal gonadotropin (menotropins) is composed of equal parts FSH and LH and is derived from the urine of menopausal women. This type of therapy is utilized after clomiphene-based therapy has failed or if a patient does not produce sufficient levels of FSH or LH and experiences amenorrhea. These hormones directly stimulate the ovaries to develop multiple follicles per reproductive cycle (95).

Human menopausal gonadotropin has a substantial role in several IVF protocols. It typically is administered

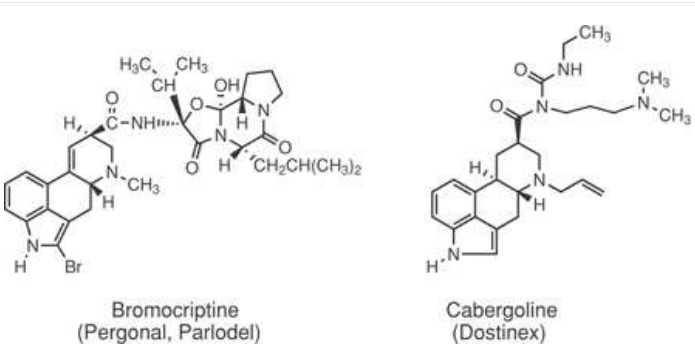
via injection (75 or 150 U) starting on day 2 or 3 of the menstrual cycle and is administered continuously (7–12 days) until shortly before the patient is ready to undergo follicle retrieval. The size and number of maturing follicles, as well as the patient's estrogen level, are closely monitored to maximize the number of follicles retrieved and to minimize the risk of ovarian hyperstimulation syndrome (OHSS) (95).

Adverse effects include injection site reactions and inflammation as well as the possibility of developing OHSS. Menopur, another formulation of menotropins that also contains equal parts FHS and LH, has been shown to cause fewer injection site reactions.

Follicle-Stimulating Hormone (Fertinex, Follistim, Gonal-F)

Two types of products are available that contain FSH. Fertinex contains FSH isolated from the urine of menopausal women and does not contain significant amounts of LH. Follistim and Gonal-F are products that contain only purified synthetic (recombinant) FSH. The recombinant products are more effective at stimulating the development of multiple follicles (92,93). All three agents are administered as a subcutaneous injection. Administration of exogenous FSH circumvents the influence of both the hypothalamus and the pituitary on the ovaries and causes direct stimulation of ovarian follicle growth. Women who fail to achieve pregnancy with clomiphene assistance or who are diagnosed with polycystic ovarian syndrome are candidates for this type of therapy (95). (For additional discussion of FSH, see Chapters 6 and 7).

Dopamine Agonists—Bromocriptine and Cabergoline



The hormone prolactin is responsible for stimulating the production of breast milk in mothers of newborns as well as for inducing lactation infertility. In this situation, FSH and LH secretion is inhibited; therefore, ovulation is prevented. In other populations of women, elevated levels of prolactin can result from the presence of an adenoma, a benign pituitary tumor, or because the pituitary cells that produce prolactin are hyperactive. This hyperactivity may have a pharmacological genesis (e.g., antipsychotics, tranquilizers, painkillers, and alcohol) or a pathophysiological origin (e.g., kidney or thyroid disease). Both bromocriptine and cabergoline suppress prolactin production. Bromocriptine is available as a tablet or capsule and is administered one to four times daily. It also is available as an intravaginal formulation. Cabergoline tablets are administered one to two times weekly. Once the prolactin levels drop to normal levels, the patient should experience improved fertility. If pregnancy is not achieved despite normal prolactin levels, then addition of clomiphene or gonadotropins is warranted (95).

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone is secreted from the hypothalamus in a pulsatile fashion once roughly every 90 minutes. It is rapidly degraded by pituitary endopeptidases and has a circulatory half-life of 2 to 4 minutes. Degradation occurs primarily at the Gly^6 residue. Synthetic efforts to improve peptide stability have resulted in several successful GnRH agonists that contain hydrophobic D-amino acids replacing Gly^6 (96) (see Chapter 7).

When GnRH binds to and activates its pituitary cell surface receptor, it sends a signal for the pituitary to biosynthesize and secrete FSH and LH. This receptor is part of the family of G protein–coupled receptors and is composed of 7-transmembrane domains. Eventually, the receptor hormone complex is internalized, the ligand degraded, and the receptor partially recycled (96).

If a patient is unable to produce sufficient quantities of GnRH, then replacement therapy is available. To mimic normal secretion patterns, this hormone is delivered by infusion every 90 minutes via an external pump worn by the patient (95).

Gonadotropin-Releasing Hormone Agonists and Antagonists

Typically, GnRH agonists are administered continuously and not in normal physiological pulses. As a result of constant stimulation of the GnRH receptors, an initial hyperstimulation of the pituitary occurs, causing a surge in FSH and LH secretion, which is quickly followed by complete cessation of their release. Ultimately, this causes the production of estrogen and progesterone to stop, which prevents ovulation from occurring. In patients who do not have a regular ovulatory cycle, these medications are utilized to squelch all internal influence over ovulation. Once internal hormonal signaling has been silenced, human menopausal gonadotropin can be administered, permitting the physician exquisite control over the levels of pituitary hormones. With exogenous FSH and LH now present, follicle development is stimulated, and oocyte retrieval for IVF is possible. When used continuously, GnRH agonists stifle the natural LH surge associated with ovulation, so hCG must be administered 34 to 36 hours before oocyte retrieval to launch ovulation.

Several GnRH agonists are available, including leuprolide acetate (Lupron) and goserelin acetate (Zoladex), which are injectable agents, and nafarelin acetate (Synarel), which is administered via nasal spray. (Discussion about structure–activity relationships can be found in Chapter 7.)

Two GnRH antagonists, ganirelix acetate (Antagon) and cetrorelix (Cetrotide), are administered by intramuscular injection (95). The primary advantage of the GnRH antagonists over the agonists is that they interact with and effectively block the GnRH receptor without causing an initial surge of FSH and LH. The primary role of both the antagonists and agonists is to prevent a premature LH surge.

In an IVF cycle, the GnRH antagonist is not administered until the dominant follicle reaches 14 mm in diameter, which is nearly a week after gonadotropin therapy is initiated. The GnRH antagonists suffer from low solubility and the tendency to form gels in aqueous solutions (96). Ganirelix acetate has a short half-life and must be administered daily until hCG is administered, whereas cetrorelix has a longer half-life and can be administered once every 3 to 4 days (93). (Discussion about structure–activity relationships can be found in Chapter 7.)

Women whose ovulatory cycle has been managed by gonadotropin therapy have a 25% risk of multiple pregnancies. Some evidence suggests a lower pregnancy rate in patients utilizing protocols that include a GnRH antagonist (96,97). Adverse effects include injection site pain and inflammation, abdominal bloating, mood swings, and menopausal symptoms, including hot flashes and vaginal dryness. The likelihood of developing OHSS is fairly small in protocols that include GnRH agonists or antagonists. In these regimens, the physician has control over the hCG injection necessary to trigger ovulation and can delay—or even withhold—this injection if estrogen levels are too high, a factor that predisposes the patient to develop OHSS (95). It should be noted that GnRH down-regulation caused by these agents may have an adverse effect on oocyte quality, which has a negative impact on an IVF cycle (92).

As part of an assisted reproductive technology protocol, the use of both a GnRH agonist or antagonist and exogenous gonadotropins provides significant benefits, including enhanced stimulation of follicular development, improved oocyte quality, and LH surge suppression, all of which lead to fewer cycle cancellations and improved reproductive capability (92).

Lutropin alfa (Luveris)

Lutropin alfa is the first recombinant human form of LH approved by the U.S. FDA. This agent serves as LH replacement therapy for those women who are hypogonadotropic and hypogonadal with a substantial deficiency in LH (<1.2 IU/L). Lutropin alfa typically is utilized in combination with follitropin alfa to induce follicular growth and development. Both of these agents are administered subcutaneously.

The half-life of lutropin alfa is approximately 10 hours. Treatment should not exceed 14 days unless follicular development is clearly evident. Adverse effects include headache, breast and abdominal pain, and nausea. Lutropin alfa can contribute to the development of OHSS and should not be utilized in women primary ovarian failure or uncontrolled thyroid or adrenal dysfunction or who are pregnant.

Menopause

Physiologically, menopause is described as the loss of ovarian follicle function, followed by the cessation of menses. Before menopause, the body typically is engaged in a 2- to 4-year preamble, complete with the signs and symptoms of menopause (e.g., hot flashes and night sweats). This stage is termed perimenopause and is characterized by a gradual decline in the secretion of estrogen and progesterone. When the ovary no longer prepares follicles for ovulation and the resulting corpus luteum is not formed, a dramatic decrease in the production of estrogen and progesterone occurs, along with the resulting physiological changes, including bone loss, urogenital atrophy, and perhaps, incontinence, vasomotor symptoms, enhanced risk of cardiovascular disease, sexual dysfunction including decreased libido, as well as reduced skin elasticity (98). Many, if not most, of these changes have a negative effect on the quality of life for women during what is considered to be an exceptionally productive time in their lives. Identification of pharmacological and nonpharmacological methods to alleviate these symptoms is essential to improving quality of life during this turbulent hormonal phase at the end of a woman's reproductive lifetime.

History

As early as 1899, the Merck Manual listed several treatments for menopausal symptoms, including the drug Ovarin, which was composed of desiccated and pulverized cow ovaries flavored with vanilla. In 1932, this formulation was largely replaced by products that contained components isolated from the urine of pregnant women. By the late 1930s, these human-derived products were supplanted by Premarin, which contained components isolated from the urine of pregnant mares (99). Other formulations that take advantage of other routes of administration have been available for quite some time as well; for example, in 1928, the first estrogen patch was developed by Searle.

By the 1960s and 1970s, the first studies regarding serious adverse effects associated with estrogen therapy were reported, including severe hypertensive episodes and increased thromboembolic events. In 1978, the U.S. FDA mandated that a comprehensive warning be distributed with all estrogen products, including OCs. This document listed the approved indications and fully described the potential risks of using an estrogen-containing formulation. Despite these warnings, the use of estrogen-containing products actually increased as a result of the U.S. FDA notice that stated that these agents were effective for the prevention of osteoporosis (99).

Hormone Replacement Therapy

Until mid-2002, hormone replacement therapy (HRT) continued to be considered as first-line therapy for the

pharmacological management of menopausal symptoms and for health preventive purposes in postmenopausal women. At that point, the results from the WHI study and, eventually, the WHI Memory Study (100) were released and clearly identified that although HRT (combination of 0.625 mg/day of CEE and 2.5 mg/day of medroxyprogesterone acetate) reduced the incidence of colorectal and endometrial cancers as well as hip fracture, it also increased the incidence of heart attacks, stroke, and breast cancer as well as increased global cognitive impairment (101). Ultimately, the U.S. FDA mandated that safety warnings appear on the package labels for both combination and estrogen-only products to warn women about these risks.

Medical management of menopause largely revolves around treatment of the symptoms caused by estrogen deficiency. Without regular maturation of ovarian eggs, follicles are not consistently formed and, therefore, do not consistently secrete the same levels of estrogen as found in premenopausal women. In postmenopausal women, the primary source of endogenous estrogen (albeit a fraction of that found in premenopausal women) comes from the transformation of androstenedione into estrone. Because the release of FSH and LH by the pituitary gland is governed by estrogen concentrations via negative feedback inhibition, it is no surprise that menopausal women have FSH levels 10- to 15-fold higher and LH levels four- to fivefold higher than those found in premenopausal women (50). In addition, low estrogen levels prevent launch of the normal LH surge that is key to follicular rupture, followed by formation of the corpus luteum. Because the corpus luteum is responsible for the secretion of progesterone, it is, again, no surprise that the levels of this hormone also are out of balance during menopause (102).

The vasomotor symptoms associated with menopause represent some of the most disturbing and, potentially, embarrassing menopause-related effects experienced by women. Since the early 1940s, estrogen replacement therapy with CEE (ERT) has been indicated for the treatment of these symptoms as well as for the treatment of urogenital atrophy and vaginal dryness. For those patients with an intact uterus, progesterone was administered along with the

estrogen to prevent endometrial hyperplasia and endometrial cancer. This type of combination therapy is referred to as HRT. Nearly 90% of menopausal patients experience symptom relief after initiation of either ERT or HRT (Table 46.14) (103,104). Each patient requires individual dose titration to maximize menopausal symptom relief and to minimize side effects (e.g., breast tenderness, weight gain, and vaginal bleeding). Because of the WHI findings, HRT is considered as safe to administer if used short term and if dose reduction occurs after 2 to 3 years of treatment.

Despite the WHI findings, estrogen remains the gold standard in relief of menopausal symptoms. Recently, pharmaceutical manufacturers have concentrated on the development of alternate dosage forms that deliver the minimum dose of estrogen to minimize adverse effects, to maximize therapeutic benefit, and to maintain a more normal ratio of estrone to estradiol. These formulations include several different types of transdermal products, vaginal rings, and vaginal creams. The estrogens found in these products include estradiol, EE (synthetic), piperazine estrone sulfate, and conjugated estrogens. Unfortunately, these estrogens do not have identical potencies. Conjugated equine estrogens, esterified estrogens, and estrone sodium sulfate at 0.625 mg are equivalent to 1 mg of micronized estrogen, 0.75 µg of piperazine estrone sulfate, 5 to 10 µg of EE, or 0.50 µg of transdermal estrogen.

Although estradiol is the most potent endogenous estrogen, it has poor oral bioavailability. Oral administration of estrogen in a conjugated (e.g., estradiol valerate) or micronized (Estrace) form enhances absorption by the GI mucosa; however, when administered via this route, estradiol undergoes extensive hepatic metabolism (CYP3A4) to the corresponding ketone (estrone), which is much less potent. Only 10% of an oral dose of estradiol reaches the circulation (50). Estrone then undergoes sulfate conjugation to an inactive product. In effect, estrone sulfate represents a stable reservoir of circulating estradiol (12,13). Piperazine estrone sulfate (estropipate) also is quickly converted to estrone sulfate when administered orally. In premenopausal women, the physiological ratio of estradiol to estrone is 2:1, but after oral administration of estradiol, this ratio shifts substantially in favor of higher circulating estrone levels.

One mechanism to increase the oral bioavailability of estradiol is to prevent metabolic oxidation of the estradiol C_{17} hydroxyl group to the corresponding ketone. This is readily accomplished via alkylation of the C_{17} position with a chemically inert alkyne group (e.g., EE). This synthetic analogue is several hundred-fold more potent than estradiol, with doses in the microgram rather than the milligram range.

Conjugated equine estrogen, isolated from the urine of pregnant mares, currently is the most popular form of ERT. In addition to the ring-B saturated hormones already discussed (45% estrone sulfate), CEE also contains equilin estrogens that have an unsaturated B ring, including equilin sulfate (25%) and 17α-dihydroequilin (15%). Comparison between human and equine-derived estrogens yields nearly equivalent binding properties between equilin and estrone as well as similar metabolic fates (12).

Another method to keep the ratio of estrone to estradiol more equivalent is to utilize formulations that deliver estrogen via routes that are not subject to first-pass metabolism (e.g., transdermal, intravaginal, and intranasal). In addition, these routes permit ratios of estradiol to estrone similar to those found in premenopausal women (50). Transdermal formulations (Table 46.14) permits utilization

of a lower drug dose and provides continuous systemic availability.

Table 46.14. Hormone Replacement Therapy for Treatment of Menopausal Vasomotor Symptoms (97,101,102)

Dosage Form	Trade Name	Estrogen	Progesterone
Tablets: estrogen only			
	Femtrace	Estradiol acetate	
	Premarin	Conjugated equine estrogens	
	Cenestin	Conjugated estrogens (plant derived)	
	Menest, Estratab	Esterified estrogen	
	Estrace	Micronized 17β-estradiol	
	Ortho-Est, Ogen	Estropipate	
	Enjuvaa	Conjugated estrogens	
		$\Delta^{8,9}$-dehydroestrone sulfate	
Tablets: estrogen/progestin combination			
	Angeliq	Estradiol	Drospirenone
	Prempro	Conjugated estrogens	Medroxyprogesterone acetate (daily)

	Premphase	Conjugated estrogens	Medroxyprogesterone acetate (cyclic)
	FemHRT	Ethynyl estradiol	Norethindrone acetate
	Activella	Estradiol	Norethindrone acetate
	Ortho-Prefest	Estradiol	Norgestimate
Transdermal or percutaneous			
• Spray • Emulsion • Gel • Patch (estrogen)	Evamista	Estradiol	
	Estrasorb	Estradiol	
	Estrogel	Estradiol	
	Climera	Estradiol	
	Estraderm	Estradiol	
	Vivelle	Estradiol	
	Vivelle dot	Estradiol	
	Ortho-Prefest		Norgestimate
• Patch (combo)	Menostar	Estradiol	Levonorgestrel
	Climera Pro	Estradiol	Norethindrone acetate
	Combipatch	Estradiol	Norethindrone acetate
Capsules			
	Prometrium		Micronized progesterone
Intravaginal delivery			
• Tablets • Cream	Vagifem	Estradiol	
	Estrace Vaginal	Estradiol	
	Premarin	Conjugated estrogens	

	Vaginal	Estropipate	
• Ring	Ogen Vaginal	Estradiol	
	Estring	Estradiol acetate	
• Gel (Controlled release)	Femring Crinone		Progesterone

[a]Investigational agent.

Intravaginal administration of micronized estradiol tablets (Table 46.14) represents another avenue for effective estradiol absorption without concern about first-pass metabolism (12). Unfortunately, vaginal creams containing estradiol only achieve 25% of the absorption expected for a similar oral dose. As a result, this formulation is best utilized for the treatment of urogenital atrophy. A sustained release depot formulation of estradiol is available in the form of a vaginal ring (Femring, Estring) (Table 46.14). This type of formulation elutes estradiol or estradiol acetate over a 90-day period, thereby limiting the effort required by the patient. Estring delivers 7.5 µg estradiol/day and is indicated for the treatment of urogenital atrophy. Available in two strengths, Femring releases the equivalent of 50 or 100 µg estradiol/day via estradiol acetate, which subsequently is hydrolyzed to estradiol after release. This ring is indicated for the treatment of several urogenital symptoms associated with postmenopausal atrophy as well as for the treatment of vasomotor symptoms as a result of delivery of sufficient systemic estrogen. Although easy to utilize, percutaneous preparations (topical emulsion, topical gel) (Table 46.14) suffer from inconsistent absorption. Estradiol also is formulated as an intranasal spray that is therapeutically equivalent to both oral and transdermal delivery.

In addition to those identified by the WHI study, the adverse effects of ERT include nausea, headache, breast tenderness, and heavy withdrawal bleeding. Transdermal delivery minimizes headache and nausea, and use of a low-dose oral regimen lessens breast tenderness (50).

Table 46.15. Combination Therapies for the Treatment of Menopausal Symptoms (50)

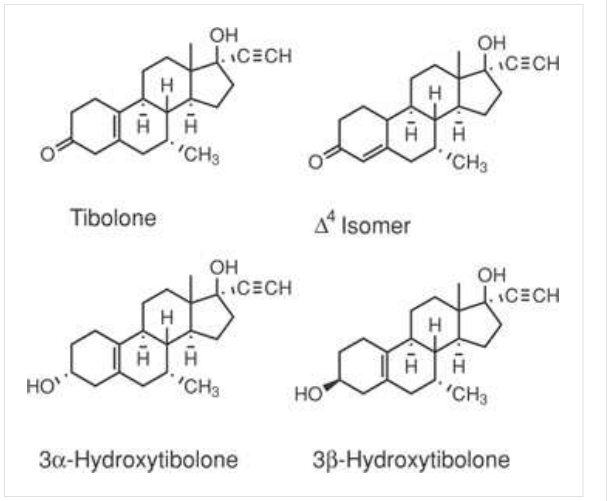
Type of Therapy	Effect of Therapy	Regimen
Oral continuous-cyclic (sequential)	Scheduled withdrawal bleeding	CEE (1-14) + [CEE + MPA] (15-28)
Transdermal continuous-cyclic (sequential)	Scheduled withdrawal bleeding	17β-Estradiol + norethindrone acetate
Oral continuous-combined	Prevents monthly bleeding; unpredictable breakthrough bleeding likely to occur for first 6–12 months	CEE + MPA, 17β-estradiol + norethindrone acetate, ethynyl estradiol + norethindrone acetate
Transdermal continuous-combined	Prevents monthly bleeding	17β-estradiol + norethindrone acetate
Continuous long cycle (cyclic withdrawal)	Reduced monthly bleeding	Estrogen administered daily, progestin given six times/year for 12–14 days
Intermittent-combined (Continuous pulse)	Prevents monthly bleeding	3 days of estrogen alone, followed by 3 days estrogen and progestin combo, repeat continuously

CEE, conjugated equine estrogen; MPA, medroxyprogesterone acetate.

Micronized progesterone (Table 46.14) in combination with oral CEE provides valuable therapeutic benefit in the treatment of menopausal symptoms without

the risk of endometrial hyperplasia. Unless micronized, progesterone is poorly absorbed when administered orally (12). Intravaginal administration of a controlled-release progesterone gel (Table 46.14) results in excellent absorption and more consistent serum levels than orally administered micronized progesterone. Systemic absorption is limited when progesterone is delivered by this route. Intramuscular administration of a progesterone in oil formulation produces the highest serum concentrations but is least likely to be tolerated by patients. The adverse effects associated with the use of oral progestins include irritability, depression, weight gain, and headache. These can be minimized if other routes of administration are utilized (e.g., IUD).

To minimize patient effort and to maximize patient adherence, a number of estrogen/progesterone combination products are commercially available (Table 46.15). Four types of combination regimens are available (oral and transdermal), including both continuous and cyclic therapeutic options. Cyclic regimens require a minimum of 12 to 14 days of progestin administration to prevent endometrial hyperplasia.



Used in perimenopause, administration of a synthetic progestin supplements the waning progesterone produced in the luteal phase of the menstrual cycle. This helps to prevent endometrial hyperplasia and to ensure regular menses despite the irregularity of the menstrual cycle.

Tibolone is a synthetic 19-norpregnane with estrogenic, progestogenic, and androgenic action. With such varied activities, it is no surprise that tibolone is able to treat multiple psychological and physiological menopausal symptoms as well as to confer beneficial health preventive benefits. Administered as a prodrug, tibolone undergoes metabolism in the GI tract to active metabolites (Δ^4 unsaturated, 3α-OH, and 3β-OH derivatives). Although tibolone induces endometrial atrophy in menopausal and postmenopausal women and, therefore, does not cause withdrawal bleeding, it should not be used in perimenopausal women, because it can cause irregular bleeding.

With such concern and confusion surrounding the use of either ERT or HRT for the treatment of menopausal symptoms and postmenopausal health benefits, women have turned to other natural or nonhormonal pharmacological sources of relief (Table 46.16) (105,106). "Hormonal herbs," such as soy, black cohosh, and red clover,

are purported to contain some or all of the phytoestrogens genistein, daidzein, and coumestrol (Fig. 46.18), which possess at least weak estrogenic activity (Table 46.17) (105,106,107) but structurally are nonsteroidal. Other sources of nonsteroidal phytoestrogens, such as resveratrol from the skin of wine grapes (e.g., *Vitis vinifera*), currently are under investigation for their purported estrogenic effects (108). Small studies have indicated that the phytoestrogens may have additional beneficial effects on lipid profile and bone density (50). There is limited evidence that gabapentin and clonidine are effective in reducing the frequency of hot flashes, but their use is limited because of significant side effect profiles.

Table 46.16. Nonhormone Replacement Remedies for Vasomotor Symptoms of Menopause (103,104)

Serotonin Based	Adrenergic Based	GABA Based	Herbals
Venlafaxine (SNRI)	Clonidine	Gabapentin	Soy
Paroxetine (SSRI)	Mirtazepine		Black cohosh
Fluoxetine (SSRI)			Garden sage
Citalopram (SSRI)			Dong quai
Sertraline (SSRI)			Kava
Mirtazepine			Valerian Red Clover Flaxseed

GABA, γ-aminobutyric acid; SNRI, serotonin and norepinephrine reuptake inhibitor; SSRI, selective serotonin uptake inhibitor.

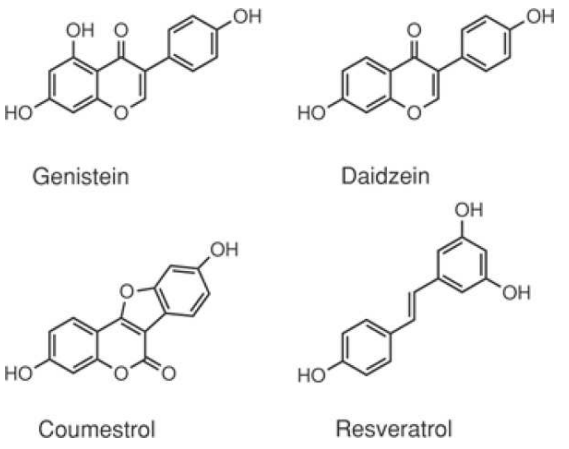


Fig. 46.18. Naturally occurring phytoestrogens.

Several of the newer antidepressants, specifically those that modulate serotonergic neurotransmission, have become more prominent in the treatment of menopausal symptoms. Some even consider this as first-line treatment when hormone therapy is contraindicated. Venlafaxine, a dual serotonin and norepinephrine reuptake inhibitor, has been found to decrease the frequency and substantially reduce the intensity of vasomotor symptoms as well as to improve problems of fatigue and sleep difficulty in more than 50% of the participants in clinical trials (105,109). In comparison, fluoxetine and sertraline, which are selective serotonin reuptake inhibitors (SSRIs), only modestly improve the frequency and intensity of vasomotor symptoms. The effectiveness of paroxetine, another SSRI, mirrors that of venlafaxine. Interestingly, the SSRI citalopram not only is similarly effective as paroxetine but also is effective in those patients in whom vasomotor symptoms did not resolve with venlafaxine treatment. Mirtazepine is an α_2-receptor antagonist as well as a serotonergic (5-HT_2) antagonist. The role of serotonin in modulation of the thermoregulatory processes is only starting to become clear. New evidence indicates that activation of central 5-HT_2 receptors results in hyperthermia; therefore, administration of a 5-HT_2 receptor antagonist should alleviate the thermoregulatory dysfunction associated with estrogen deficiency (105). Interestingly, an endogenous estrogen deficiency causes a reduction in the expression of central 5-HT_2 receptors, which is reversible on administration of an exogenous source of estrogen. There are nonpharmacological avenues to consider when trying to limit the rise in body temperature, including avoidance of caffeine, alcohol, spicy foods, anxiety, and physical contact.

Table 46.17. Herbal Products with Purported Utility in Postmenopausal Women (103,104,105)

Herb	Purported Use	Potential Problems
Soy (beans) *Glycine max*	Contains phytoestrogens—varied evidence for success in treatment of hot flashes	No concurrent treatment with tamoxifen
Black cohosh (root) *Actacea racemosa*	Contains phytoestrogens—purported use for hot flashes, additional studies needed	Possible liver issues
Sage (leaves, flowers) *Salvia officinalis*	Reduces night sweats and hot flashes	Kidney damage (large amounts)
Kava *Piper methysticum*	Reduces anxiety—no evidence for use in hot flashes	Liver damage
Red clover (leaf) *Trifolium pretense*	Contains phytoestrogens—not clinically significant reduction in hot flashes	Interaction with warfarin that can cause bleeding issues
Dong quai (root) *Angelica*	Not effective in treating hot flashes	Interaction with warfarin that can cause bleeding issues

sinensis		
Valerian (root) *Valeriana officinalis*	Treats hot flashes and insomnia	Morning drowsiness
Ginseng (root) *Panax ginseng*	May help with quality of life issues (mood, sleep) but does not help with hot flashes	
Flaxseed	No significant evidence that it helps hot flashes	Alters activity of antiplatelet and anticoagulant drugs

Hormone-Dependent Breast Cancer

Background and Introduction

In the United States, the lifetime risk of developing breast cancer is one in eight, with the greatest incidence in women older than 60 years of age (110). It is the second leading cause of death from cancer in women (lung cancer is number one). An evaluation of 51 studies that represented 52,000 women with breast cancer

P.1332
P.1333

showed a 15% increase in the risk of breast cancer in patients who had taken a combination of estrogen and progestin for less than 5 years. As treatment duration increased, this risk was amplified (111). In the HRT arm of the WHI study, the risk of breast cancer increased, yet in the ERT arm, there was no change in this risk (112). It should be noted that this increase in risk occurred 3 years after initiation of the study. To make matters worse, the breast cancers found in women of the HRT arm were likely to be more advanced than those found in women of the placebo arm of the study. Both arms of the WHI study were terminated prematurely, because the health risks incurred outweighed the benefits. No increased incidence of breast cancer was found in the ERT arm. The incidence of stroke did increase, however, and there was no benefit as it related to coronary heart disease (121).

Menopause and Libido

Despite what you might gather from promotional ads on the television and radio, sexual dysfunction in women occurs much more frequently than in men. Regardless of age (18–59 years), the prevalence of a lack of interest in sex among U.S. women is approximately 30% (113). This loss of sexual desire, a general feeling of lethargy or loss of energy, and reduced muscle strength can be attributed largely to an androgen deficiency. Urogenital atrophy and a decrease in vaginal lubrication in postmenopausal women also are potential reasons for a woman to experience an arousal disorder. These symptoms are directly linked to an estrogen deficiency. Administration of an exogenous androgen, typically testosterone, eases some of these symptoms, but it is unclear if this is a result of androgen receptor activation or of conversion into estradiol. Testosterone can be administered via several routes, including intramuscularly, subcutaneously (implants), or transdermally (patches). Estrogen replacement therapy effectively manages vasomotor symptoms as well as urogenital atrophy and dryness and diminishes some of the psychological symptoms, but it has virtually no effect on the waning libido experienced by many menopausal women. A method to address both sets of symptoms is to administer an oral estrogen/androgen combination (Estratest [methyltestosterone + esterified estrogen]) daily (50). With this type of regimen, it is imperative that the testosterone dose only generates physiological serum testosterone levels so as to maximize therapeutic benefit and minimize undesirable side effects, including virilization and fluid retention (114).

Nonhormonal strategies also are available to treat female sexual arousal disorder. A transdermal formulation of alprostadil, used to treat male erectile dysfunction, has been shown to improve the arousal success rate. Applied 15 minutes before intercourse, this cream can cause local irritation, which is reversible on cleansing (115).

Menopause and Osteoporosis

Osteoporosis causes 1.5 million fractures annually, including hip and spine fractures that increase both morbidity and mortality. In women older than 50 years, one in six will experience a hip fracture, and only 40% of patients older than 55 years with a hip fracture actually recover their mobility (116). (A comprehensive review of pharmacological therapies available for the treatment and prevention of osteoporosis can be found in Chapter 35.)

The estrogen deficiency associated with menopause has a detrimental effect on bone composition and quality. Before 65 years of age, postmenopausal women lose 3 to 5% of their bone mass on an annual basis. After this point, bone loss occurs at a rate of 0.5 to 1.0% annually. This results, in part, from an increase in circulating cytokines (e.g., tumor necrosis factor α, interleukin-1, and interleukin- 6) when estrogen levels are low. These cytokines stimulate differentiation and proliferation of osteoclasts, the cells that normally degrade bone. The WHI study shows a positive correlation between HRT and a substantial decrease in fractures (24%). Currently, HRT (0.625 mg of CEE with 2.5 mg of medroxyprogesterone acetate) is recommended for the prevention, but not the treatment, of osteoporosis. This type of therapy should be initiated shortly after menopause and continued for at least 7 years (102). A lower dose of estrogen (0.3 mg) along with a progestin also may afford ample prevention. Despite the well-documented benefits of HRT in the prevention of osteoporosis, this should not be the primary therapeutic indication. In addition, no estrogen- or progestin-containing products have a U.S. FDA indication for the treatment of osteoporosis (99).

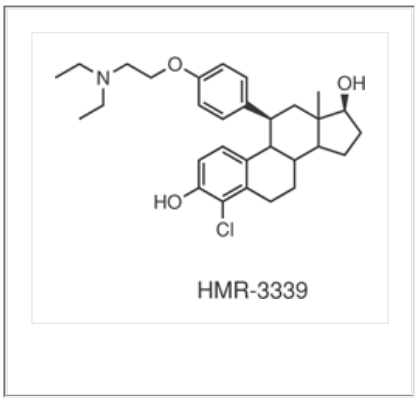
Studies that evaluate the benefit of combination OCs on bone mineral density have produced mixed results. Nearly one-third of these studies indicate no benefit, but the rest show a beneficial effect, including a 25% reduction of hip fractures in postmenopausal women (117). In those patients using a combination OC containing at least 50 µg of the estrogen component, this reduction in the risk of hip fracture improved to 44% (66). In general, the maximal benefits on bone mineral density are observed when the patients are older, have taken OCs for 5 or more years, and have used an OC preparation containing at least 50 µg of estradiol.

Climara Pro (transdermal patch with estradiol [0.045 mg/day] and levonorgestrel [0.015 mg/day]) is indicated for the treatment of the vasomotor symptoms related to menopause. Recently, it has been approved for the prevention of postmenopausal osteoporosis.

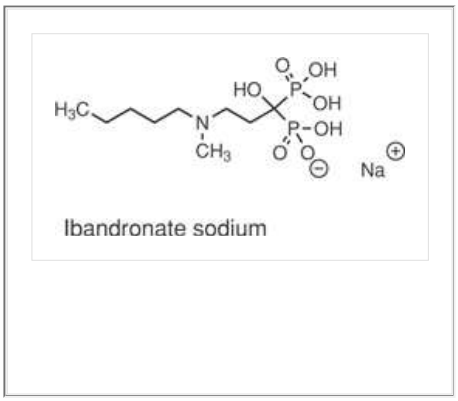
Tamoxifen and raloxifene are SERMs and represent effective nonsteroidal therapy for the treatment of breast cancer and bone loss, respectively. The SERMs are a unique drug class in that a single agent may act as a receptor agonist in select tissues but a receptor antagonist in other tissues. In theory, it might be possible to protect a woman from osteoporosis and to reduce her risk for endometrial, breast, and colorectal cancers without worsening menopausal vasomotor symptoms with one drug. To date, no SERM can meet all these goals simultaneously. Raloxifene, a second-generation SERM, is an estrogenic agonist at the bone and is very effective for preventing osteoporosis without negative endometrial consequences or increasing the risk of breast cancer (see Chapter 35) (50). It is classified as an antiresorptive agent and has been approved by the U.S. FDA for both the treatment and prevention of osteoporosis. It also has a beneficial role in reducing the risk of cardiovascular events in postmenopausal women because of its antiatherogenic effects (reduces low-density lipoprotein [LDL] levels) as well as in decreasing the risk of breast cancer (118). Unlike the bisphosphonates, which decrease both hip and vertebral fractures by 30 to 50%, raloxifene reduces only vertebral fracture by the same percentage. Raloxifene only has an effect on skeletal sites composed of cancellous bone. Unfortunately, raloxifene causes or worsens vasomotor symptoms in approximately 25% of patients, which represent a limitation to its use. In addition, raloxifene causes a threefold increase in the risk for venous thromboembolism, which makes it contraindicated in women with a history of thrombosis. Following oral administration, raloxifene undergoes rapid first-pass metabolism to form its glucuronide conjugates (see Fig. 35.4) and, thus, has an oral bioavailability (~2%).

Because raloxifene only reduces the risk of vertebral fracture, there is a need to identify agents that are effective at multiple skeletal sites with minimal side effects. The novel SERM HMR-3339 improves bone mineral density in adult ovariectomized rats at a variety of skeletal sites (e.g., lumbar spine, tibia, and femur), including those sites composed of cortical bone (118,119). An additional benefit afforded by HMR-3339 is a reduction in total

cholesterol (10–15%) and LDL (10–24%). This antiatherogenic activity, coupled with promising reductions in fracture risk across multiple skeletal sites, makes HMR-3339 a very exciting drug candidate for the treatment of multiple postmenopausal conditions.



Additional SERMs are presently undergoing clinical evaluation for treatment of osteoporosis and menopause-related vaginal atrophy (see Chapter 35).



Ibandronate sodium (Boniva) is one example of the bisphosphonate class of antiresorptive agents and is effective in the treatment and prevention of postmenopausal osteoporosis (see Chapter 35) (120). It was first approved as a tablet (2.5 mg) to be administered daily and later approved as the first once-monthly formulation (150 mg) for the treatment and prevention of osteoporosis (120). In January 2006, the U.S. FDA approved an intravenous formulation of ibandronate sodium (3 mg) to be administered every three months for the treatment of osteoporosis. This type of formulation benefits those patients who have difficulty swallowing oral dosage forms or are unable to remain upright for 30 to 60 minutes. The injectable formulation generated a larger increase in lumbar spine bone mineral density compared to the oral formulations. Bone mineral density in the hip, femoral neck, and trochanter were improved as well. Adverse events associated with the injectable formulation included arthralgia, back and abdominal pain, and hypertension. There is a risk of renal toxicity that is inversely related to the rate of administration of this formulation. Caution is advised in patients who have renal impairment or who are receiving other pharmacological therapy that may negatively affect renal function (118).

According to the WHI study, there was no increased risk of endometrial cancer in patients taking HRT. If unopposed estrogen is administered to a patient with an intact uterus, then a significant increase in the risk of uterine cancer occurs within 2 years of treatment initiation (122). As the dose and duration of treatment increase, this risk grows.

Estrogen deficiency has been correlated with the development of colorectal cancer, the third most commonly diagnosed cancer. When estrogen levels are low, expression of the ER diminishes. Colorectal cells without ER expression are ripe to become cancerous. If estrogen levels are boosted by HRT, then ER expression should improve correspondingly, thereby reducing the number of colorectal cells primed to become malignant. The WHI study clearly shows a substantial decrease (37%) in the occurrence of colorectal cancer in patients treated with HRT.

Molecular Mechanism of Action of the SERMs

The precise mechanism of SERM action is not well understood, but clearly, the ER is a primary target, as a signal transduction pathway, to modulate drug action in different tissues. Different concentrations of ER are present in breast cancers, which can be explained by heterogeneity in the tumor cell population. The more cells in the tumor that contain ERs, the higher the overall ER content, and the more likely the tumor will respond to antiestrogen therapy. Approximately 60% of ER-positive (receptor-rich) tumors are responsive to any form of additive or ablative endocrine therapy, whereas only 10% of ER-negative (receptor-poor) tumors respond to endocrine therapy (123). The current standard of care is to determine the ER status of the tumor in all patients with breast cancer.

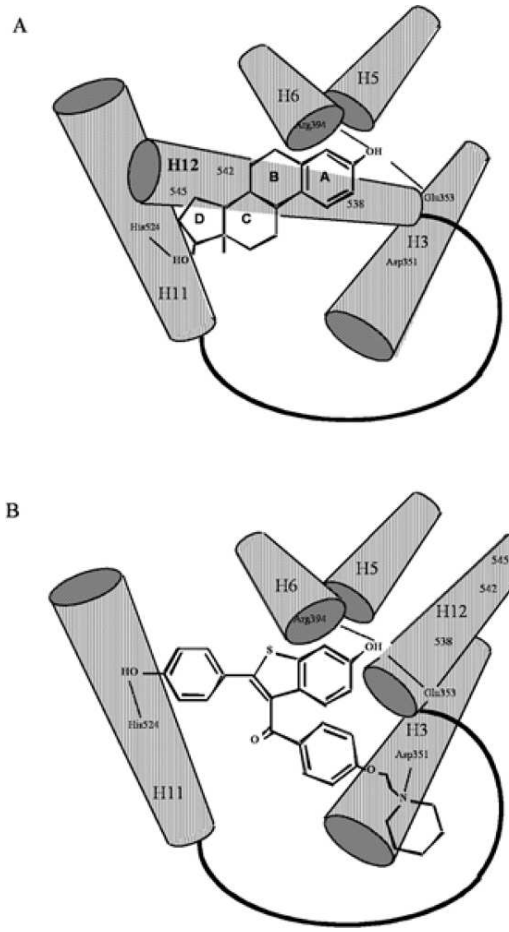


Fig. 46.19. Comparison of the binding of estradiol (A) and raloxifene (B) in the ligand binding domain of the human estrogen receptor (ER). The key event in estrogen action is the repositioning of helix 12 (H12) to seal the steroid into the hydrophilic pocket so that coactivators can bind at the key amino acids indicated on H12. This cannot happen in the raloxifene-ER complex.

The ER is divided into six regions (A–F, as shown in Fig. 46.5) (124). The DNA-binding domain (region C) is essential for the interaction of the ER with an estrogen-response element (125). The ligand-binding domain (region E) is the site of estradiol binding and the site of competitive binding by antiestrogens. The activating function (AF-1 and AF-2) regions are the areas of the ER that interact with coactivator molecules to form an effective transcription unit at an estrogen-responsive gene (126).

Crystallization of the ligand-binding domain (region E) of the ER with estradiol, DES, and raloxifene (127) as well as 4-hydroxytamoxifen (128) has provided an important insight regarding the conformational changes that occur with agonist or antagonist ER complexes. Figure 46.19 illustrates the crystal structure of the estradiol and raloxifene receptor complexes. The most important difference is the position of helix 12, which is essential for the correct binding of coactivators to form a transcription complex at an estrogen-responsive gene. Estradiol causes helix 12 to seal the ligand inside the hydrophobic pocket of the ligand-binding domain. It is hypothesized that this conformation allows coactivator binding. By contrast, raloxifene prevents helix 12 from sealing the hydrophobic pocket, and gene transcription is prevented (because coactivators cannot bind) (127). A similar model is proposed for the 4-hydroxytamoxifen ER complex, but it is clear from studies in vitro that the raloxifene– and 4-hydroxytamoxifen–receptor complexes have different efficacies (129).

The antiestrogenic and some of the estrogen-like actions of SERMs can be explained by the different conformations of the ER-α complexes attracting novel coactivators or corepressors (CoR) (Fig. 46.5) to modulate estrogen action at different sites. In this model, the receptor would be the same at each site, yet the coactivators and corepressors would be distributed differently at different targets (130).

Alternatively, ER-α could be modulated by different concentrations of ER-β at different sites. It has been suggested that ER-β could enhance estrogen-like gene activation through a protein–protein interaction at AP-1 (*fos* and *jun*) sites (131). At present, it is not entirely clear how SERM action is modulated at each target. Indeed, more than one mechanism may occur.

Selective Estrogen Receptor Modulators

Introduction

Lerner et al. (132) described the first nonsteroidal antiestrogen, ethamoxytriphetol (MER25) (Fig. 46.20). This compound is an antiestrogen, with no other hormonal or antihormonal action. Although MER25 behaved as a “morning after” pill in laboratory animals (133), clinical trials associated with other reproductive

and gynecologic applications showed that the drug had low potency and that the dose required caused central nervous system toxicity (134). In the search for more potent antiestrogens, clomiphene also was identified as an effective postcoital contraceptive in laboratory animals (Fig. 46.9) (135). Clinical trials in humans, however, demonstrated that clomiphene induces ovulation (136) and does not prevent implantation. Tamoxifen, a related triphenylethylene (Fig. 46.9), also was discovered as part of a fertility-control program (137). This drug is administered as the Z-diastereomer and, in some countries, is used for ovulation induction (138). Interestingly tamoxifen, clomiphene, and a rigid analogue of tamoxifen, nafoxidine (Fig. 46.20), all inhibit the binding of [^{3}H]estradiol to ER; therefore, it was logical to test their efficacy as breast cancer treatments. Clomiphene and nafoxidine were not pursued after initial

testing as a result of concerns about toxic side effects (139). Although a very low incidence of side effects is associated with tamoxifen, vasomotor symptoms often are evident and negatively affect patient quality of life (140,141,142). During the past 25 years, tamoxifen has become the endocrine treatment of choice for all stages of breast cancer and the first agent to reduce the incidence of breast cancer in high-risk pre- and postmenopausal women (143,144,145). Tamoxifen has now replaced endocrine ablative surgery in both pre- and postmenopausal patients with advanced breast cancer.

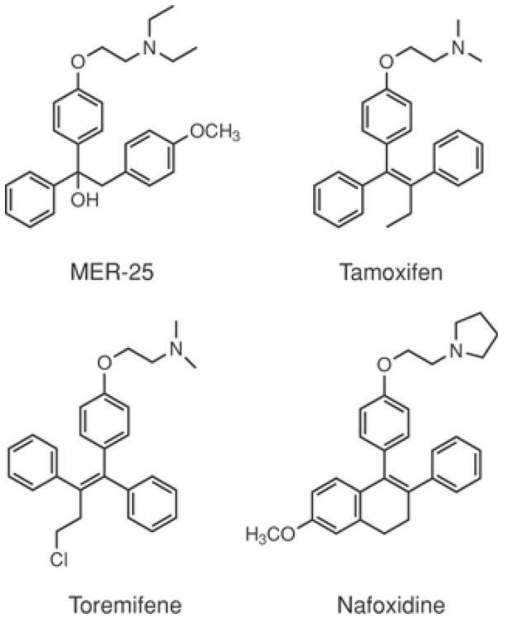

Fig. 46.20. Nonsteroidal antiestrogens.

Tamoxifen (nolvadex)

Tamoxifen (Fig. 46.20) is a SERM that is used as an antiestrogen in the treatment of estrogen-dependent breast cancer following primary treatment (chemotherapy and/or surgery). Therapy is limited to 5 years, because no additional benefit has been identified for treatment regimens of longer duration. Tamoxifen demonstrates only weak estrogenic effects at several sites, including the endometrium and bone, and on the lipid profile (142). Tamoxifen undergoes rapid N-demethylation to its major metabolite, N-demethyltamoxifen, by CYP3A4 and via CYP2D6 to its minor metabolite, 4-hydroxytamoxifen (Fig. 46.21). Evidence suggests that 4-hydroxytamoxifen is the active metabolite of tamoxifen (146,147), with a higher binding affinity than the parent drug for the ER (148). Circulating levels of the demethylated metabolite at steady state are up to twice the level of the parent drug, because the elimination half-life of N-demethyl tamoxifen is 14 days, compared with 7 days for tamoxifen (149). The aminoethyl ether side chain of the triphenylethylene antiestrogens is critical for the antiestrogenic activity of these agents.

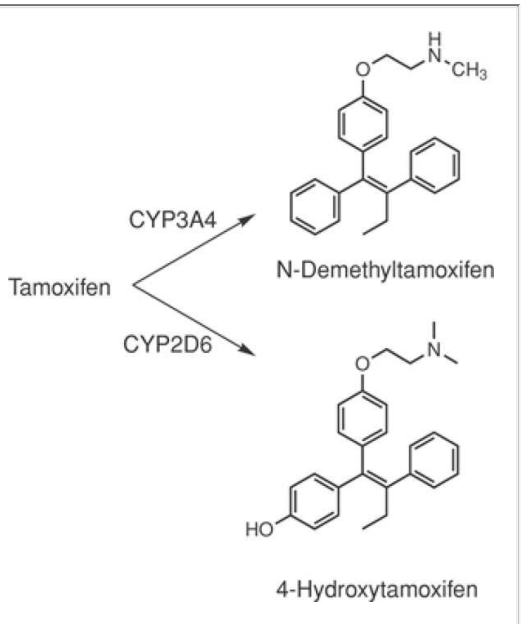

Fig. 46.21. Metabolism of tamoxifen.

Tamoxifen is rapidly absorbed from the GI tract with 100% bioavailability. It undergoes minimal first-pass metabolism and is highly protein bound, primarily to albumin. Tamoxifen's terminal elimination half-life is 5 to 7 days, which is indicative of enterohepatic recycling, elevated protein binding, and metabolic

autoinhibition (142). For those patients receiving concurrent anticoagulation therapy, a dosage reduction of the anticoagulant may be warranted.

After 5 years of tamoxifen therapy, a significant number of patients experience a relapse, primarily because of tamoxifen resistance. What is observed clinically is that the weak estrogenic effects of tamoxifen begin to predominate and effectively "feed" the hormone-dependent tumor.

Toremifene (fareston)

Toremifene is structurally and pharmacologically related to tamoxifen. It differs structurally from tamoxifen because of halogenation (chlorination) of the ethyl side chain, which reduces its antiestrogenic potency (Fig. 46.20). Toremifene demonstrates beneficial effects on the bone and cardiovascular system and increases HDL levels (142).

Toremifene is rapidly absorbed from the GI tract, with 100% bioavailability. It undergoes minimal first-pass metabolism and is highly protein bound, primarily to albumin. Toremifene, like tamoxifen, undergoes rapid N-demethylation, catalyzed by CYP3A4, to its active metabolite, N-demethyltoremifene. It also undergoes deamination-hydroxylation to ospemifene (Fig. 46.22) (142). Because toremifene is extensively metabolized in the liver, it should be used cautiously in patients with hepatic impairment. The terminal elimination half-life for toremifene is 5 to 6 days, which again is indicative of enterohepatic recycling and high protein binding (140).

Ospemifene is another SERM that is currently in Phase III clinical trials for the treatment of postmenopausal osteoporosis and urogenital atrophy (150). As a metabolite of toremifene, it also is under evaluation as an effective treatment for breast cancer. In addition

to its beneficial effects on the bone, ospemifene lowers LDL levels and improves the symptoms of vaginal dryness.

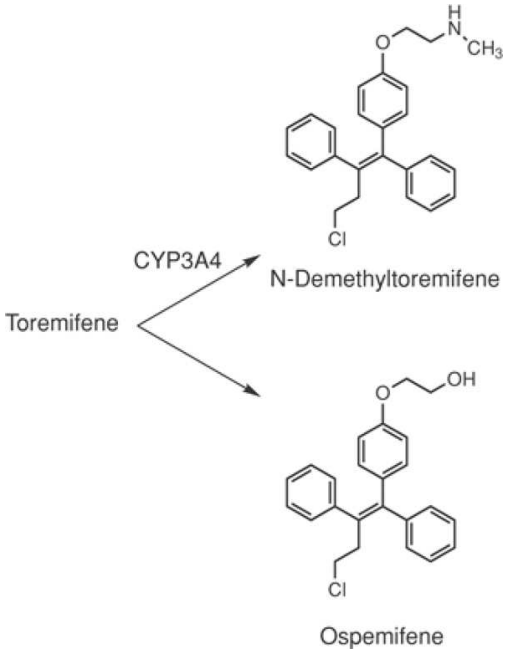

Fig. 46.22. Metabolism of toremifene.

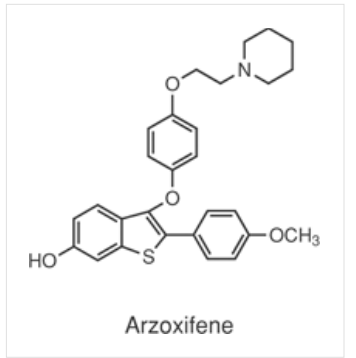


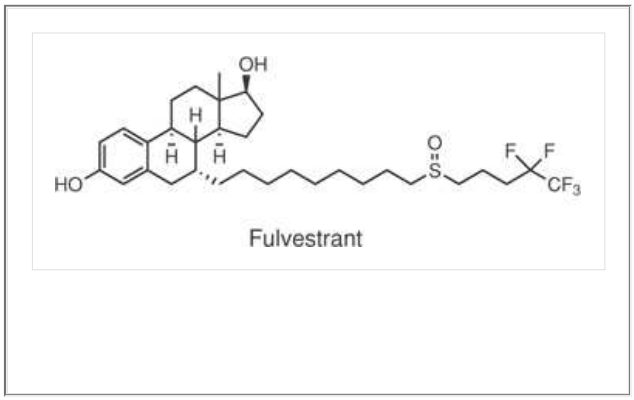
Arzoxifene

Arzoxifene is a third-generation SERM currently in Phase III clinical trials for the treatment of ER-positive recurrent/metastatic breast cancer. Similar to raloxifene, it is an ER antagonist in both breast and uterine tissues and an ER agonist on bone and the cardiovascular system (142,151). Arzoxifene is able to both preserve and build bone mineral density, which makes it a viable candidate for the treatment of osteoporosis. Ample evidence from early clinical trials indicates that arzoxifene also can be utilized as a chemopreventive agent against breast cancer (151,152). Adverse effects include hot flashes (major) and headache, nausea, vomiting, and constipation (minor) (142).

Pure Antiestrogens

Despite the fact that 30 to 40% of patients with advanced breast cancer respond to tamoxifen therapy, this response only lasts for 12 to 18 months.

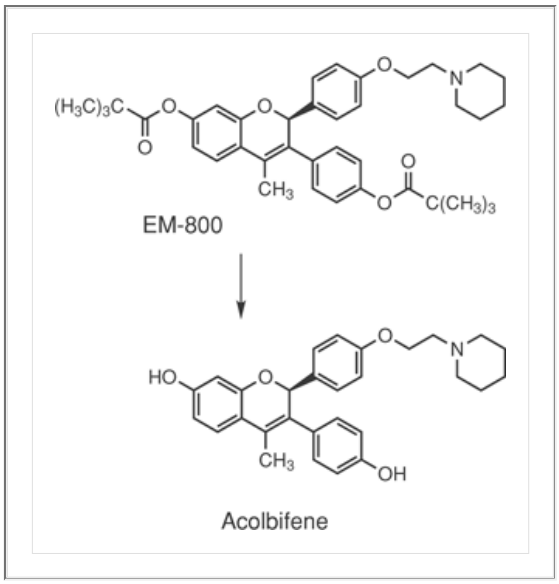
Tamoxifen resistance is caused, in part, by its intrinsic agonist activity at the ER. In addition, tamoxifen only inhibits the AF-2 activation pathway but does not play a role in AF-1 pathway inhibition. Pure antiestrogens do not possess any estrogenic activity in any species or target tissue and, therefore, offer an additional avenue of treatment when resistance to tamoxifen occurs. In addition, because they are devoid of estrogenic action, these agents cannot be classified as SERMs.



Fulvestrant

Fulvestrant (faslodex)

Fulvestrant is effective in preventing the growth of tamoxifen-resistant breast cancers (153) both in the laboratory (154,155) and in clinical trials. It is indicated following antiestrogen therapy for the treatment of ER-positive metastatic breast cancer that has continued to progress (156). Fulvestrant is an estradiol analogue with a hydrophobic side chain in the 7α position. Oral bioavailability is poor despite metabolic protection on the end of the hydrophobic side chain. The rationale for this stems from the fact that fulvestrant is virtually insoluble. As a result, it is administered by intramuscular injection once a month. Metabolism of fulvestrant to both active and less active metabolites is similar to that observed with the endogenous steroids (156). Side effects appear to be minimal and include several GI symptoms, headache, and hot flashes. There is no clinical evidence of uterine stimulation or laboratory evidence of stimulation of endometrial carcinoma models (157). Fulvestrant should not be administered to women who are pregnant, who are taking anticoagulants, or who have thrombocytopenia.



Acolbifene

The prodrug EM-800 is an orally active nonsteroidal antiestrogen and is a triphenylethylene rigid analogue. EM-800 undergoes ester hydrolysis to the

active metabolite acolbifene (158). This fourth-generation antiestrogen is 200-fold more potent than tamoxifen in breast and uterine cancer cells and is effective in patients for whom tamoxifen therapy has failed. The mechanistic rationale for the effectiveness of acolbifene in tamoxifen-resistant tumors is based on the fact that it inhibits both the AF-1 and AF-2 activation pathways and does not possess any intrinsic estrogenic action. Acolbifene enjoys a 60% breast cancer cure rate (159). Structurally, acolbifene resembles raloxifene, with a benzopyran ring substituted for the benzothiophene ring. An additional benefit observed with acolbifene is its protective effect on bone loss. Adverse effects include nausea and vomiting.

Aromatase Inhibitors

Aromatase inhibitors are considered to be first-line therapy in postmenopausal women with metastatic, hormone receptor–positive breast cancer who do not tolerate tamoxifen. Aromatase is a viable target for drug action in the treatment of breast cancer, because it is the enzyme that catalyzes the conversion of androstenedione and testosterone to estrone and estradiol, respectively (Fig. 46.3, g and h). Inhibition of this enzyme limits estrogen production and effectively starves the hormone-dependent tumor. Studies do not clearly indicate that aromatase inhibitors are better first-line agents than tamoxifen and have not clearly identified a portion of this patient population that is more likely to benefit from this class of agents. It is recommended that postmenopausal women who have completed a 5-year regimen of tamoxifen for the treatment of early stage, hormone receptor–positive breast cancer consider extending their treatment with an aromatase inhibitor. It has not yet been definitively established what the optimum duration of treatment should be or whether an aromatase inhibitor should supplant or be sequenced after tamoxifen therapy. The aromatase inhibitors are associated with a lower risk of endometrial cancer and thromboembolic events but with higher rates of fractures and myalgia as compared to tamoxifen.

Letrazole (femara)

Letrazole (Fig. 46.11) is a non-steroidal aromatase inhibitor that was approved for the treatment of postmenopausal women with hormone receptor–positive or hormone receptor–unknown, locally advanced or metastatic breast cancer. By binding to the heme group of aromatase, letrazole inhibits the aromatase and causes a reduction in plasma estrogen levels. Inhibition of aromatase by letrazole is competitive and highly specific, with no effect on enzymes that are responsible for the production of glucocorticosteroids and mineralocorticosteroids (160).

This agent is significantly more effective than tamoxifen in treating hormone-dependent cancer. Letrazole reduces the rate of tumor progression for 9.4

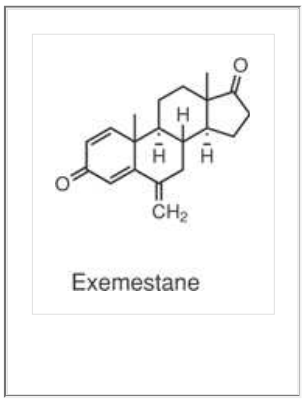
months, compared with 6 months for tamoxifen. Because tamoxifen therapy is limited to only 5 years, patients with breast cancer are left vulnerable to the return of their cancer. There is a 2 to 4% chance each year that the cancer might return. Taking letrazole after this 5-year period decreases the risk of the cancer returning by half. Letrazole also is used in patients who were treated for early forms of breast cancer to prevent disease from recurring. In clinical trials, it was shown that this type of preventive treatment cut the recurrence risk in half.

Letrazole is administered orally (2.5 mg daily) and is rapidly absorbed from the GI tract. Absorption is not affected by food. It is slowly metabolized (CYP3A4 and CYP2A6) to an inactive agent that is subsequently glucuronidated and eliminated renally. Letrazole strongly inhibits CYP2A6 and moderately inhibits CYP2C19. Its metabolism is induced by tamoxifen (142). Letrazole may increase the risk of osteoporosis and can cause hot flashes and night sweats. An increased incidence of hypercholesterolemia also has been documented.

Anastrozole (arimidex)

Anastrozole (Fig. 46.11) is a potent and highly selective, nonsteroidal aromatase inhibitor utilized in the treatment of advanced breast cancer that is hormone-responsive. It is considered to be second-line therapy (after tamoxifen) in the treatment of postmenopausal breast cancer. Anastrozole, a benzyltriazole derivative, competes with the natural substrate for binding to the active site of the aromatase. The mechanism of enzyme inhibition resides in the coordination of the triazole ring with the heme iron atom of the aromatase enzyme complex (161,162). This coordination ultimately prevents aromatization of androgens into estrogens and, therefore, deprives the tumor of estrogen. This effect is reversible. In the presence of anastrozole, estradiol levels are reduced to undetectable levels, with no adverse effects on levels of any other hormone, including cortisol and aldosterone.

Anastrozole is well absorbed orally, with biliary elimination as its primary route (85%) and an elimination half-life of approximately 50 hours (161). Approximately 60% of an oral dose is metabolized in the liver by N-dealkylation, hydroxylation, and glucuronidation to inactive triazole metabolites.



Exemestane

Exemastane (aromasin)

Exemastane is a steroid-based, irreversible aromatase inhibitor that is approved for the treatment of estrogen-dependent tumors and postmenopausal breast cancer. It also has been

approved overseas as adjuvant therapy after 2 to 3 years of adjuvant tamoxifen treatment of ER-positive, invasive early breast cancer. The structure of exemastane is related to androstenedione. It is important to consider the woman's menstrual status when utilizing this agent, because the synthesis of ovarian aromatase is part of a negative feedback loop such that decreased levels of circulating estrogen will promote increased biosynthesis of aromatase. As a result, exemastane should not be administered to premenopausal women or those who are pregnant. Exemastane binds irreversibly to aromatase and, therefore, is classified as a suicide inhibitor. Because this agent has high binding affinity and specificity for aromatase, it is able to suppress the activity of this enzyme by 97.7% (anastrozole, 92–96%; letrozole, 98%) (163).

Exemastane is administered orally (25 mg daily); however, only 50% of a given dose is absorbed. Absorption is improved if the medication is taken following a high-fat meal. Approximately 90% of a dose is bound to plasma proteins. Exemastane undergoes extensive metabolism by CYP3A4, and dosage adjustments may be necessary if given concomitantly with a CYP3A4 inducer (163). Adverse reactions reported in patients with early breast cancer include hot flashes, arthralgia, and fatigue, whereas hot flashes and nausea were the primary adverse reactions noted in patients with advanced breast cancer.

Conclusions

Throughout a woman's reproductive life cycle there are a number of disease states or life circumstances that can be successfully managed with one or more hormone-related therapeutic strategies. Not only is it important to select an appropriate therapeutic regimen for each individual, it also is essential to determine which route of administration and, therefore, which formulation is the most therapeutically advantageous. A number of formulations are available for several single and multicomponent products, and maximizing patient compliance should be considered when recommending a particular product. There are no products devoid of adverse effects, so it is important that these be explained to the patient to minimize discontinuation of the recommended therapy.

The alarming results generated by the WHI studies have fueled the development of new estrogen-containing products designed to deliver lower doses of estrogen to minimize systemic exposure and decrease the risk of cardiovascular disease and development of cancer. In addition, a number of alternative therapies are under investigation for the treatment of menopausal symptoms. Agents that modulate serotonergic neurotransmission seem to be especially promising, because many of these therapies are already known commercial entities.

Pharmacological management of breast cancer continues to make progress with advanced characterization techniques and the use of aromatase inhibitors and SERMs. Future generations of SERMs will need to be completely devoid of estrogenic activity to prevent the development of resistance, as is occurring with tamoxifen.

Case Study

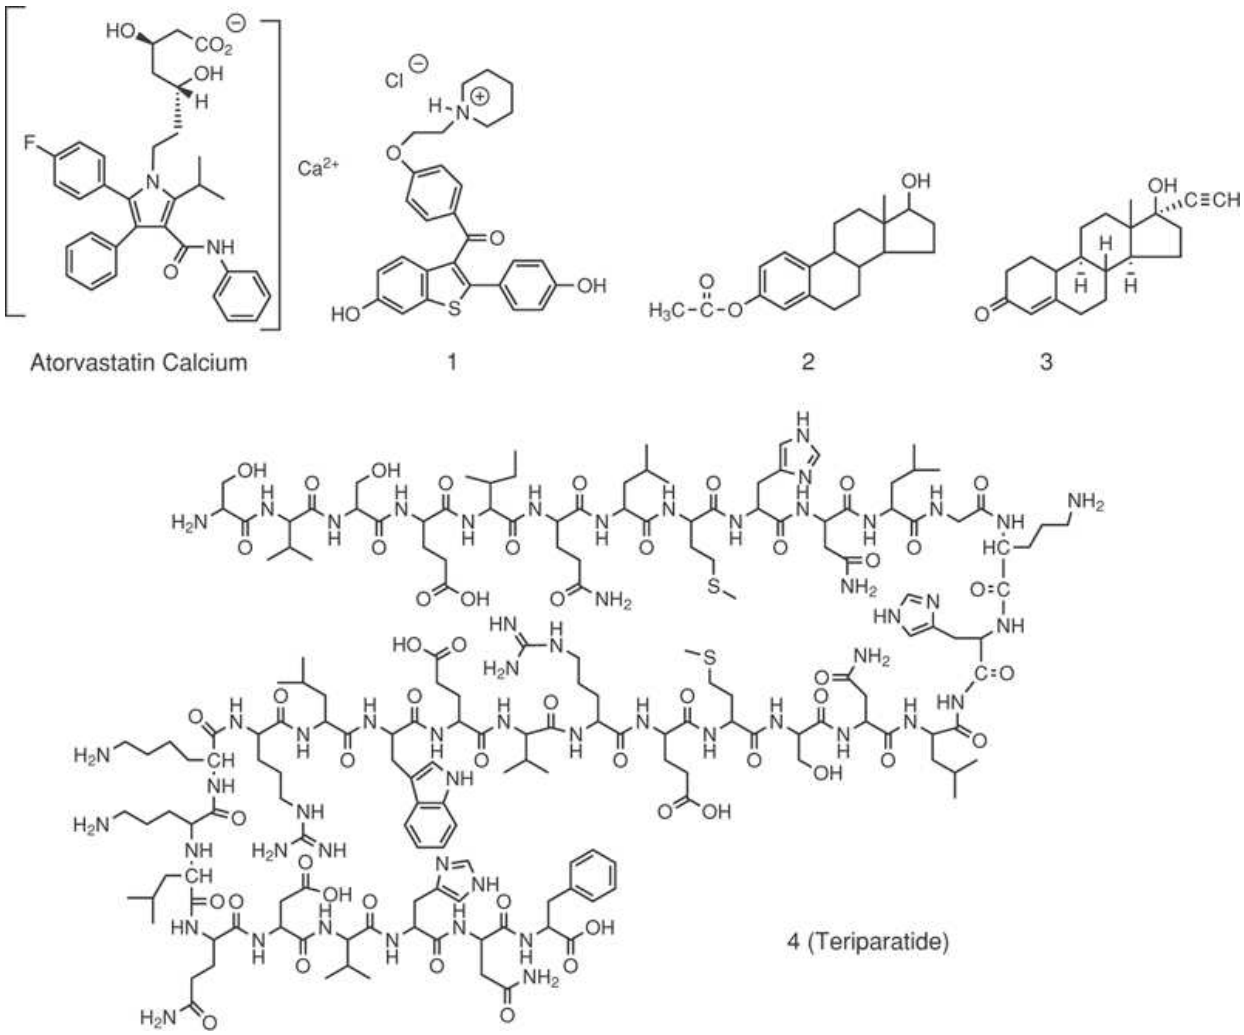
Victoria F. Roche

S. William Zito

AF is a 55-year-old female forensic chemist who has always taken pride in her healthy lifestyle. She has exercised regularly all her life and enjoys sports such as tennis, bicycling, and strenuous hiking. More recently, she has been working out in a gym, running approximately 12 to 15 miles per week, and engaging in a strengthening routine using the gym's weight-training machines. The only medicines that she takes are multivitamins and atorvastatin (Lipitor, 10 mg q.d.) to keep her total cholesterol, triglyceride, and LDL levels low. AF's blood pressure is normal, and her cardiac function is good.

AF's medical history includes uterine cysts that developed during her early forties and, ultimately, resulted in hemorrhagic monthly bleeding. After being diagnosed as severely anemic, she underwent a partial hysterectomy (uterus only) when she was 44 years old. When she began to show signs and symptoms of menopause at age 48, her gynecologist put her on HRT to control regular and severe hot flashes and night sweats. She took her HRT religiously for 6 years, until information from the WHI indicated that she might be at risk for ovarian cancer. There is no history of cancer in AF's family, but she was concerned enough to halt HRT even though her hot flashes and night sweats returned with a vengeance. Her intake of calcium is moderate, with the consumption of one to two glasses of milk per day. She tries to avoid cheese because of a slow but steady gain in weight over the past 2 years.

On noting that AF had lost a quarter-inch in height since her last clinic visit, her gynecologist recommended a bone density determination. The results showed a thinning of the bone. That, along with the fact that her 83-year-old mother has significant osteoporosis, prompted a decision to initiate therapy. Consider the structures of the therapeutic agents drawn below, and prepare to make a recommendation to AF's gynecologist.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Appendix A. *pK_a Values for Some Drugs and Miscellaneous Organic Acids and Bases*

David A. Williams

Table A.1. pK_a Values for Some Drugs and Miscellaneous Organic Acids and Bases

Drugs	pK_a Values HA	pK_a Values HB^+	Reference
Acebutolol		9.2	1
Acenocoumarol	4.7		1
Acetaminophen	9.7		1
Acetanilide		0.5	1
Acetazolamide	7.4, 9.1		3
Acetohydroxamic acid	9.4		1
α-Acetylmethadol		8.6	1
Acetysalicylic acid	3.5		1
Acyclovir	9.3	2.3	1
Adriamycin		8.2	1
Ajamaline		8.2	1
Albuterol	10.3	9.3	9
Alclofenac	4.3		1

Alfentanil		6.5	1
Allobarbital	7.8		1
Allopurinol	9.4		1,4
Alphaprodine		8.7	1
Alprenolol		9.7	1,5
Altretamine		10.3	1
Amantadine		9.0	1
Amidinocillin	3.4	8.9	1
Amiloride		8.7	1
Aminoacrine		10.0	1
p-Aminobenzoic acid	4.9	2.5	1
Aminocaproic acid	4.4	10.8	1
Aminohippuric acid	3.8		1
Aminopterin	5.5		1
Aminopyrine		5.0	1
p-Aminosalicylic acid	3.6	1.8	1
Aminothiadiazole		3.2	1
Amiodarone		6.6	1

Amitriptyline		9.4	15
Amobarbital	7.8		1
Amoxapine		7.6	1,4
Amoxicillin	2.4	9.6	12
Amphetamine		10.0	1
Amphotericin B	5.5	10.0	11
Ampicillin	2.5	7.2	16
Anileridine		3.7, 7.5	1
Antazoline		2.5, 10.1	1
Antipyrine		1.5	1
Apomorphine	8.9	7.0	1
Aprobarbital	8.0		1
Ascorbic acid	4.2, 11.6		1
Atenolol		9.6	6
Atropine		9.8	1
Azatadine		9.3	1
Azathioprine	8.0		9
Azlocillin	2.8		1

Aztrenam	0.7, 2.9	3.9	1
Bacampicillin		6.8	1
Baclofen	5.4	9.5	1
Barbital	7.9		1
Bendroflumethiazide	8.5		5
Benzocaine		2.5	1
Benzphetamine		6.6	1
Benzquinamide		5.9	1
Benztropine		10.0	1
Betahistine		3.5, 9.8	1
Betaprodine		8.7	1
Bethanidine		10.6	1
Bromazepam	11.0	2.9	1
Bromocriptinea		9.8	1
Bromodiphenhydramine		4.9	7
Brompheniramine		3.6, 9.8	1
Brucine		8.2, 2.5	1
Bufuralol		8.9	1

Bumetanide	5.2, 10.0		1
Bunolol		9.3	1
Bupivacaine		8.1	1
Bupropion		7.0	8
Burimamide		7.5	1
Butabarbital	7.9		1
Butacaine		9.0	1
Butaclamol		7.2	1
Butamben		5.4	1
Butorphanol		8.6	1
Butylated hydroxytoluene	7.5		1
Butylparaben	8.5		3
Caffeine	>14.0	0.6	1
Camptothecin		10.8	1
Captopril	3.7, 9.8		4
Carbachol		4.8	1
Carbenicillin	2.7		1
Carbenoxolone	6.7, 7.1		1

Carbinoxamine		8.1	1
Carisoprodol		4.2	4
Carpindolol		8.8	1
Cefaclor	1.5	7.2	8
Cefamandole	2.7		9
Cefazolin	2.1		1
Cefoperazone	2.6		4
Cefotaxime	3.4		4
Cefoxitin	2.2		10
Ceftazidime	1.8, 2.7	4.1	11
Ceftizoxime	2.7	2.1	4
Ceftriaxone	3.2, 4.1	3.2	1
Cefuroxime			4
Cephacetrile			3
Cephalexinb	3.2		1
L-Cephaloglycin	4.6	7.1	1
Cephaloridine	3.4		1
Cephalothin	2.5		1

Cephapirin			4
Cephradine			4
Chenodiol	4.3		1,4
Chloral hydrate	10.0		16
Chlorambucil	5.8		4
Chlorcyclizine		2.1, 8.2	1
Chlordiazepoxide		4.8	1
Chlorhexidine		10.8	1
Chlorocresol	9.6		1
Chloroquin		8.1, 9.9	1
8-Chlorotheophylline	8.2		1
Chlorothiazide	6.8, 9.5		1
Chlorpheniramine		9.0	1
Chlorphentermine		9.6	1
Chlorpromazine		9.3	1
Chlorpropamide	4.9		1
Chlorprothixene		8.8, 7.6	16
Chlortetracyclinec	3.3, 7.4	9.3	1

Chlorthalidone	9.4	1	
Chlorzoxazone	8.3		1
Cimetidine		6.8	1
Cinchonine		4.3, 8.4	1
Ciprofloxacin	6.0	8.8	1
Clindamycin		7.5	9
Clofibrate	3.5		1
Clonazepam	10.5	1.5	1
Clonidine		8.3	1
Clopenthixol		6.7, 7.6	1
Clotrimazole		4.7	10
Cloxacillin	2.8		1
Clozapine		8.0	1
Cocaine		8.7	1
Codeine		8.2	1
Colchicine		1.9	1
Cromolyn	1.1, 1.9		1
Cyanocobalamin		3.4	9

Cyclacillin	2.7	7.5	4
Cyclazocine		9.4	1
Cyclizine		8.0, 2.5	1
Cyclobarbital	8.6		1
Cyclobenzapine		8.5	1
Cyclopentamine		11.5	1
Cyclopentolate		7.9	1
Cycloserine		4.5, 7.4	1
Cyclothiazidec	9.1, 10.5		1
Cyproheptadine		8.9	4
Cytarabine		4.3	1
Dacarbazine		4.4	1
Dantrolene	7.5		1
Dapsone		1.3, 2.5	1
Daunorubicin		8.4	1,4
Debrisoquin		11.9	1
Dehydrocholic acid	5.12		1
Demeclocycline	3.3, 7.2	9.4	1

Demoxepam		4.5, 10.6	1
Deserpidined		6.7	1
Desipramine		10.4	1
Dextroamphetamine		9.9	1
Dextrobrompheniramine		9.3	1
Dextrochlorpheniramine		9.2	1
Dextrofenfluramine		9.1	1
Dextroindoprofen	4.6		1
Dextromethorphan		8.3	1
Dextromoramide		7.0	1
Diacetylmorphine (heroin)		7.8	1
Diatrizoic acid	3.4		1
Diazepam		3.4	1
Diazoxide	8.5		1
Dibenzepin		8.3	8
Dibucaine		8.9	1
Dichlorphenamide	7.4, 8.6		1
Diclofenac	4.5		1

Dicloxacillin	2.8		1
Dicoumarol	4.4, 8.0		1
Dicyclomine		9.0	1
Diethazine		9.1	1
Diethylcarbamazepine		7.7	1
Diflunisal	3.0		1
Dihydroergocriptine		6.9	1
Dihydroergocristine		6.9	1
Dihydroergotamine		6.9	1
Dihydrostreptomycin		7.8	1
Dilevolol		9.5	1
Diltiazem		7.7	1
Dimethadione	6.1		1
Dimethisoquin		6.3	1
Dinoproste	4.9		1
Dinoprostone	4.6		1
Diperodon		8.4	11
Diphenhydramine		9.1	1

Diphenoxylate		7.1	1
Diphenylpyraline		8.9	1
Dipipanone		8.5	1
Dipyridamole		6.4	1
Disopyramide	10.2	8.4	1
Dobutamine		9.5	1,4
Dopamine	10.6	8.9	1
Doxepin		9.0	1
Doxorubicin		8.2, 10.2	1
Doxycycline	3.4, 7.7	9.5	1
Doxylamine		4.4, 9.2	1
Droperidol		7.6	1
Emetine		8.2, 7.4	1
Enalapril	3.0	5.5	1
Enalaprilat	2.3, 3.4	8.0	1
Ephedrine		9.6	1
Epinephrine	8.9	10.0	1
Ergometrine		7.3	1

Ergonovine		6.8	1
Ergotamine		6.4	1
Erythromycin		8.8	1
Estronef	10.8		13
Ethacrynic acid	3.50		1
Ethambutol		6.3, 9.5	1
Ethoheptazine		8.5	1
Ethopropazine		9.6	1
Ethosuximide	9.5		1
Ethoxazolamide	8.1		1
Ethyl biscoumacetate	7.5		1
Ethylmorphine		8.2	1
Ethylnorepinephrine		8.4	1
Etidocaine		7.9	1
Etileprine	9.0	10.2	1
Etomidate		4.2	1
Eugenol	9.8		1
Fenclofenac	4.5		1

Fenfluramine		9.1	1
Fenoterol	10.0	8.6	1
Fenprofen	4.5		1
Fentanyl		8.4	14
Floxuridine	7.4		1
Flubiprofen	4.3		1
Flucloxacillin	2.7		1
Flucytosine	10.7	2.9	1
Flufenamic acid	3.9		10
Flumizole	10.7		1
Flunitrazepam		1.8	1
Fluorouracil	8.0, 13.0		1
Flupenthixol		7.8	1
Fluphenazine enanthate		3.5, 8.2	1
Fluphenazine		3.9, 8.1	1
Flupromazine		9.2	1
Flurazepam	8.2	1.9	1
Furosemide	3.9		1

Fusidic acid	5.4		1
Gentamicinb		8.2	1
Glibenclamide	5.3		9
Glipizide	5.9		1
Glutethimide	9.2		1
Glyburide	5.3		1
Glycyclamine		5.5	1
Guanethidine		8.3, 11.9	1
Guanoxan		12.3	1
Haloperidol		8.3	1
Hexetidine		8.3	12
Hexobarbital	8.2		1
Hexylcaine		9.1	1
Hexylresorcinol	9.5		1
Hippuric acid	3.6		1
Histamine		5.9, 9.8	1
Homatropine		9.7	1
Hycanthone		3.4	1

Hydralazine		0.5, 7.1	1
Hydrochlorothiazide	7.0, 9.2		1
Hydrocodone		8.9	1
Hydrocortisone sodium succinate	5.1		1
Hydroflumethiazide	8.9, 10.7		1
Hydromorphone		8.2	1
Hydroquinone	10.0, 12.0		1
Hydroxyamphetamine		9.3	1
Hydroxyzine		2.0, 7.1	1
Hyoscyamine		9.7	1
Ibuprofen	5.2		1
Idoxuridine	8.3		1
Imipramine		9.5	1
Indapamide	8.8		5
Indomethacin	4.5		1
Indoprofen	5.8		1
Indoramin		7.7	1

Iocetamic acidg	4.1 or 4.3		4
Iodipamide	3.5		1
Iodoquinol	8.0		1
Iopanoic acid	4.8		4
Iprindole	8.2		1
Ipronidazole		2.7	1
Isocarboxazid		10.4	1
Isoniazid		2.0, 3.5, 10.8	1
Isoproterenol	10.1, 12.1	8.6	1
Isoxsuprine	9.8	8.0	1
Kanamycin		7.2	1
Ketamine		7.5	1,11
Ketobemidone		8.7	1
Ketoconazole		2.9, 6.5	1,4
Ketoprofenh	4.8		1,9
Labetalol	8.7	7.4	1
Leucovorin	3.1, 8.1, 10.4		1

Levallorphan tartrate	4.5	6.9	1
Levobunolol		9.2	1
Levodopa	2.3, 9.7, 13.4	8.7	1
Levomethorphan		8.3	1
Levomoramide		7.0	1
Levonordefrin	9.8	8.6	1
Levopropoxyphene		6.3	1
Levorphanol		9.2	1
Levothyroxine	2.2, 6.7	10.1	1
Lidocaine		7.8	1
Lincomycin		7.5	1
Liothyronine	8.4		1
Lisinopril	1.7, 3.3, 11.1	7.0	1
Loperamide		8.6	1
Lorazepam	11.5	1.3	1
Loxapine		6.6	1
Lysergide		7.5	1

Maprotiline		10.2	4
Mazindol		8.6	1
Mecamylamine		11.2	1
Mechlorethamine		6.4	1
Meclizine		3.1, 6.2	1
Meclofenamic acid	4.0		4
Medazepam		6.2	1
Mefenamic acid	4.2		1
Mepazine		9.3	1
Meperidine		8.7	1
Mephentermine		10.4	1
Mephobarbital	7.7		1
Mepindolol		8.9	1
Mepivacaine		7.7	1
Mercaptomerin	3.7, 5.1		1
Mercaptopurine	7.8	11.0	1
Mesalamine	2.7	5.8	1
Mesna	9.1		1

Metaproterenol	11.8	8.8	1
Metaraminol		8.6	1
Methacycline	3.5, 7.6	9.5	1
Methadone		8.3	1
Methamphetamine		10.0	1
Methapyrilene		3.7, 8.9	1
Methaqualone		2.5	1
Metharbital	8.2		1
Methazolamide	7.3		1
Methdilazine		7.5	1
Methenamine		4.8	4
Methicillin	3.0		1
Methohexital	8.3		1
Methotrexate	3.8, 4.8	5.6	1
Methotrimeprazine		9.2	1
Methoxamine		9.2	1
Methoxyphenamine		10.1	1
Methyclothiazide	9.4		1

Methyl nicotinate		3.1	1
Methyl paraben	8.4		1
Methyl salicylate	9.9		1
Methyldopa	2.3, 10.4, 12.6	9.2	1
Methylergonovine		6.6	1
Methylphenidate		8.8	1
Methylthiouracil	8.2		1
Methyprylon	12.0		1
Methysergide		6.62	1
Metoclopramide		0.6, 9.3	1
Metolazone	9.7		1
Metopon		8.1	1
Metoprolol		9.7	1
Metronidazole		2.6	4
Metyrosine	2.7, 10.1		1
Mexiletine		9.1	1
Mezlocillin	2.7		1
Miconazole		6.7	1

Midazolam		6.2	1
Minocycline	2.8, 5.0, 7.8	9.5	1
Minoxidil		4.6	4
Mitomycin		10.9	1
Molindone		6.9	1
Morphine	9.9	8.0	1
Moxalactam	2.5, 7.7, 10.2		4
Nabiloneb	13.5		9
Nadolol		9.4	5
Nafcillin	2.7		1
Nalbuphine	10.0	8.7	4
Nalidixic acid	6.0		1
Nalorphine		7.8	1
Naloxone		7.9	1
Naphazoline		10.9	1
Naproxen	4.2		1
Natamycin	4.6	8.4	8

Neostigmine		12.0	1
Niacin	2.0	4.8	1
Nicotinamide		0.5, 3.4	1
Nicotine		3.1, 8.0	1
Nikethamide		3.5	1
Nitrazepam	10.8	3.2	1
Nitrofurantoin	7.1		1
Norcodeine		5.7	1
Nordefrin	9.8	8.5	1
Norepinephrine	9.8, 12.0	8.6	1,2
Norfenephrine		8.7	1
Normorphine		9.8	1
Nortriptyline		9.7	1
Noscapine		6.2	1
Novobiocin	4.3, 9.1		1
Nystatini	8.9	5.1	11
Octopamine	9.5	8.9	1
Orphenadrine		8.4	1

Oxacillin	2.7		1
Oxazepam	11.6	1.8	
Oxprenolol		9.5	5
Oxybutynin		7.0	4
Oxycodone		8.9	1
Oxymorphone	9.3	8.5	1
Oxyphenbutazone	4.7		1
Oxypurinol	7.7		1
Oxytetracyclinec	3.3, 7.3	9.1	1
Pamaquine		1.3, 3.5, 10.0	1
Papaverine		6.4	1
Pargyline		6.9	1
Pemoline		10.5	1,2
Penbutololc		9.3	1
Penicillamine	1.8, 10.5	7.9	1
Penicillin G	2.8		1
Penicillin V	2.7		1
Pentamidine		11.4	4

Pentazocine	10.0	8.5	2,9
Pentobarbital	8.1		1
Pentoxiphylline		0.3	1
Perphenazine		3.7, 7.8	1
Phenacetin		2.2	1
Phenazocine		8.5	1
Phencyclidine		8.5	2
Phendimetrazine		7.6	1
Phenethicillin	2.8		1
Phenformin		2.7, 11.8	1
Phenindamine		8.3	1
Phenindione	4.1		1
Pheniramine		4.2, 9.3	1
Phenmetrazine		8.5	1
Phenobarbital	7.4		1
Phenolphthalein	9.7		1
Phenolsulfonphthalein	8.1		1
Phenothiazine		2.5	1

Phenoxybenzamine		4.4	4
Phenoxypropazine		6.9	1
Phentermine		10.1	1
Phentolamine		7.7	1
Phenylbutazone	4.5		1
Phenylephrine	10.1	8.8	1
Phenylpropanolamine		9.4	1
Phenyltoloxamine		9.1	1
Phenyramidol		5.9	1
Phenytoin	8.3		1
Physostigmine		2.0, 8.2	1
Pilocarpine		1.6, 7.1	1
Pimozide		7.3, 8.6	1
Pindolol		8.8	1
Piperazine		5.6, 9.8	1
Pipradrol		9.7	1
Pirbuterol		3.0, 7.0, 10.3	1
Piroxicam	4.6		1

Pivampicillin		7.0	1
Polymyxin		8.9	1
Polythiazide	9.8		1
Practolol		9.5	1
Pralidoxime		7.9	1
Pramoxine		6.2	1
Prazepam		2.9	1
Prazosin		6.5	1
Prenalterol	10.0	9.5	1
Prilocaine		7.9	1
Probenecid	3.4		1
Procainamide		9.2	1
Procaine		8.8	1
Procarbazine		6.8	1
Prochlorperazine		3.7, 8.1	1
Promazine		9.4	1
Promethazine		9.1	1
Proparacaine		3.2	11

Propiomazine		9.1	1
Propoxycaine		8.6	1
Propoxyphene		6.3	1
Propranolol		9.5	1
Propylhexedrine		10.4	1
Propylthiouracil	7.8		1
Pseudoephedrine		9.5	1
Pyrathiazine		8.9	1
Pyrazinamide		0.5	1
Pyridoxine	8.96	5.0	1
Pyrilamine		4.0, 8.9	1
Pyrimethamine		7.3	1
Pyrrobutamine		8.8	1
Quinacrine		8.2, 10.2	1
Quinethazone	9.3, 10.7		1
Quinidine		4.2, 7.9	1
Quinine		4.2, 8.5	1
Ranitidine		2.3, 8.2	4

Rescinnamine		6.4	4
Reserpine		6.6	1
Rifampin	1.7	7.9	1
Rimoterol	10.3	8.7	1
Ritodrine		9.0	1
Rolitetracycline	7.4		1
Rotoxamine		8.1	1
Saccharin	1.6		1
Salicylamide	8.2		3
Salicylic acid	3.0, 13.4		1
Salsalate	3.5, 9.8		1,2
Scopolamine		7.6	1
Secobarbital	7.9, 12.6		1
Serotonin	9.8	4.9, 9.1	1
Sotalol	8.5	9.8	1
Sparteine		4.8, 12.0	1
Spiperone		8.3, 9.1	1
Streptozocin		1.3	4

Strychnine		2.3, 8.0	1
Succinylsulfathiazole	4.5		1
Sufentanil		8.0	4
Sulfacetamide	5.4	1.8	1
Sulfadiazine	6.5	2.0	1
Sulfadimethoxine	6.7	2.0	1
Sulfaguanidine	12.1	2.8	1
Sulfamerazine	7.1	2.3	1
Sulfamethazine	7.4	2.4	1
Sulfamethizole	5.5	2.0	1
Sulfamethoxazole	5.6		1
Sulfaphenazole	6.5	1.9	1
Sulfapyridine	8.43	2.6	1
Sulfasalazine	2.4, 9.7, 11.8		1
Sulfathiazole	7.1	2.4	1
Sulfinpyrazone	2.8		1
Sulfisoxazole	5.0		1
Sulindac	4.5		1

Sulpiride		9.1	1
Sulthiame	10.0		1
p-Synephrine	10.2	9.3	1
Talbutal	7.8		1
Tamoxifen		8.9	4
Temazepam		1.6	1
Terbutaline	10.1, 11.2	8.8	1
Tetracaine		8.4	1
Tetracycline	3.3, 7.7	9.7	1
Tetrahydrocannabinol (THC)	10.6		2
Tetrahydrozoline		10.5	1
Thenyldiamine		3.9, 8.9	1
Theobromine	10.1	0.1	1
Theophylline	8.6	3.5	1
Thiazbendazole		4.7	4
Thiamine		4.8, 9.0	1
Thiamylal	7.5		1
Thioguanine	8.2		3

Thiopental	7.5		1
Thiopropazate		3.2, 7.2	1
Thioridazine		9.5	1
Thiothixene		7.7, 7.9	1
Thiouracil	7.5		1
Thonzylamine		2.2, 9.0	1
L-Thyroxine	2.2, 6.7	10.1	1
Ticarcillin	2.6, 3.4		1
Ticrynafen	2.7		1
Timolol		8.8	1
Timoprazole		3.1, 8.8	1
Tiotidine		6.8	1
Tiprofenic acid	30.0		1
Tobramycin		6.7, 8.3, 9.9	2
Tocainide		7.5	1
Tolamolol		7.9	5
Tolazamide	3.1	5.7	1
Tolazoline		10.3	1

Tolbutamide	5.4		1
Tolmetin	3.5		1
Tramzoline		10.7	1
Tranylcypromine		8.2	1
Trazodone		6.7	1
Triamterene		6.2	1
Trichlormethiazide	8.6		1
Trifluperazine		3.9, 8.1	1,3
Triflupromazine		9.2	1
Trimeprazine		9.0	1
Trimethobenzamide		8.3	1
Trimethoprim		6.6	3
Trimipramine		8.0	4
Tripelennamine		4.2, 8.7	1
Triprolidine		6.5	1
Troleandomycin		6.6	1
Tromethamine		8.1	1
Tropicamide		5.3	1

Tuaminoheptane		10.5	1
Tubocurarine		8.1, 9.1	1
Tyramine	10.9	9.3	1
Valproic acid	4.8		1,3
Verapamil		8.9	1
Vidarabine		3.5, 12.5	1
Viloxazine		8.1	1
Vinbarbital	8.0		1
Vinblastine		5.4, 7.4	1
Vincristinej		5.0, 7.4	1
Vindesine		6.0, 7.7	1
Warfarin	5.1		1
Xylometazoline		10.2	1
Zimeldine		3.8, 8.74	1
Miscellaneous organic acids and bases			
Acetic acid	4.8		
Allylamine		10.7	

6-Aminopenicillanic acid	2.3	4.9
Ammonia		9.3
Aniline		4.6
Benzoic acid	4.2	
Benzyl alcohol	18.0	
Benzylamine		9.3
Butyric acid	4.8	
Carbonic acid	6.4, 10.4	
Citric acid	3.1, 4.8, 5.4	
Diethanolamine		8.9
Diethylamine		11.0
Dimethylamine		10.7
p-Dimethylaminobenzoic acid		5.1
Ethanol	15.6	
Ethanolamine		9.5
Ethylamine		10.7
Ethylenediamine		7.2, 10.0

Fumaric acid	3.0, 4.4	
Gluconic acid	3.6	
Glucuronic acid	3.2	
Guanidine		13.6
Imidazole		7.0
Isopropylamine		10.6
Lactic acid	3.9	
Maleic acid	1.9	
Mandelic acid	3.4	
Monochloroacetic acid	2.9	
N-propylamine		10.6
Nitromethane	11.0	
Phenol	9.9	
Phthalic acid	2.9	
Resorcinol	9.2, 11.3	
Sorbic acid	4.8	
Succinimide	9.6	
Tartaric acid	3.0, 4.4	

p-Toluidine		5.3
Trichloroacetic acid	0.9	
Triethanolamine		7.8
Triethylamine		10.7
Tropic acid	4.1	
Tropine		10.4
Uric acid	5.4	

[a]Determined in methyl cellosolve/water (8:2 w/w mixture).
[b]Determined in 66% dimethylformamide.
[c]Determined in 25 to 30% ethanol.
[d]Determined in 40% methanol.
[e]Prostaglandin $F_{2\alpha}$.
[f]Spectrophotometric determination.
[g]The pK_a values of the four optical isomers are 4.1 for two isomers and 4.25 for two isomers.
[h]Determined in methanol/water (3:1 mixture).
[i]Determined in dimethylformamide/water (1:1 mixture).
[j]Determined in 33% dimethylformamide.

Appendix B. *pH Values for Tissue Fluids*

David A. Williams

Table B.1. pH Values for Tissue Fluids

Fluid	pH
Aqueous humor	7.2
Blood, arterial	7.4
Blood, venous	7.4
Blood, maternal umbilical	7.3
Cerebrospinal fluid	7.4
Colona	
Fasting	5–8
Fed	5–8
Duodenuma	
Fasting	4.4–6.6
Fed	5.2–6.2
Fecesb	7.1 (4.6–8.8)
Ileuma	
Fasting	6.8–8.6

Fed	6.8–8.0
Intestine, microsurface	5.3
Lacrimal fluid (tears)	7.4
Milk, breast	7.0
Muscle, skeletalc	6.0
Nasal secretions	6.0
Prostatic fluid	6.5
Saliva	6.4
Semen	7.2
Stomacha	
Fasting	1.4–2.1
Fed	3–7
Sweat	5.4
Urine	5.8 (5.5–7.0)
Vaginal secretions, premenopause	4.5
Vaginal secretions, postmenopause	7.0

[b]Value for normal, soft, formed stools. Hard stools tend to be more

alkaline, whereas watery, unformed stools are acidic.

[c]Studies conducted intracellularly on the rat.
