indolealkylamine or tryptamine derivatives bind at 5-HT_3 receptors in a nonselective manner. Simple O-methylation of 5-HT, however, significantly decreases its affinity for 5-HT_3 receptors. Ergolines either do not bind or bind only with very low affinity. 5-HT is a nonselective 5-HT_3 agonist that binds only with modest affinity (K_i ~ 500–1,000 nM). Its 2-methyl analogue, 2-methyl 5-HT (K_i = 1,200 nM) (Fig. 14.12) is somewhat more selective but binds with slightly lower affinity than 5-HT. Although 2-methyl 5-HT may be only a partial agonist, it has found widespread application in 5-HT_3 research because of its greater selectivity over 5-HT. Recently, however, 2-methyl 5-HT was shown to bind at 5-HT_6 receptors. The N,N,N-trimethyl quaternary amine analogue of 5-HT, 5-HTQ, binds with approximately 10-fold greater affinity than 5-HT and is much more selective than 5-HT; however, because of its quaternary nature, it might not readily penetrate the blood-brain barrier when administered systemically. Using cloned mouse 5-HT_3 receptors, 5-HT and 5-HTQ act as full agonists, suggesting that the quaternary nature of 5-HTQ has little effect on efficacy, whereas 2-methyl 5-HT and tryptamine act as partial agonists. Another example of a low-affinity (K_i ~ 1,000 nM) 5-HT_3 agonist is phenylbiguanide. *meta*-Chlorophenylbiguanide (*m*CPBG), which binds in the low nanomolar range (K_i ~ 20–50 nM) and retains agonist character, has largely replaced phenylbiguanide. Because of its polar nature, *m*CPBG does not readily penetrate the blood-brain barrier. *meta*-Chlorophenylguanidine (MD-354; *m*CPG) shows that the entire biguanide moiety is not required for serotonergic activity. Adding multiple chloro groups to *m*CPBG or *m*CPG increases their lipophilicity and affinity (72).

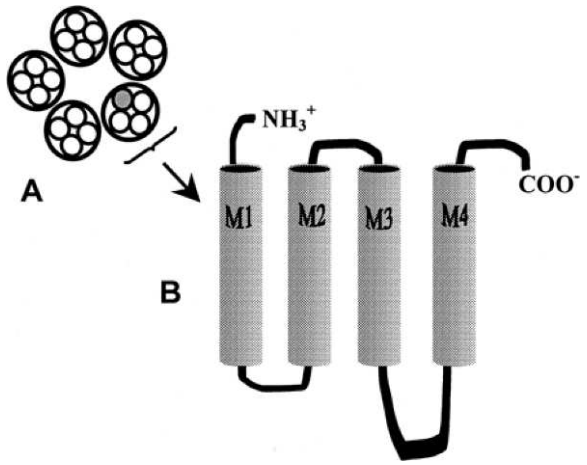

Fig. 14.11. Top (A) and side (B) views of a schematic representation of an ion channel receptor. Ion channel receptors are pentameric units arranged to form a pore or ion channel. Each subunit consists of four transmembrane-spanning amino acid chains (M_1–M_4) constructed such that the M_2 chain faces the channel. The transmembrane portions are connected by extracellular and intracellular loops. In the serotonin family, only 5-HT_3 receptors have been identified as ion channel receptors.

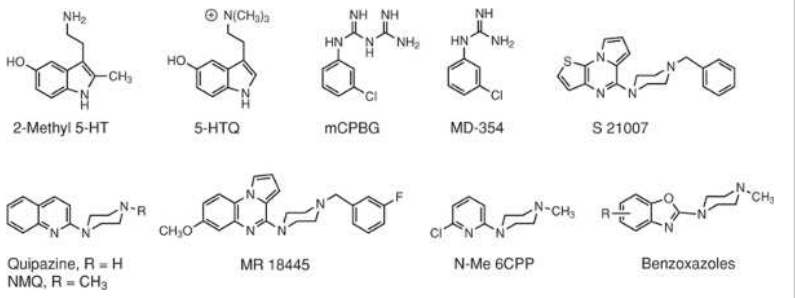

Fig. 14.12. 5-HT_3 agonists or partial agonists.

Simple arylpiperazines were among the first serotonergic agents investigated at 5-HT_3 receptors. Many are nonselective 5-HT_3 ligands (see previous discussion of 5-HT1A receptors). Depending on the particular substitution pattern, they can behave as 5-HT_3 agonists, partial agonists, or antagonists (72). This nonselectivity probably accounts for the initial lack of interest in arylpiperazines as 5-HT_3 ligands, but today, there is renewed interest in these types of agents. Quipazine was the first arylpiperazine shown to bind at 5-HT_3 receptors, even though it also is a 5-HT_{2A} agonist. It binds with much higher affinity than 5-HT at 5-HT_3 receptors (K_i ~ 1 nM), and was subsequently shown to act as an agonist in certain assays and as an antagonist in others. Interestingly, its structure was quite different from that of other 5-HT_3 antagonists known at that time. Early structure–affinity studies showed that its (pyridine-ring) centroid to N_4-piperazine nitrogen distance (~5.5 Å) was similar to that of 5-HT. Other findings indicated that 1) the N_4-piperazine nitrogen atom, but not the N_1-piperazine nitrogen atom, was important for binding; 2) the quinoline ring nitrogen atom was a major contributor to binding; 3) the benzene ring portion of the quinoline nucleus was not required for binding, but its presence was optimal for high affinity; and 4) N_4-methylation (N-methylquipazine) enhances 5-HT_3 receptor selectivity (Fig. 14.12) (72). With the availability of newer arylpiperazines, it has been possible to conduct more comprehensive structure–activity studies. A summary of quipazine SAR is shown in Figure 14.13; results of other SAR studies and several pharmacophoric models have been described (72). Appropriate structural modification of arylpiperazines can result in rather selective 5-HT_3 agonists (Fig. 14.12). For example, ring-fused quipazine-related analogues, such as the pyrrolo[1,2-a]quinoxalines, represent novel 5-HT_3 agonists. Some are full agonists, whereas other (e.g., MR 18445) are partial agonists (72,73,74,75).

Structure–Activity Relationship of 5-HT_3 Antagonists

Bemestron (MDL-72222) was the first selective 5-HT_3 antagonist (Fig. 14.14). Its development stems from the structural modification of cocaine, an agent that had been previously shown to be a weak 5-HT-M antagonist. Since then, many hundreds of 5-HT_3 antagonists have been identified (75,76). Many of these agents belong to the structural

class of compounds broadly referred to as keto compounds and contain an amide, reverse amide, ester, reverse ester, carbamoyl, or ketone function. Typical of these 5-HT_3 antagonists is retention of the bulky tropane or tropane-like amine group. Some of the more widely used or newer agents include dolasetron (Anzemet), granisetron (Kytril), itasetron, renzapride, ricasetron, tropisetron, WAY-100289, zacopride, and zatosetron. It should be noted that some of these keto compounds also bind at 5-HT_{1P} and 5-HT_4 receptors.

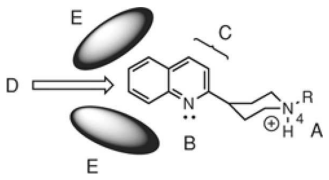

Fig. 14.13. Structure–activity composite for quipazine binding at 5-HT_3 receptors (4,97,100,105). (A) The N_4-piperazine nitrogen atom, but not the N_1-piperazine nitrogen atom, is important for binding; an R_5-CH_3 is tolerated and results in somewhat greater 5-HT_3 selectivity. (B) The quinoline nitrogen atom is required for high affinity, and its replacement by an sp2-hybridized carbon atom results in a more than 100-fold decrease in affinity. (C) Substituents in this region are tolerated and can influence intrinsic activity (105). (D) An aromatic moiety (e.g., benzene ring or isosteric structure), although not required for binding, results in optimal affinity. (E) Regions of limited bulk tolerance.

A related group of antagonists that possess an imidazole or related heterocyclic terminal amine include ondansetron (Zofran), alosetron (Lotronex), fabesetron, and ramosetron (Fig. 14.15). Many others have been described (75,76). The SARs of 5-HT_3 antagonists have been reviewed in detail elsewhere (75,76,77).

Molecular modeling studies have identified a pharmacophore (Fig. 14.16) that is common to many 5-HT_3 antagonists (75,78). The 5-HT_3 antagonists remain a very important area of research, and refinements of 5-HT_3 pharmacophores (76) are very likely to lead to the development of novel therapeutic agents.

5-HT_3 Receptors: Clinical Implications

Preclinical studies suggest that 5-HT_3 antagonists may enhance memory and be of benefit in the treatment of anxiety, depression, pain, and dementia (71,79,80). There have been claims that 5-HT_3 antagonists may represent a novel class of atypical antipsychotics. Additional clinical trials, however, are required to substantiate these claims (80). Finally, evidence suggests that 5-HT_3 antagonists may suppress the behavioral consequences of withdrawing chronic treatment with drugs of abuse, including alcohol, nicotine, cocaine, and amphetamine (75,80). It has been mentioned that one of the most attractive features of 5-HT_3 antagonists is their general lack of the undesirable side effects characteristic of many psychotherapeutic agents. Very little is known about the possible therapeutic application of 5-HT_3 agonists (72).

One of the most noteworthy clinical success stories in 5-HT research relates to the antiemetic properties of 5-HT_3 receptor antagonists. Ondansetron was introduced as an antiemetic in the 1990s, and 5-HT_3 receptor antagonists are now the "gold standard" for treatment of chemotherapy- and radiation-induced nausea and vomiting (81). Twenty or so years ago, nausea and vomiting were inevitable side effects that forced many patients to delay or avoid chemotherapy (82). With the current antiemetic therapy, nausea and vomiting can be prevented

in nearly 80% of patients (82). The most commonly employed 5-HT_3 receptor antagonists are ondansetron, granisetron, dolasetron, and in Europe, tropisetron; a new 5-HT_3 antagonist in clinical use in the United States is palonosetron (83). The various 5-HT_3 antagonists are commonly perceived as being of comparable efficacy and safety (84); however, they vary widely in their pharmacological and pharmacokinetic properties (81,82,83,84) (Table 14.4). For example, their duration of action and elimination half-lives differ considerably. Ondansetron displays the shortest half-life (~4 hours), whereas the half-life of palonosetron has been reported to be up to 128 hours (84). Another difference in their pharmacology is that ondansetron is a competitive 5-HT_3 antagonist, whereas granisetron and tropisetron (and, perhaps, palonosetron) produce an insurmountable antagonism (83,84). Selection of a particular 5-HT_3 antiemetic follows specific guidelines that are related, at least in part, to such factors as the emeticity of the chemotherapeutic regimen, side effect tolerability, patient history, and financial considerations. Patients who are refractory to the effect of a particular antiemetic may benefit by switching antiemetic agents—improvement might be related to different routes of metabolism (81) (Table 14.4).

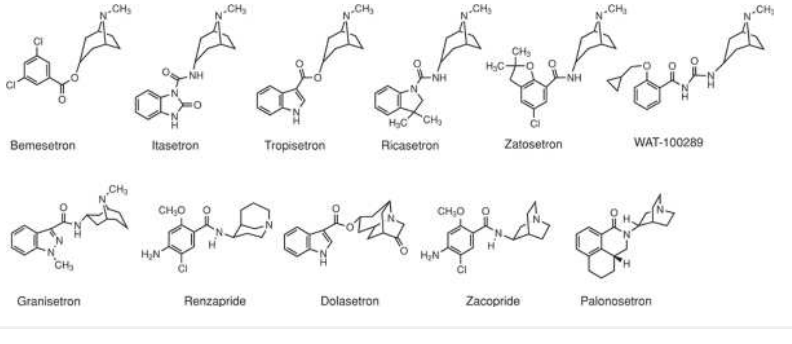

Fig. 14.14. 5-HT_3 antagonists.

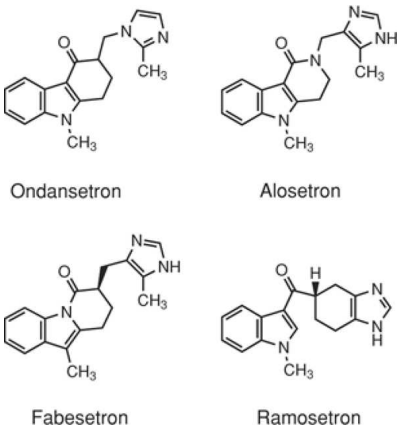

Fig. 14.15. Imidazole-containing 5-HT_3 antagonists.

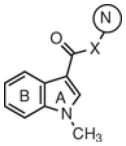

Fig. 14.16. A general pharmacophore model for 5-HT_3 antagonists. An aromatic centroid (A) to oxygen (O) distance of 3.3 to 3.5 Å is thought to be optimal. Distances calculated from the terminal amine (N) to the oxygen atom (O) and from the terminal amine N to centroid A are from 5.1 to 5.2 and from 6.7 to 7.2 Å, respectively. It has been speculated that ring A is not required for binding and acts as a spacer. Ring B may be more important for binding, and associated hydrophobic binding regions has been proposed (74,147).

5-HT_4 Receptors and Agents

A novel population of serotonergic receptors, originally identified in primary cell cultures of mouse embryo colliculi neurons and later termed 5-HT_4 receptors, have broad tissue distribution and are positively coupled to adenylate cyclase (85). In the brain, 5-HT_4 receptors appear to be localized on neurons and may mediate the slow excitatory responses to 5-HT. Peripherally, these receptors facilitate acetylcholine release in guinea pig ileum and may play a role in peristalsis. The uniqueness of this receptor type and its potential therapeutic utility spurred initial interest in drug development. Human 5-HT_4 receptors have been cloned and display low transmembrane sequence homology (<50%) with other 5-HT receptors. In fact, two 5-HT_4 isoforms have been isolated, a long form (5-HT_{4L}) and a short form (5-HT_{4S}). These isoforms are splice variants and differ only in their C-terminus ends, with identical transmembrane regions (86). In general, the potency of agonists to stimulate cyclic adenosine monophosphate (cAMP) was greater for the 5-HT_{4S} receptor than for the 5-HT_{4L} receptor. It has been suggested that 5-HT_4 receptors might exist in high- and low-affinity states, as previously described for 5-HT_2 receptors (87). A mouse 5-HT_{4L} receptor has been cloned, and a human pseudogene has been identified that codes for a 5-HT_4-like receptor. Indeed, several new human 5-HT_4 receptor isoforms have been recently cloned and expressed (88). The new 5-HT_4 receptors have been termed 5-$HT_{4(b)}$, 5-$HT_{4(c)}$, and 5-$HT_{4(d)}$; the stimulatory pattern of cAMP formation in response to the 5-HT_4 agonist renzapride was found to be different for the various isoforms, suggesting that the splice variants might differ in the manner by which they trigger signal transduction following receptor activation (88). In the rat gastrointestinal tract, both 5-HT_{4L} and 5-HT_{4S} receptors are expressed, whereas only 5-HT_{4S} receptors are found in the heart, with localization almost exclusively in the atrium. The 5-HT_{4a} receptors have been cloned from human atrium and appear to correspond to the rodent 5-HT_{4S} isoform. It has been proposed that the cardiac effects of 5-HT are mediated by this short splice variant, whereas 5-HT_{4L} determines the neuronal effects of 5-HT (88).

Although 5-HT_3 receptors are ion channel receptors and 5-HT_4 receptors represent G protein–coupled receptors (Table 14.2), a number of 5-HT_3 ligands are active at 5-HT_4 receptors. Even more interesting is that a number of 5-HT_3 antagonists, or what were considered at one time to be 5-HT_3-selective antagonists (e.g., renzapride and zacopride), actually exhibited 5-HT_4 agonist activity. Even today, there is considerable structural similarity among the various 5-HT_3 and 5-HT_4 ligands. In addition to their lack of selectivity for 5-HT_4 versus other 5-HT

P.434

P.435

receptors, many early 5-HT_4 ligands suffered from several other disadvantages, such as their affinity for other receptor types, inability or difficulty in penetrating the blood-brain barrier, and hydrolytic instability (89).

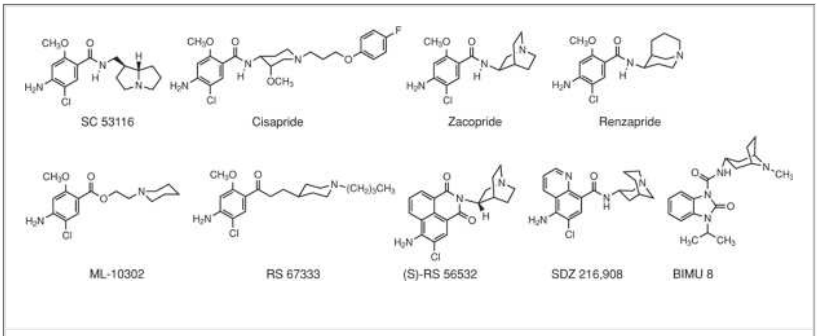

Fig. 14.17. 5-HT$_4$ agonists.

Structure–Activity Relationships of 5-HT$_4$ Agonists

In general terms, 5-HT$_4$ agonists can be divided into several different categories (Fig. 14.17) (90): tryptamines (e.g., 5-HT and 5-CT, with 2-methyl 5-HT and 5-methoxy-N, N-dimethyltryptamine being nearly inactive), benzamides (particularly those bearing a 2-methoxy-4-amino-5-chloro substitution pattern, e.g., SC 53116, renzapride, zacopride, and cisapride), benzimidazolones (e.g., BIMU 8), quinolines (e.g., SDZ 216,908), naphthalimides (e.g., *S*-RS 56532), benzoates (ML-10302), and ketones (e.g., RS 67333).

Structure–Activity Relationships of 5-HT$_4$ Antagonists

The 5-HT$_3$ antagonist tropisetron was the first agent to see application as a 5-HT$_4$ antagonist, and its low affinity for 5-HT$_4$ receptors prompted a search for higher-affinity agents. Various agents now have been identified (76,90,91,92), and 5-HT$_4$ antagonists are derived from structural classes similar to those from which the 5-HT$_4$ agonists are derived. These include indole esters and amides (e.g., GR 113,808), benzoates (e.g., SB 204070), benzimidazolones (e.g., DAU 6285), imidazoles (e.g., SC 53606), and ketones (e.g., RS 100235) (Fig. 14.18). These are just a few representative examples of the many agents that have been examined as 5-HT$_4$ antagonists. Structure–activity details for several different receptor preparations have been reviewed (76,90,91,92). It is worth noting that apart from 5-HT$_3$ receptors, 5-HT$_4$ receptors

are the only other population of serotonergic sites that seem to accommodate quaternary amines.

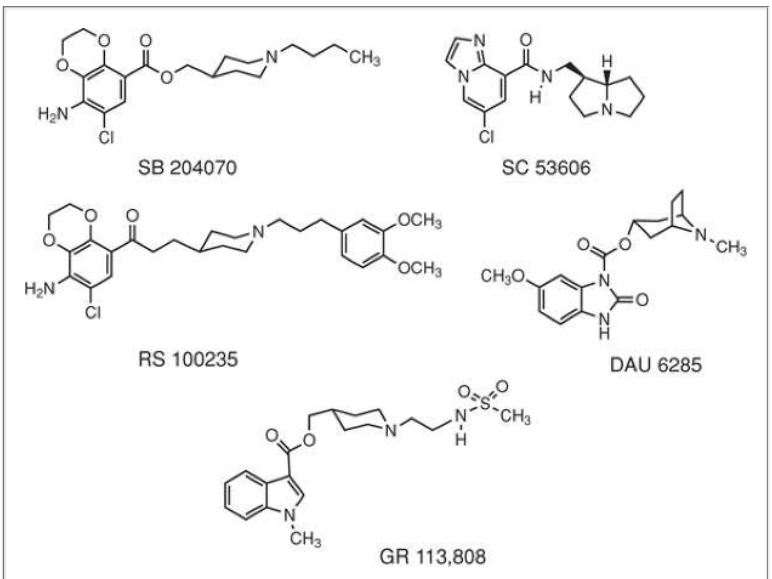

Fig. 14.18. 5-HT$_4$ antagonists.

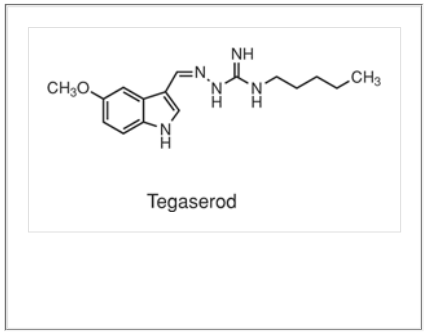
5-HT$_4$ Receptors: Clinical Implications

Only relatively recently have selective 5-HT$_4$ agents been developed, and studies regarding the clinical potential of 5-HT$_4$ agents are still in their infancy. Peripheral actions currently being examined include irritable bowel syndrome (IBS), gastrointestinal tract motility, bladder contraction, gastroesophageal reflux, corticosteroid secretion, and atrial contractility (90). Cisapride was available as a prokinetic agent. With respect to their central effects, it has been suggested that 5-HT$_4$ agonists may restore deficits in cognitive function and that 5-HT$_4$ antagonists may be useful as anxiolytics or in the treatment of dopamine-related disorders. It is further speculated that 5-HT$_4$ receptors may be involved in memory and learning, and it has been noted that 5-HT$_4$ receptors are markedly decreased in patients with Alzheimer's disease (93,94). A high density of 5-HT$_4$ receptors in the nucleus accumbens has led some to speculate that these receptors may be involved in the reward system and that they might influence drug self-administration behavior. Other central roles also are beginning to emerge; for example, repeated administration of antidepressants decreases the responsiveness of central 5-HT$_4$ receptors to activation (95). It would appear that therapeutic roles exist for both 5-HT$_4$ antagonists and 5-HT$_4$ agonists. It has been cautioned, however, that the use of highly potent and selective 5-HT$_4$ agonists might result in cardiovascular side effects (94). If different 5-HT$_4$ receptor isoforms can be shown to mediate the various effects for which 5-HT$_4$ receptors have been implicated, the potential exists for the development of selective agents. Another problem associated with 5-HT$_4$ agents is their lack of oral bioavailability; progress is now being made in this area (96).

Irritable bowel syndrome is one of the most common gastrointestinal disorders in the United States accounting for more than 3.5 million doctor visits per year (97). Irritable bowel syndrome is characterized by abdominal discomfort or pain associated with altered bowel function (i.e., constipation [IBS-C]), diarrhea (IBS-D), or alternating constipation and diarrhea (IBS-A). Until recently, treatment has been limited by the poor efficacy or side effects of available agents. Agents commonly employed to treat IBS include laxatives, antispasmodics and smooth muscle relaxants (e.g., dicyclomine and hyoscyamine), and tricyclic antidepressants, but only 40% of patients are satisfied with these medications (97). Because more than 95% of all serotonin in the body is found in the gut, it would seem logical that serotonergic agents should be of benefit in the treatment of IBS.

In general, peristaltic and secretory reflexes are initiated by 5-HT acting at 5-HT_{1P} receptors (98). The 5-HT_3 receptors are associated with excitation of the gastrointestinal tract resulting in increased motility, secretion, and excitation (97) as well as signaling to the CNS (98); 5-HT_3 antagonists reduce colonic transit and improve fluid absorption (97). The 5-HT_3 antagonists tend to be constipating (98). The 5-HT_4 receptors mediate both excitatory and inhibitory effects on gut function (97).

Alosetron (Fig. 14.15), a 5-HT_3 antagonist, and tegaserod (Zelnorm®), a 5-HT_4 agonist, are two of the most recent entries for the treatment of IBS. Recent clinical trials have found that both agents are more effective than placebo for the treatment of IBS-C and IBS-D (97). Tegaserod acts by accelerating small bowel and colonic transit in patients with IBS. It is rapidly absorbed following oral administration, with a bioavailability of approximately 10%, except that food reduces the bioavailability by 40 to 65%. Peak plasma concentrations are reached in approximately 1 hour. Tegaserod is approximately 98% bound to plasma proteins, primarily to α_1-acid glycoprotein. Its volume of distribution is approximately 368 L/kg. Tegaserod undergoes presystemic acid-catalyzed hydrolysis in the stomach, followed by hepatic oxidation to its principal inactive metabolite (5-methoxyindole-3-carboxylic acid), its acyl glucuronide, and three isomeric N-glucuronides. The terminal half-life is approximately 11 hours following intravenous administration. Approximately two-thirds of the orally administered dose of tegaserod is excreted unchanged in feces, with the remainder excreted in urine, primarily as glucuronide. Tegaserod exhibits dose-proportional kinetics when given twice daily at therapeutic doses for 5 days, with no relevant accumulation. No dosage adjustment is required in elderly patients or those with mild to moderate hepatic or renal impairment. No clinically relevant drug–drug interactions have been identified with tegaserod.



5-HT_5 Receptors and Agents

Overview

Two 5-HT_5 receptors, expressed primarily in the mouse CNS, have been identified as 5-HT_{5A} and 5-HT_{5B} receptors (99). The two 5-HT_5 receptors exhibit 77% amino acid sequence homology but less than 50% homology with other cloned serotonergic receptors. To some extent, the 5-HT_5 receptors appear to resemble 5-HT_1 receptors (e.g., high affinity for 5-HT and 5-CT); however, their low homology with other 5-HT_1 receptors suggest that they represent a distinct family of receptors. Only 5-HT_{5A} receptors have been identified in humans (99). Recent studies provide evidence that human 5-HT_{5A} receptors are G protein–coupled receptors that are coupled in a complex manner to multiple signaling cascades; apparently, they are coupled to adenylate cyclase

and also can transiently open K^+ channels after formation of inositol 1,4,5-triphosphate (100).

Radiolabeled LSD binds to both HT_{5A} and 5-HT_{5B} receptors, with 5-CT having 10-fold greater affinity for human 5-HT_{5A} receptors than 5-HT, which binds with modest affinity (K_i = 100–250 nM). The SAR for the binding of various ligands at 5-HT_{5A} receptors has been reviewed elsewhere (101). Ergotamine and methiothepin bind with high affinity at human 5-HT_{5A} receptors, whereas agents such as spiperone, sumatriptan, yohimbine, ketanserin, propranolol, zacopride, and clozapine bind with much lower affinity (K_i > 1,000 nM). To date, no 5-HT_{5A}-selective agonists or antagonists have been reported.

5-HT_5 Receptors: Clinical Implications

Pharmacological functions of 5-HT_5 receptors are currently unknown. It has been speculated, on the basis of their localization, that they may be involved in motor control, feeding, anxiety, depression, learning, memory consolidation, adaptive behavior, and brain development (99). The 5-HT_{5A} receptors also may be involved in a neuronally driven mechanism for regulating astrocyte physiology with relevance to gliosis; disruption of 5-HT neuronal–glial interactions may be involved in the development of certain CNS pathologies, including Alzheimer's disease, Down's syndrome, and some drug-induced developmental deficits. Recent evidence indicates that genes that encode for the human 5-HT_{5A} receptor might be involved in schizophrenia (102) and that spinal 5-HT_{5A} receptors could play a role in nociception and control of pelvic floor musculature (103).

5-HT_6 Receptors and Agents

Overview

A novel G protein–coupled serotonergic receptor that appears to be localized exclusively in the CNS was cloned from rat brain (104) and named 5-HT_6. This receptor exhibits only 40% transmembrane homology with 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1D}, 5-HT_{1E}, 5-HT_{2A}, and 5-HT_{2C} receptors. Both LSD and 5-HT display modest affinity for 5-HT_6 receptors (K_i ~ 50–150 nM). Of interest is that a number of typical and atypical antipsychotic agents and tricyclic antidepressants bind with K_i values in the nM range. For example, Lisuride acted as a partial agonist, and amoxapine, clozapine, and methiothepin acted as antagonists (104).

More recently, the human 5-HT_6 receptor has been cloned, and its gene structure, distribution, and pharmacology are similar to those of the rat receptor (105). Like the rat receptor, the human receptor is positively coupled to adenylate cyclase. 5-HT binds at human 5-HT_6 receptors with moderate affinity (K_i = 65 nM), and one of the highest-affinity, albeit nonselective, agents is methiothepin (K_i = 0.4 nM). Agents that bind at human 5-HT_6 receptors with K_i < 50 nM include 5-methoxytryptamine, bromocriptine, octoclothepin, and the antipsychotic agents clozapine, olanzapine, chlorpromazine, loxapine, and fluphenazine (106). Agents with K_i >500 nM include 5-CT, sumatriptan, quipazine, ketanserin, 8-OH DPAT, haloperidol, risperidone, and mesulergine (106). A number of other antipsychotic agents, both typical and atypical, as well as antidepressants bind with low nanomolar affinity (101,105,106).

5-HT_6 Agonists and Antagonists

Just a few years ago, there were no 5-HT_6-selective agents; however, tremendous progress has been made recently. 2-Ethyl-5-methoxy-N,N-dimethyltryptamine

(EMDT) represented the first reasonably selective 5-HT_6 agonist (107), and Ro 04-6790 and Ro 63-0563 represented the first 5-HT_6-selective antagonists (108) (Fig. 14.19). These were soon followed by the antagonists SB-271046 (109), MS-245 (107,110) and PMDT (2-phenyl-5=mutroxy-N,N-dimethyl

tryptamine, also known as BGC20-761) (107). Since then, work has continued on related structure-types, leading to agents with greater metabolic stability and bioavailability (101). It might be noted that most of the early 5-HT_6 antagonists contained an arylsulfonamide moiety. Interestingly, the importance of this functionality was an independent discovery from several different laboratories, and this structural feature is now commonplace among many 5-HT_6 agents. In some cases, the sulfonamido moiety can be replaced by a sulfone (e.g., naphthylsulfones) (Fig. 14.19). Numerous structural modifications have now been reported, and among some of the interesting findings are that the basic side chain of MS-245–type compounds can be moved to the indole 4-position (Fig. 14.19) (111,112) or removed altogether (e.g., amino-BSS) (101) with retention of antagonist action. 5-Sulfonamidotryptamines also bind with high affinity at 5-HT_6 receptors and, depending on the nature of their pendent substituents, act as 5-HT_6 agonists, partial agonists, or antagonists (113,114).

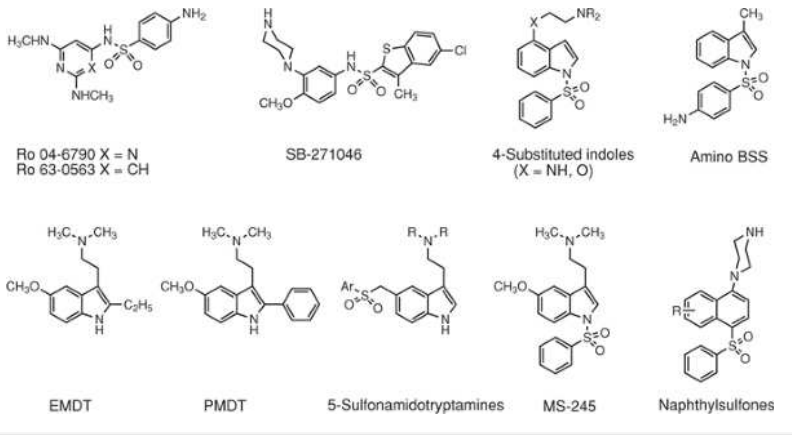


Fig. 14.19. 5-HT_6 agonists and antagonists.

5-HT_6 Receptors: Clinical Implications

The exact clinical significance of 5-HT_6 receptors is unknown at this time. The high affinity of various antipsychotics, particularly atypical antipsychotics, and antidepressants suggests a possible connection between 5-HT_6 receptors and certain psychiatric disorders (115). The different binding profiles of atypical antipsychotics may be responsible for their atypical nature (e.g., D_2:5-HT_{2A} ratio); for example, certain agents, such as clozapine, may be classified as atypical on the basis of their binding with higher affinity at 5-HT_{2A} than at D_2 receptors. However, antipsychotics that produce the fewest extrapyramidal side effects in humans (e.g., clozapine, olanzapine, and fluperlapine) also possess high affinity for 5-HT_6 receptors (106). The atypical antipsychotic agent risperidone, which produces some extrapyramidal symptoms, binds with 1,000-fold higher affinity at 5-HT_{2A} than at 5-HT_6 receptors; thus, the affinity of agents for 5-HT_6 receptors may contribute to the difference between typical and certain atypical antipsychotics (106). Furthermore, preclinical studies indicate that combinations of a 5-HT_6 antagonist and a 5-HT_{2A} antagonist were effective in models of psychosis and cognition (116). PMDT differs from most other 5-HT_6 antagonists in that it combines both types of antagonist action in the same molecule (101). The 5-HT_6 knockout mice produce a behavioral syndrome that seems to involve an increase in cholinergic function. Blocking the receptors in rats with 5-HT_6 antagonists produces a similar effect. This has led to speculation that one of the roles of 5-HT_6 receptors may be to control cholinergic neurotransmission and that 5-HT_6-selective antagonists could be useful in the treatment of anxiety and memory deficits. Other studies have shown that although 5-HT_6 antagonists might not influence basal levels of dopamine by themselves, they apparently increase amphetamine-induced increases in brain dopamine and can potentiate certain dopamine-mediated behavioral effects (117,118). The exact mechanisms underlying this process are not understood, but 5-HT_6 receptors play a role in neuronal plasticity (119) and can influence the actions of dopaminergic agents. Evidence also suggests that 5-HT_6 receptors might be involved in motor function, mood-dependent behavior, anxiety disorders, appetite control, anticonvulsant activity, and early growth processes involving 5-HT (105,107,111). With the newly identified 5-HT_6 agonists and antagonists, interest in the therapeutic potential of such agents is on the upswing.

5-HT_7 Receptors and Agents

Overview

Like 5-HT_5 receptors, 5-HT_7 receptors were once considered to be orphan receptors. Rat, mouse, guinea pig, and human 5-HT_7 receptors have now been cloned and are expressed mainly in the CNS (101,120). Hydropathic analysis suggests a seven transmembrane-spanning G protein–coupled receptor. The 5-HT_7 receptors are positively coupled to adenylate cyclase, and several splice variants have been identified. Alternative splicing in rat and human receptors results in four 5-HT_7 receptor isoforms that vary with respect to the length of their C-terminus chains (101,121). In rat, the isoforms are named 5-HT_{7a}, 5-HT_{7b}, and 5-HT_{7c}. Two of the isoforms are homologous in rat and human (5-HT_{7a} and 5-HT_{7b}). The third human isoform is named 5-HT_{7d}. These different isoforms could have important functional consequences, such as different distribution or G protein–coupling efficiency, or different susceptibility to desensitization (121,122). Apparently, however, the three human isoforms are pharmacologically indistinguishable and show similar affinity for various ligands. Evidence suggests that 5-HT_7 receptors are constitutively active and that the degree of constitutive activity might vary among the isoforms. Nonselective agents with K_i values at 5-HT_7 receptors of 10 nM or less include 5-HT, 5-methoxytryptamine, LSD, methiothepin, and mesulergine; those with K_i values in the range of 10 to 100 nM include 8-OH DPAT (long considered a 5-HT_{1A}-selective agonist!), spiperone, ritanserin, metergoline, mianserin, and chlorpromazine; those with K_i values in the range of 100 to 1,000 nM include NAN-190, sumatriptan, and haloperidol; and those with K_i values of greater than 1,000 nM include 2-methyl 5-HT, tropisetron, pindolol, and ketanserin. Reportedly, 5-HT, 5-CT, and 8-OH DPAT act as agonists, whereas methiothepin, mianserin, mesulergine, ritanserin, spiperone (a 5-HT_{1A}, 2-HT_{2A}, and D_2 antagonist), NAN-190 (a 5-HT_{1A} antagonist), and clozapine act as antagonists. Numerous antidepressants and antipsychotic agents bind at 5-HT_7 receptors with nanomolar or subnanomolar affinity ($K_i \leq 10$ nM) include fluphenazine, acetophenazine, chlorprothixene, zotepine, clorotepine, clozapine, fluperlapine, pimozide, tiospirone, and risperidone (101,122).

5-HT_7 Antagonists

Only during the last few years have reasonably selective 5-HT_7 agents been identified. The first reported 5-HT_7

antagonist was SB-258719 (K_i ~ 30 nM) (123), and attempts to optimize binding affinity and selectivity led to SB-269970 (*S*-isomer, K_i = 1.3 nM) (Fig. 14.20). Both compounds displayed some inverse agonist action. The high in vivo blood clearance of SB-269970 resulted in further structural modification, leading to

compounds such as SB-656104 (*S*-isomer, K_i = 2 nM) (101). Another early series of 5-HT_7 antagonists was the DR-compounds: DR4004 was the first of these to show activity as a competitive antagonist; structural modification resulted in others, including DR4365 (K_i = 4 nM) (124). Other antagonists (Fig. 14.20) include phenylpyrrole-containing LCAPs (Fig. 14.20), which because of their structural similarity to other 5-HT_{1A} ligands might have been expected to—and do—bind at 5-HT_{1A} receptors (125), as well as arylpiperazinosulfonamides and tetrahydroisoquinolinylsulfonamides (126). Actually, the latter two types of compounds have been demonstrated to act as inverse agonists (126).

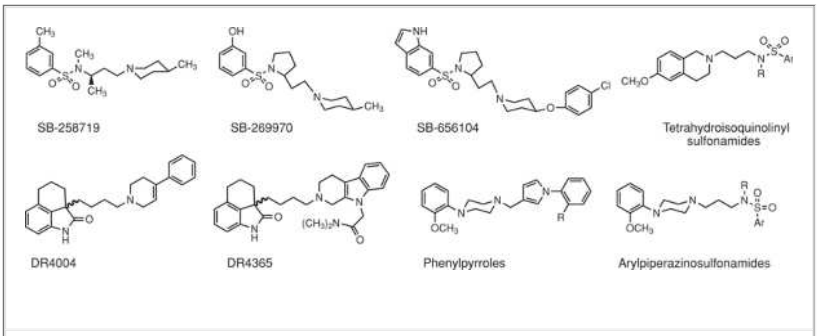

Fig. 14.20. 5-HT_7 antagonists.

5-HT_7 Agonists

N-Arylaminoimidazolines (Fig. 14.21) were identified as the first 5-HT_7 agonists (127); however, they have not been pursued because of their profound effects on blood pressure and heart rate, which is probably a consequence of their affinity for α-adrenoceptors. Several new 5-HT_7 agonists have been recently reported, including the piperazinylhexanones (128) and 2-aminotetralins (129) (Fig. 14.21); the later can function either as agonists (e.g., R = *n*Pr) or antagonists (e.g. R = Me) depending on the nature of the R group. Pharmacophore models have been proposed for 5-HT_7 agonists (130), antagonists (131), and inverse agonists (126).

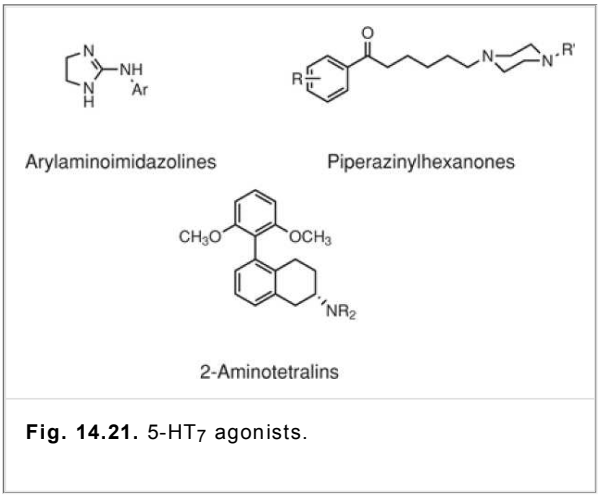

Fig. 14.21. 5-HT_7 agonists.

5-HT_7 Receptors: Clinical Implications

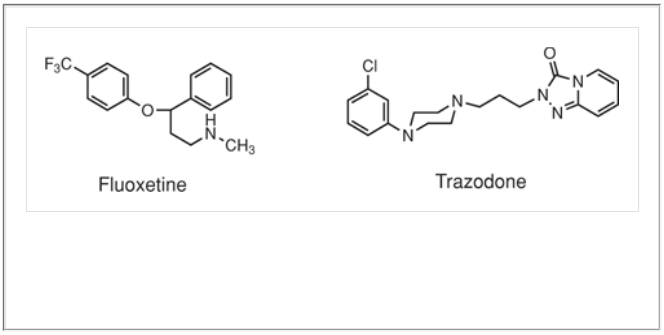
Because of the previous unavailability of 5-HT_7-selective agents, the pharmacology of the 5-HT_7 system is still relatively unexplored. Nevertheless, studies with nonselective agents, 5-HT_7 receptor knockout animals, and some of the first few selective agents that were identified have provided some tantalizing clues (101,122,132,133,134). The 5-HT_7 receptors might be involved in mood and learning as well as in neuroendocrine and vegetative behaviors. The 5-HT_2 ligand ritanserin, certain tricyclic antidepressants (e.g., amitriptyline), classical antipsychotic agents (e.g., chlorpromazine), and nonclassical antipsychotic agents (e.g., clozapine) bind with K_i values of less than 100 nM (115). On this basis, it has been speculated that 5-HT_7 receptors may play a role in certain neuropsychiatric disorders. Consistent with these suggestions, 5-HT_7 receptors are sensitive to antidepressant treatment (135). The 5-HT_7 receptors have been implicated in serotonergic-regulation of circadian rhythm, leading to suggestions that 5-HT_7-selective agents might be effective in the treatment of jet lag or sleep disorders of a circadian nature (136). Additionally, 5-HT_7 receptors might be involved in sleep disorders, anxiety, memory and cognition, epilepsy, pain, migraine, and thermoregulation. In the periphery, 5-HT produces both contraction and relaxation of coronary artery from various species (137). It has been proposed that relaxation of coronary artery may be mediated by 5-HT_7 receptors. Agents active at 5-HT_7 receptors might thus be effective in the treatment of coronary heart disease. Now that newer, more selective

agents are finally available, many of these hypotheses can be further tested.

The Serotonin Transporter

The actions of a neurotransmitter are terminated by diffusion away from the synapse, by enzymatic degradation, and by reuptake into the presynaptic terminal. Following reuptake, once the neurotransmitter is inside the neuron, it can be re-stored in storage vesicles or metabolized. The reuptake process involves a high-affinity transporter protein that is localized in the presynaptic terminal membrane. The transporter appears to regulate the duration and magnitude of postsynaptic response to the neurotransmitter. A different transporter is associated with different neurotransmitters. The 5-HT transporter (or SERT) has been cloned and expressed (138), and its putative structure is roughly similar to the general receptor structure shown in Figure 14.3 except that 1) it consists of 12 membrane-spanning helices, 2) both the amino terminus and the carboxy terminus are located on the intracellular side, and 3) it has an exaggerated extracellular loop between TM3 and TM4 (Fig. 14.22). The 5-HT transporter possesses approximately 50% homology with the norepinephrine transporter (NET) and the dopamine transporter. For 5-HT transport, a ternary complex of protonated 5-HT, Na^+, and Cl^2 binds to the transporter protein to form a quaternary complex; the transporter undergoes a conformational change to release 5-HT into the cytoplasm of the neuron (138).

The 5-HT transporter has been implicated as playing a role in affective disorders (53). Agents that block the transporter and, thereby, increase synaptic levels of 5-HT are useful for the treatment of depression, obsessive-compulsive behavior, and panic disorders (53). Tricyclic antidepressants block the 5-HT transporter and the NET to varying degrees. Some display a preference for one transporter over the other, but most are nonselective (139). The SSRIs display greater selectivity for the 5-HT transporter over the NET. The first SSRI to be used clinically was fluoxetine; several other agents have since become available. The SARs of SSRIs have been reviewed elsewhere (140); see Chapter 21 for further discussion and examples. Certain drugs of abuse (e.g., cocaine) also block the 5-HT transporter, although cocaine's primary mechanism of action likely involves the dopamine transporter.



Various tricyclic antidepressants and SSRIs, including fluoxetine, also bind at 5-HT_{2A} and 5-HT_{2C} receptors (141,142). The role, if any, that is derived from a direct interaction of these agents with 5-HT_2 receptors versus their interaction at the 5-HT transporter remains to be elucidated. In general, 5-HT_2 antagonists downregulate

5-HT_2 receptors. The antidepressant trazodone, for example, is a weak reuptake blocker but binds at 5-HT_2 receptors and is a 5-HT_2 antagonist (142). The 5-HT_{2C} agonist *m*CPP induces panic attacks in patients with panic disorder and increases obsessive compulsions in patients with obsessive-compulsive disorder (143), implicating a role for this specific 5-HT_{2C} subpopulation. The 5-HT_{2C} receptor antagonists might be useful targets for the development of novel agents to treat these disorders (53). This issue is complicated, however, by findings that trazodone is metabolized to *m*CPP and that, in some instances, trazodone possesses 5-HT_{2C} agonist properties (144). In any event, long-term treatment with tricyclic antidepressants (and MAO inhibitors) leads to a downregulation in the number of 5-HT_2 receptors, the time course for which approximates the clinical response in depressed patients (139). Some SSRIs produce adaptive changes involving decreased responsiveness of 5-HT_2 receptors, whereas electroconvulsive therapy increases the number of 5-HT_2 receptors (139). Several 5-HT receptor populations have been implicated in the actions of antidepressants (e.g., 5-HT_1, 5-HT_2, 5-HT_6, and 5-HT_7), but the 5-HT transporter remains an attractive target for the development of novel psychotherapeutic agents (53).

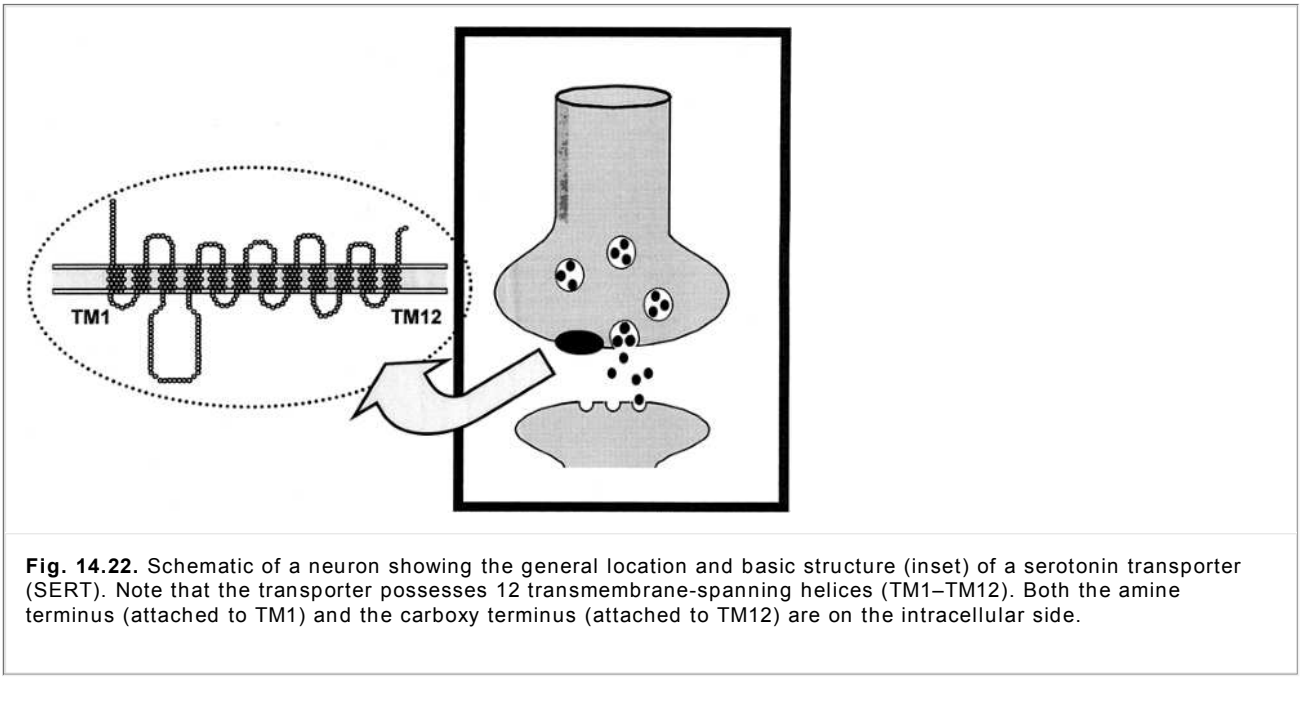


Fig. 14.22. Schematic of a neuron showing the general location and basic structure (inset) of a serotonin transporter (SERT). Note that the transporter possesses 12 transmembrane-spanning helices (TM1–TM12). Both the amine terminus (attached to TM1) and the carboxy terminus (attached to TM12) are on the intracellular side.

Summary

Serotonin is a major neurotransmitter in the brain and also is involved in a number of peripheral actions. Seven families or populations of 5-HT receptors have been identified (5-HT_1–5-HT_7), and several are divided into distinct subpopulations (Table 14.2). Excluding splice variants, 14 different populations and subpopulations of 5-HT receptors have been cloned. Over the past 20 years, selective agonists and antagonists have been developed and identified for some of the subpopulations, but subpopulations remain for which selective agents have yet to be synthesized. The availability of such agents is important, because it aids functional investigations of the different 5-HT receptors. In addition to acting directly on 5-HT receptors, therapeutic agents with other mechanisms are available for influencing serotonergic transmission, including SSRIs and MAO inhibitors. Studies with 5-HT receptors have led to the introduction of agents useful for treating anxiety (e.g., buspirone), migraine (e.g., sumatriptan), IBS (e.g. tegaserod), and chemotherapy-induced emesis (e.g., ondansetron); numerous other agents are currently in clinical trials for the treatment of depression, schizophrenia, and obsessive-compulsive and other disorders (21). Investigations also have led to a greater understanding of cardiovascular pharmacology, obesity, neurodegenerative disorders, aggression, sexual behavior, and drug abuse, just to mention a few examples. Serotonin may even play an indirect role in techniques as diverse as acupuncture (145) and transcendental meditation (146). To reiterate a phrase from the introduction, “[I]t almost appears that serotonin is involved in everything” (1).

Chapter 15

Amino Acid Neurotransmitters in the Central Nervous System

Timothy J. Maher

Historical Background

In the late 1800s and early 1900s, scientists studying the physiology of the body began to postulate that drugs produced their responses by interacting with a special group of structures termed “receptive substances.” This suggestion was based on the observation that seemingly very minor changes in the chemical structures of a series of compounds greatly altered the biological responses observed following administration of these compounds to animals or people. Later, it was recognized that many of these drugs typically were acting as mimics or antagonists of endogenous compounds and that their responses were caused by interactions with what we today term “receptors.” Thus was born the era of chemical neurotransmission, which challenged the long-accepted dogma that communication between cells was the result of electrical transmission.

Acetylcholine released from the parasympathetic nerves innervating the heart and termed “vagustuff” was one of the first neurotransmitters to be recognized. Drugs that acted similarly to the then-unknown acetylcholine, including muscarine and nicotine, led to the eventual characterization of muscarinic cholinergic and nicotinic cholinergic receptors, respectively. Epinephrine found in adrenal gland extracts and termed “adrenaline” also was described in those early days of discovery in the field of neurotransmitter pharmacology. Each of these compounds could produce very powerful responses when released from nerves or tissues or when applied exogenously to isolated tissues or intact animals. Today, we know that these compounds serving as neurotransmitters, neuromodulators, and/or hormones are normal mediators of information transfer throughout the body.

The earliest characterizations of chemical compounds as neurotransmitters involved studies of physiological systems in the periphery and used both chemical and physiological techniques. Later, investigators started to apply some of the same techniques used in characterizing these peripheral neurotransmitters and their receptors to the central nervous system (CNS), which is comprised of the brain and spinal cord. These investigations often were much more difficult because of the complex structures and functions in the CNS. The seemingly less well defined and more ambiguous areas (e.g., limbic system, temporal lobe, and prefrontal cortex) in the CNS as well as the smaller and more diverse synaptic connections (e.g., axo-axonal and somato-dendritic) presented significant challenges to early investigators. In the periphery, stimulation of a nerve innervating a target tissue often led to an easily observable end point (e.g., changes in heart rate or blood pressure, hormone release), but stimulation of nerves in the brain or spinal cord often failed to produce easily observable and quantifiable endpoints (e.g., sensations of warmth, fear, memory, and hallucinations), making such studies very challenging, especially when performed in experimental animals.

Early studies by Falk and Hillarp used formaldehyde to visualize neurons containing the monoamines dopamine, norepinephrine, and epinephrine (fluoresces green) as well as serotonin (fluoresces yellow) in brain slices. With improvements in the chemical techniques for measuring these classical monoamines and acetylcholine and, eventually, the enzymes involved with their synthesis and degradation, investigators began to map the neurons in the CNS that used these neurotransmitters and began to appreciate the neurochemical basis of drug action in the brain and spinal cord. In the late 1950s and early 1960s, however, investigators began to observe the neuronal effects of simple amino acids in these brain tissues. The suggestion that simple amino acids could be sophisticated neurotransmitters was met with considerable resistance and skepticism. These compounds usually are reserved for protein synthesis and serve many metabolic functions, and they did not appear to have the same unique functional characteristics of the classical monoamine neurotransmitters and acetylcholine. As studies continued to support the neurotransmitter role of amino acids such as γ-aminobutyric acid (GABA), glutamic acid (glutamate [Glu]) and glycine, however, overwhelming evidence has led to their nearly universal acceptance as the major neurotransmitters in the CNS. Quantitatively, the amino acids are the most prevalent neurotransmitters in the CNS. For example, it has been estimated that more than 40% of all neurons in the CNS use GABA as a neurotransmitter substance and that less than 10% use one of the other monoamines, such as norepinephrine and serotonin, or acetylcholine.

Although neuronal functioning is very complex, a simplistic view of the two major effects of neurotransmitters involve changes in membrane potential toward states of depolarization and hyperpolarization (Fig. 15.1). Such

changes in membrane potential usually result from alterations in membrane conductance to ions such as Na^+, K^+, Ca^{2+}, and Cl^-, which typically flow down their electrochemical gradients when a selective ion channel is opened. Ion channels need only open for 0.1 to 100 milliseconds to effect this change. Thus, when a neuron is to be depolarized, Na^+ or Ca^{2+} typically enters the cell, making the membrane potential more positive and more likely to reach the threshold potential and exhibit an action potential (Fig. 15.1A). On the other hand, when a neuron is hyperpolarized, typically either K^+ moves out of the cell into the extracellular space or Cl^- moves

into the cell (Fig. 15.1B). Both of these ion fluxes result in a hyperpolarization of the membrane, which decreases the likelihood that a neuronal cell will fire. Thus, these two opposing alterations in neuronal membrane potentials commonly are referred to as excitatory (depolarization) and inhibitory (hyperpolarization). When amino acid neurotransmitters produce their effects on neuronal function, they commonly are categorized as either excitatory amino acids (EAAs) or inhibitory amino acids (IAAs) (Fig. 15.2). The major established EAA neurotransmitter in the CNS is Glu. Other endogenous EAAs include aspartate (Asp), cysteine, and homocysteine. The major endogenous IAAs in the CNS include GABA and glycine, but much evidence also supports a role for taurine and β-alanine.

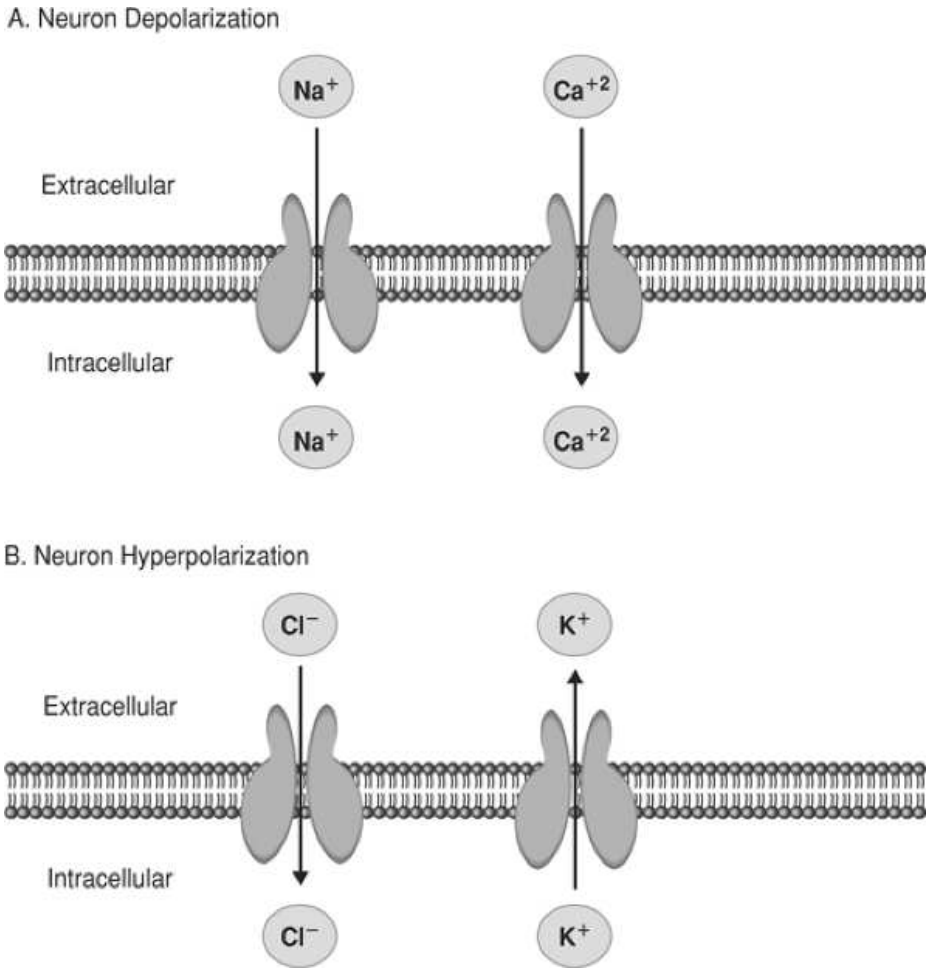

Fig. 15.1. Electrophysiology of excitatory and inhibitory neurotransmitters. The tendency of an ion to move across the membrane depends on the difference in its electrochemical gradient on either side of the membrane. The electrochemical gradient depends on the difference in the concentration of the ion between the two sides of the membrane, the charge of the ion, and the transmembrane potential (the difference in voltage between the two sides of the membrane).

Neurotransmitter Criteria

For a compound to be classified as a neurotransmitter substance, a number of criteria must be satisfied. Firstly,

the neurotransmitter must be present. Usually, the concentrations of the neurotransmitter in various parts of the CNS will vary such that a unique and unequal distribution results. For some amino acids, this unequal distribution is difficult to demonstrate, because most of these compounds also are used to support protein synthesis and for intermediary metabolism, unlike the monoamine neurotransmitters, for which an unequal distribution is relatively easy to demonstrate. Although compounds such as glucose and sodium are present in the CNS, their regional distribution is rather uniform, and few would consider either of these to be a classical neurotransmitter substance. Besides determining the concentration of the neurotransmitter itself, evidence that also can be used to support this criterion include the distribution of specific receptors, reuptake systems, and enzymes involved with synthesis and/or degradation of the particular amino acid neurotransmitter. Today, with the aid of molecular biological techniques (e.g., mRNA, cloning techniques, and in situ hybridization), the location and quantification of proteins that serve as receptors, transporters, or metabolizing enzyme is more readily achieved. Second, the compound must be released when the nerve cell is stimulated. To date, the vast majority of amino acid neurotransmitter release, like that of the monoamines and acetylcholine, has been found to be Ca^{2+}-dependent and originating from presynaptic storage vesicles. Release can be determined using brain slices prelabeled with radioactive neurotransmitter or with in vivo microdialysis, in which the extracellular fluid surrounding neurons is continuously sampled. Additionally, there should be a mechanism in place that terminates the action of the neurotransmitter compound (e.g., reuptake, removal into astroglia or other cells, metabolism, or some other form of inactivation). Finally, for a compound to be considered a neurotransmitter, the exogenous administration or application of the suspected neurotransmitter compound must mimic the effects (e.g., depolarization, hyperpolarization, activation of protein kinase C, or inhibition of adenylyl cyclase) that are observed when the neurotransmitter is released endogenously following nerve cell stimulation.

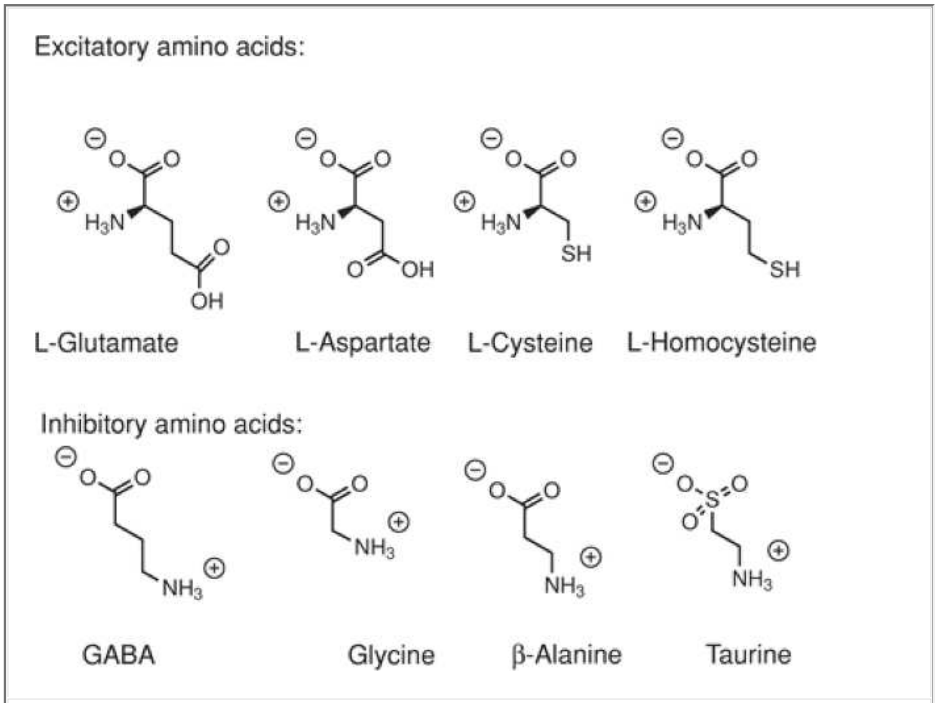

Fig. 15.2. Endogenous excitatory and inhibitory amino acids.

Excitatory Amino Acid Neurotransmitters

Glutamate

The major EAA neurotransmitter in the CNS is L-Glu. (Note that all amino acids with the exception of glycine mentioned in this chapter are considered to be in the “L” configuration; thus, the “L” will be omitted, unless

specifically indicated as “D”). Early studies in invertebrates demonstrated the potent actions of the acidic amino acid Glu, as well as another acidic amino acid, Asp. Acceptance of Glu as a neurotransmitter in the CNS was delayed for many years as neuroscientists attempted to distinguish its role as a component of protein and peptides (e.g., glutathione), an important intermediate in numerous metabolic processes, and as a precursor to the inhibitory neurotransmitter GABA. Whereas Glu is found in all cells within the CNS, an unequal distribution of this amino acid as well as of Asp has been demonstrated.

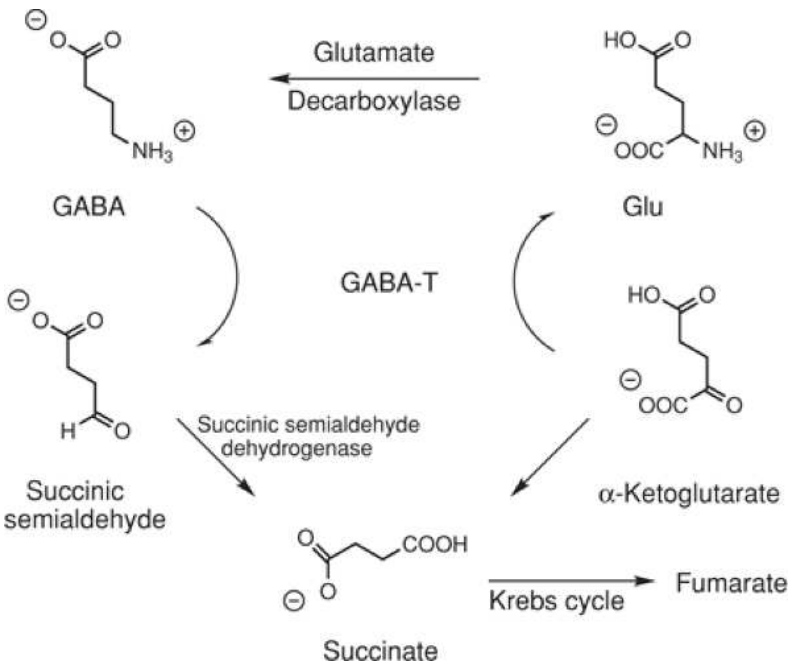

Fig. 15.3. GABA biosynthesis.

Glutamate Synthesis, Storage, and Release

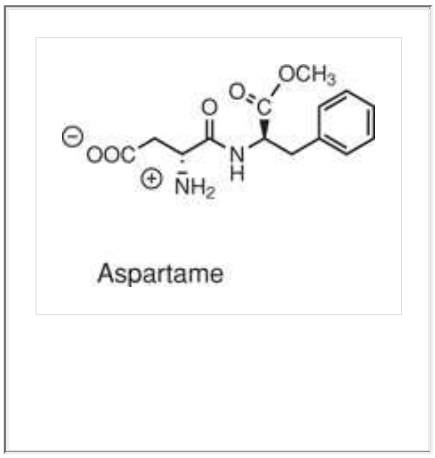
Glutamate is synthesized in the CNS via the transamination of α-ketoglutarate (Fig. 15.3), which is produced from glucose in the Krebs cycle. Additionally, Glu can be synthesized from glutamine via glutaminase. Once produced, Glu can be stored in vesicles. With the vast number of compounds that can feed into the Krebs cycle and the various sources of glucose, it is not surprising that the control of Glu synthesis in the CNS is still poorly understood.

The oral ingestion of Glu in protein, as the individual amino acid in the form of a dietary supplement or in the form of the flavor enhancer monosodium glutamate (MSG), fails to significantly increase CNS levels of this amino acid neurotransmitter. Following its ingestion, blood Glu levels do increase transiently, but largely because of the ability of the blood-brain barrier to regulate the entry of Glu into the CNS, no significant changes in brain Glu are observed. This ability to regulate synaptic Glu levels in brain despite fluctuations in peripheral levels is very important, because uncontrolled variations in CNS Glu would lead to serious consequences, ranging between seizures and coma for increases and decreases of Glu, respectively. Within the blood-brain barrier, there exists transport proteins that are responsible for controlling the influx of amino acids into the CNS. Of the three major types—acidic, basic, and neutral amino acid transporters—it is the acidic amino acid transporter that carries Glu. These transporters act via facilitated diffusion and cannot operate against a concentration gradient (active transport). In actuality, the acidic amino acid transporter normally functions to move Glu out of the

CNS. There have been studies in which Glu, often in the form of MSG, has been injected subcutaneously to neonatal mice or nonhuman primates and hypothalamic lesions noted. The lesions are mostly restricted to the circumventricular organs (those near the fourth ventricle), where the blood-brain barrier is significantly diminished. Additionally, when MSG is directly injected into the brains of laboratory animals, cellular necrosis is observed. When MSG is given in very high doses orally, however, the homeostatic processes in liver and other

tissues help to regulate plasma Glu concentrations, and large changes are not observed. Additionally, the blood-brain barrier functions to keep CNS Glu at appropriate levels. The studies in which Glu is injected do not reflect the chemical changes that occur following oral ingestion and should not be interpreted as an indicator of toxicity of MSG (1).

Similar concerns have been voiced regarding the safety of the acidic amino acid Asp in the artificial sweetener aspartame (L-aspartyl-L-phenylalanine methylester). As with MSG, however, the homeostatic mechanisms regulating plasma Asp levels following Asp consumption do not allow for large increases in plasma Asp that could alter CNS function. In fact, the concern regarding the safety of aspartame results from the other amino acid phenylalanine, which much more readily crosses the blood-brain barrier and can alter CNS function. This is especially important for people who unknowingly are heterozygous for phenylketonuria (2).



Aspartame

The transporter, VGLUT1, transports Glu into storage vesicles in preparation for the Ca^{2+}-mediated release of this neurotransmitter that uses adenosine triphosphate (ATP) to concentrate Glu against its concentration gradient (ATP-dependent transporter). Unrelated to any of the other families of neurotransmitter vesicle transporters, VGLUT1 originally was thought to be an inorganic phosphate membrane transporter. Today, it is known that VGLUT1 uses a vacuolar ATPase to cleave ATP to provide the energy required to generate and maintain an electrochemical proton gradient that allows the concentration of Glu to remain extremely high in synaptic vesicles compared to that in the cytoplasm—and especially compared to that in the synapse. Although probably not the basis of their main pharmacological actions, known inhibitors of VGLUT1 include the ergot bromocriptine (a dopamine agonist used in the treatment of Parkinson's disease and hyperprolactinemia) and some of the azo-dyes, including Evans Blue (3). Recently, a family of endogenous inhibitory proteins has been identified that not only blocks Glu vesicular transport but also GABA vesicular transport. The significance of the role that these proteins, known as IPF_{α}, IPF_{β}, and IPF_{γ}, play in regulating glutamatergic neurotransmission is still poorly understood (4). As more is learned about such proteins and other yet unknown regulatory mechanism, a better appreciation regarding the pathology of various disease states may be realized and therapeutic interventions designed based on this knowledge.

Like most other recognized neurotransmitter substances, vesicular release of Glu occurs in a Ca^{2+}-dependent manner following depolarization of the presynaptic terminal. In cell culture or isolated tissue studies, agents that bind Ca^{2+}, such as ethylenediamine tetra-acetic acid (EDTA) or Ca^{2+}-free perfusion solutions, the vesicular release of Glu can be diminished or prevented. Thus, this is one of the techniques that can be employed to distinguish, in part, between the neurotransmitter and metabolic roles of Glu in a particular biological system.

Glutamate Reuptake and Metabolism

Transporter proteins that regulate the synaptic concentrations of Glu are essential in keeping the basal levels of this EAA neurotransmitter low and in helping to terminate the responses to neuronally released Glu. These high-affinity, sodium-dependent transporters are so efficient at sequestering Glu from the synaptic cleft that the concentration of Glu inside the presynaptic terminal usually is several thousand-fold greater than that found in the synapse (5).

These EAA transporters (EAATs) have been identified and characterized into five major subtypes: EAAT1, EAAT2, EAAT3, EAAT4 and EAAT5 (Table 15.1 and Fig. 15.4). Their distribution tends to be primarily cellular, and relative anatomical distribution of the subtypes in brain for each subtype is such that EAAT1 and EAAT2 are mostly found in astroglial cells in the cerebellum and forebrain, respectively. The astroglial reuptake of

neuronally released Glu is believed to be very important in terminating the Glu-mediated synaptic signal. The EAAT3 and EAAT4 subtypes are highly concentrated in the cortical and cerebellar Purkinje neurons, respectively, whereas the EAAT5 is most abundant in the retina. The reuptake of Glu or Asp via any of the EAAT subtypes is coupled to the cotransport of H^+ and $3Na^+$ into astroglia or neurons, with the extrusion of K^+, as shown in Figure 15.4.

Table 15.1. Excitatory Amino Acid Transporters

Subtype	Predominant Brain Distribution
EAAT1	Cerebellar glia
EAAT2	Forebrain glia
EAAT3	Cortical neurons
EAAT4	Cerebellar Purkinje neurons
EAAT5	Retina

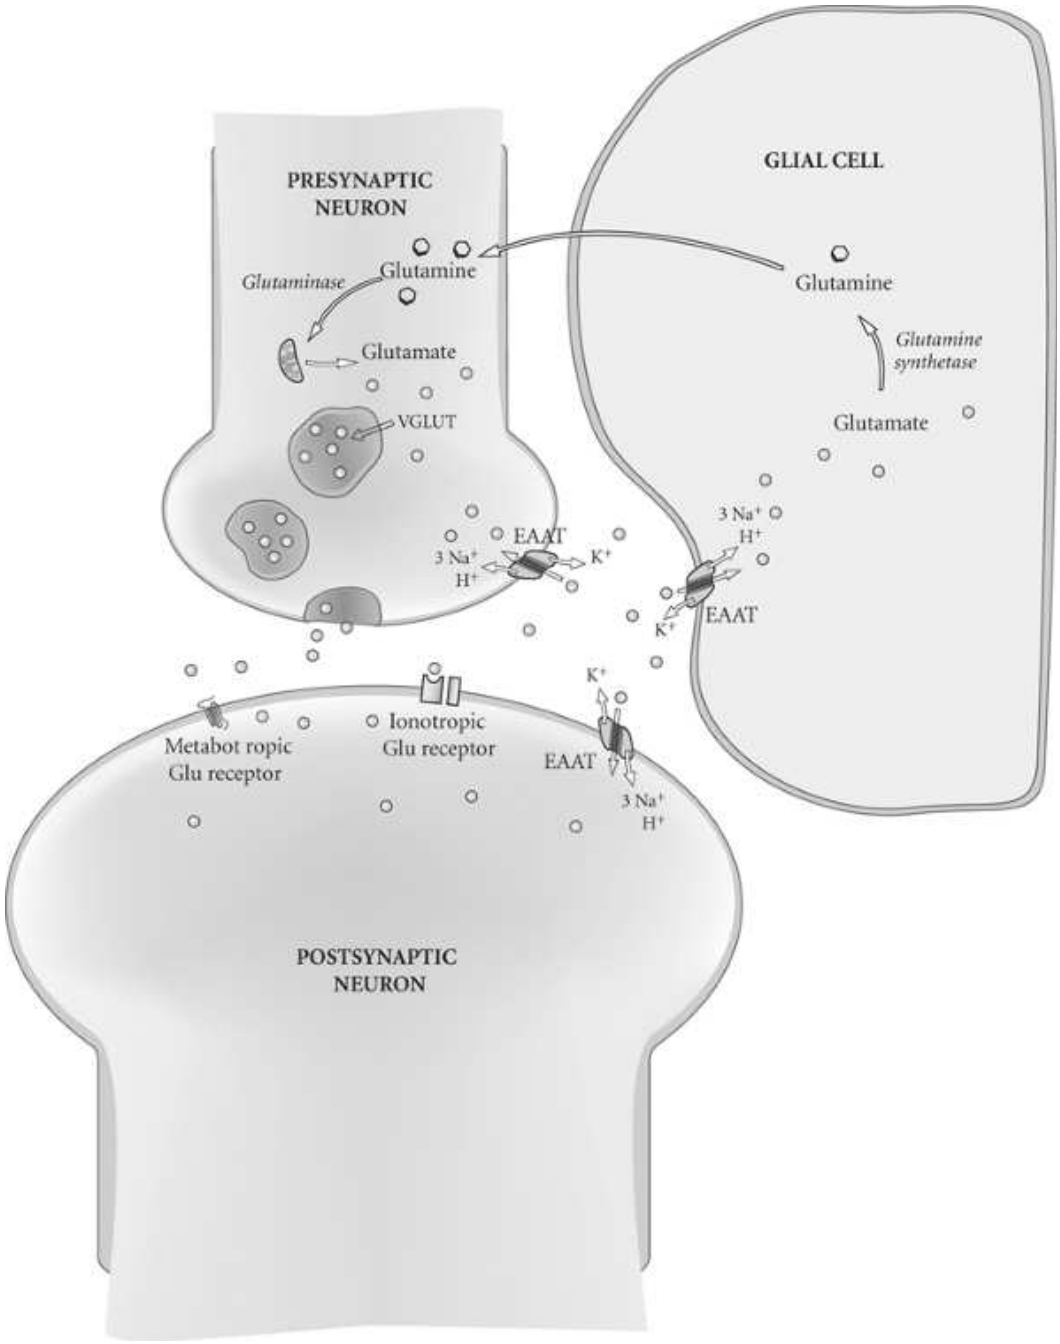


Fig. 15.4. The glutamate neuron showing the formation of glutamate (o) from glutamine (◊), ionotropic and metabotropic receptors, storage vesicles, and reuptake transporters.

The EAATs are capable of transporting D-Asp, L-Asp, and L-Glu but do not transport D-Glu. The known inhibitors of Glu reuptake transport are classified as either competitive (these usually act as substrates and are transported) or noncompetitive (these are nontransported), but no therapeutically useful agents have yet been discovered. The actions of Glu are terminated via its reuptake into the presynaptic neuron, from where it originally was released, into the surrounding glia and into the postsynaptic neuron, as demonstrated, that houses the various target EAA receptors (6). Following its release, Glu that is taken up via EAATs into neurons or astroglial cells may be recycled, in part, directly into vesicles for subsequent release or, more likely, is converted to glutamine via glutamine synthetase and is available for eventual recycling to Glu via the activity of

the enzyme glutaminase, as shown in Figure 15.4.

EAA Receptors

The receptors for Glu and the other EAAs are categorized into major two groups: ionotropic, and metabotropic (Fig. 15.4). The three ionotropic receptor types are classified based on their selective affinity for the EAA ligands: N-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and kainite

P.449

(Table 15.2). AMPA is a homologue of the neurotoxin ibotenic acid found in *Amanita* mushrooms. Kainate is a neurotoxin isolated from red algae.

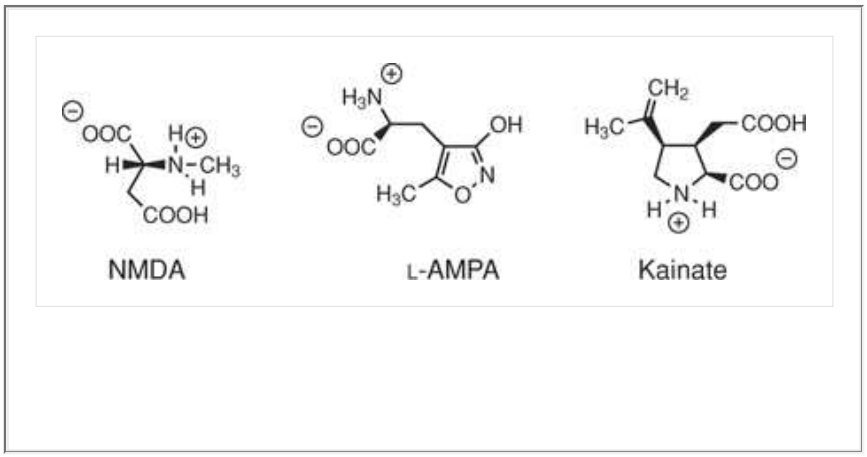

Table 15.2. Ionotropic Glutamate Receptor Subtypes

Subtype	Subunits	Agonists	Actions
AMPA	GluR1 GluR2 GluR3 GluR4	Glutamate or AMPA	Increases Na^+ and Ca^{2+} influx, increases K^+ efflux
Kainate	GluR5 GluR6 GluR7 KA1 KA2	Glutamate or kainate	Increases Na^+ influx, increases K^+ efflux
NMDA	NR1 NR2A NR2B NR2C NR2D	Glutamate or NMDA	Increases Ca^{2+} influx, increases K^+ efflux and glycine

These ligand-gated ion channel receptors are composed of homo- or heterotetramers of individual subunits that confer cation-selectivity. Each subunit has an extracellular N-terminus with three transmembrane domains, an intramembrane reentrant “p-loop” between the first and third transmembrane domains, and an intracellular C-terminus (Fig. 15.5) (7). The metabotropic Glu receptors belong to the larger family of G protein–coupled receptors (GPCRs). When activated, these metabotropic receptors can alter the activity of effector proteins, such as adenylyl cyclase and

P.450

phospholipase C (PLC). To date, at least eight distinct EAA metabotropic receptor subtypes appear to exist. The

EAA receptors, in balance with the receptors for the IAAs, likely are crucial for the regulation of neuronal plasticity involving dynamic changes of neurons in response to environmental stimuli. Neuronal plasticity accounts for the ability of an organism to learn and adapt, which includes both long-term potentiation and long-term depression.

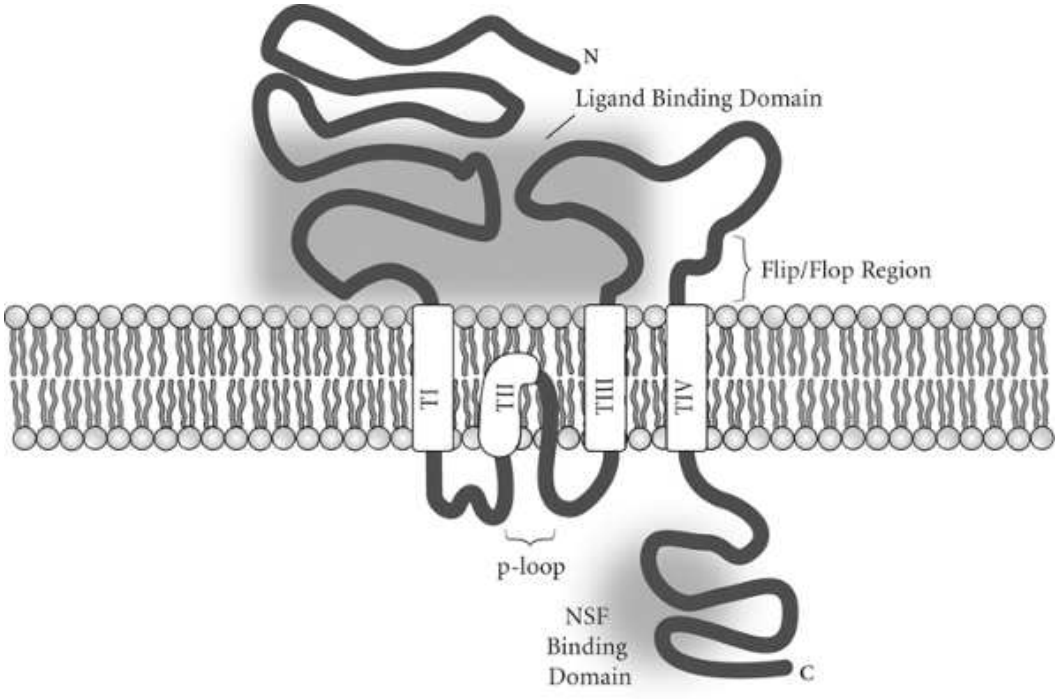

Fig. 15.5. The metabotropic glutamate receptor showing the p-loop, ligand binding domain, N-ethylmaleimide-sensitive fusion protein (NSF) binding domain (shaded area), flip/flop region, and the N- and C-terminal regions.

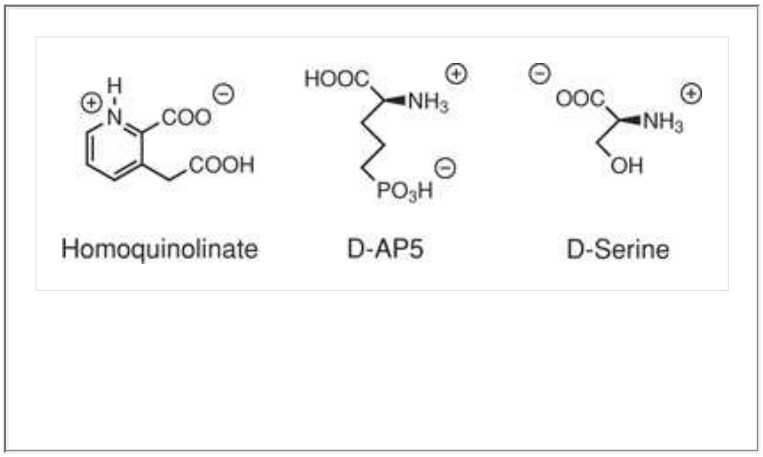
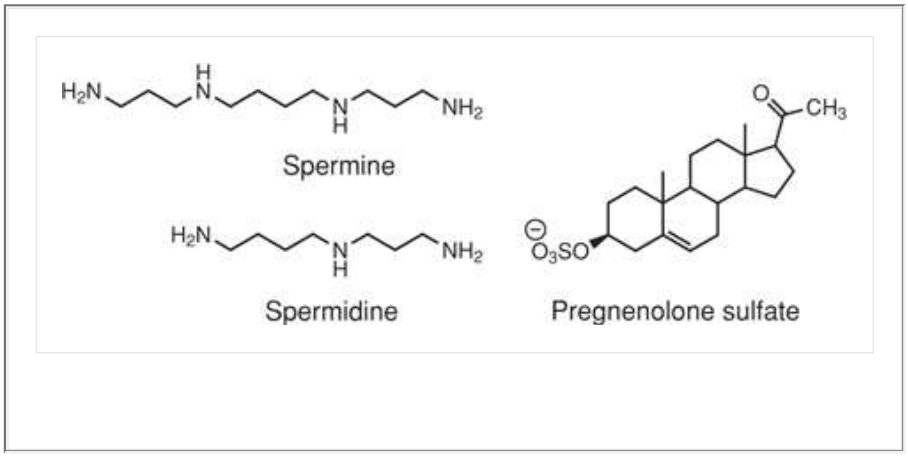
Ionotropic Receptors

NMDA receptor

The NMDA receptor is a heterotetramer comprised of a number of subunit forms—GLU_{N1}, GLU_{N2A}, GLU_{N2B}, GLU_{N2C}, GLU_{N2D}, GLU_{N3A}, and GLU_{N3B}—that can confer unique pharmacology to individual receptors (Table 15.2). Additionally, splice variants can lead to a number of isoforms of the above subunits with the potential of changing the binding characteristics and functions on the receptor. Activation of the NMDA receptor requires the binding of two agonists: Glu to the GLU_{N2} subunit, and glycine to a binding site on the GLU_{N1} subunit (8). Glycine appears to act as an important coagonist positive modulator at a unique recognition site on the GLU_{N1} subunit, and unlike the actions of glycine as an IAA neurotransmitter, this recognition site is not sensitive to blockade by strychnine (see the following section on glycine). Thus, this glycine binding site often is referred to as the strychnine-insensitive receptor or site. Agonists at the Glu binding site on the GLU_{N2} subunit include NMDA, Glu, Asp, and homoquinolinic acid. The best-characterized antagonist at this site is D-2-aminophosphonopentanoate. D-Serine is a well-known agonist at the GLU_{N1} glycine site. D-Serine, which normally is found only in glia and astrocytes, is synthesized from L-serine via serine racemase and is thought to be one of the important modulators of NMDA receptor activity.



The NMDA receptor also has many sites for channel modulation by pharmacological agents. Endogenous inhibitory channel modulators include Mg^{2+}, Zn^{2+}, and protons. Neurosteroids can either inhibit or potentiate NMDA receptor channel function depending on how the subunits comprising the tetrameric structure are assembled. For instance, the neurosteroid pregnenolone sulfate inhibits NMDA receptors that are assembled as GLU_{N1}/GLU_{N2C} but potentiates those assembled as GLU_{N1}/GLU_{N2A} and GLU_{N1}/GLU_{N2B} (9). Polyamines, such as spermine and spermidine, are known to be positive channel modulators.



A number of important NMDA channel antagonists (Fig. 15.6) also exist, and these include amantadine (an antiviral agent that also releases dopamine and is used in Parkinson's disease), ketamine (a dissociative anesthetic agent that acts via the NMDA receptor), phencyclidine (a psychoactive drug of abuse also known as PCP), and memantine (recently approved for the treatment of Alzheimer's disease). Whereas the antitussive agent dextromethorphan, via its metabolite dextrorphan, is known to block within the NMDA channel, its cough-suppressant activity likely is not the result of action at this site. The psychotomimetic effects observed with the abuse of this compound, however, are likely mediated by the NMDA receptor. An endogenous antagonist of the NMDA receptor is Mg^{2+}, which normally prevents the flow of Ca^{2+} through the channel. When both Glu or another suitable agonist binds, along with glycine, the inhibition normally maintained by Mg^{2+} is relieved, Ca^{2+} can flow, and the cell can depolarize. Some studies in experimental animals have demonstrated the NMDA receptor–mediated neuroprotective effects of Mg^{2+} in models of stroke and other CNS insults.

One of the first NMDA receptor antagonists to be identified was dizocilpine, commonly known as MK-801 (Fig. 15.6). Initially, much excitement was generated with the discovery of MK-801, because the ability to block the excessive intracellular cation flow (Ca^{2+}, Na^{+}) that follows neuronal hypoxic insults, as are seen following cerebral vascular accidents (stroke) or head trauma, might lead to effective treatments for such pathological conditions. Whereas MK-801 was very effective in decreasing infarct size in various rodent models of stroke, poor efficacy was

noted in humans. Additionally, the generation of severe psychotic behaviors was deemed to be unacceptable.

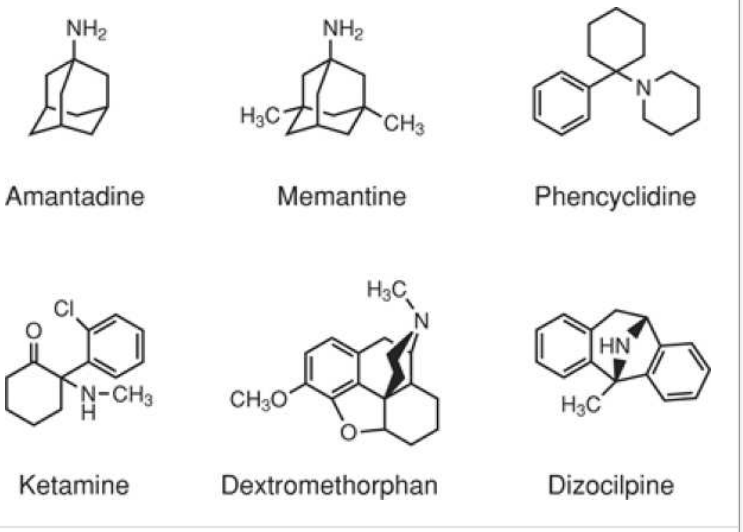


Fig. 15.6. NMDA channel antagonists.

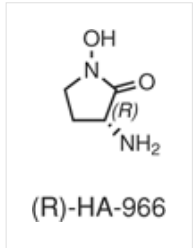
The strychnine-insensitive binding site on the NMDA receptor also has been a target for researchers, because an agent that would antagonize this binding site might be useful in preventing the neuronal damage that occurs following hypoxic insults that lead to excessive Glu release or in controlling electrical neuronal dysfunction associated with epilepsy. One agent, R-(+)-3-amino-1-hydroxypyrrolidin-2-one ((R)-HA-966), is a glycine re-ceptor antagonist that, unfortunately, has not been used therapeutically because of its hepatotoxic properties unrelated to the NMDA receptor. Whereas the dicarbamate anticonvulsant felbamate (see Chapter 20) produces part of its activity by inducing conformational (allosteric) changes in the receptor (allosterism) that alters the binding of glycine at the NMDA glycine binding site. Felbamate also has interactions at the AMPA and kainate receptors that contribute to its anticonvulsant activity (10,11).



(R)-HA-966

AMPA Receptors

Another ionotropic EAA receptor is preferentially activated by AMPA. While at one time, this receptor was referred to as the quisqualate receptor, but the AMPA receptor mediates fast synaptic activity via the influx of Na^+ and, in some neurons, K^+ efflux (Table 15.2). The AMPA receptor, which is found in high abundance in the cerebral cortex and hippocampus, is comprised of four subunits: GluR1, GluR2, GluR3, and GluR4. One of these subunits, GluR2, when present prevents the formation of an ionophore that can efficiently conduct Ca^{2+}. When the AMPA receptor does not contain a GluR2 subunit, however, Ca^{2+} can be conducted through the ion channel. On the extracellular loop between transmembrane segments III and IV exists a region termed the “flip-flop” that is sensitive to splice variants of the gene coding for each subunit. Such splice variants can lead to significant differences in the desensitization kinetics of the receptor (12). Additionally, intracellular sites on the C-terminus, where modulatory proteins such as N-ethylmaleimide-sensitive fusion protein and protein interacting with C

kinase can bind, allow another important site where regulation of receptor trafficking can be influenced.

Recently, the discovery that some of the 2,3-benzodiazepines (e.g., GYK1 53655) can selectively bind the AMPA receptor has aided in studies to understand its location and functions, especially where mixed populations of EAA receptors are present (13). Agents known to potentiate AMPA receptor activity include piracetam (a drug for improving mental performance), a cyclic derivative of GABA, and the benzothiazide diuretic, cyclothiazide (Fig. 15.7). Additionally, some evidence suggests that certain barbiturates and volatile anesthetics have binding sites on the AMPA receptor. Agents that act to cause conformational changes that positively modulate the AMPA receptor have been termed “ampakines” and have been suggested to improve memory, to enhance the activity of certain antipsychotic agents, to improve attention-deficit hyperactivity disorder, to improve Parkinson's disease symptoms, and to provide neuroprotection following CNS ischemic insults (14).

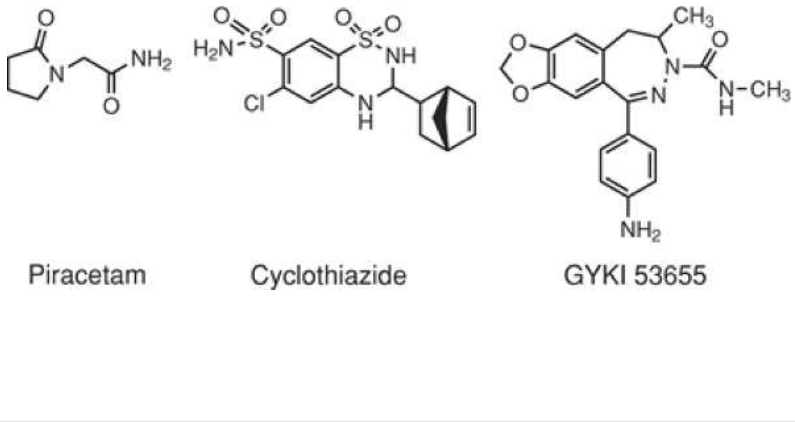


Fig. 15.7. AMPA agonists.

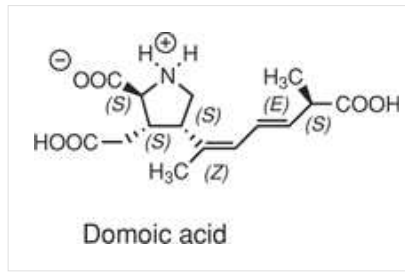
Kainate Receptors

The ionotropic kainate receptor is a heterotetramer comprised of subunits GluR5, GluR6, GluR7, KA1, and KA2 (Table 15.2). The subunits GluR5, GluR6, and GluR7 can form functional homo- and heteromeric receptors; the KA1 and KA2 subunits require the presence of the GluR5, GluR6, and GluR7 subunits to properly assemble into functional receptors. Similarities exist between the binding characteristics of AMPA receptors and kainite receptors such that few pharmacological agents are available that effectively differentiate between the two (15). Kainate receptors tend to be more sensitive to the phycotoxin domoic acid, an EAA found in red algae (*Pseudonitzschia* sp.), than are AMPA receptors. Domoic acid causes Amnesic shellfish poisoning that may cause in humans nausea, vomiting, abdominal cramps, short-term memory loss, seizures, arrhythmias, and death in severe cases of ingestion. Domoic acid bioaccumulates in shellfish that feed on the red algae phytoplankton.



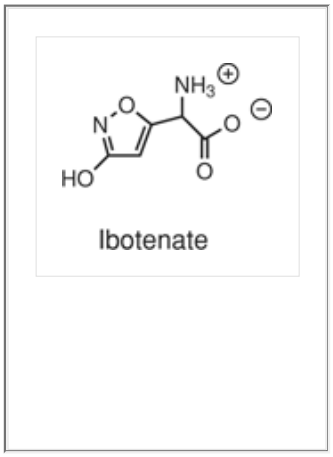
Kainate receptors are located postsynaptically and mediate neuronal excitation, as do NMDA and AMPA receptors, but kainate receptors also have been found to be located presynaptically. Such presynaptic receptors

appear to regulate the release of GABA in the hippocampus and Glu in other brain regions. Additionally, some

kainate receptors have been shown to be linked to a pertussis toxin–sensitive G protein, which via interaction with PLC may in turn act to influence nearby voltage-dependent Ca^{2+} channels (16). This dual signaling capability of kainate receptors appears to be unique for an EAA ionotropic receptor and may facilitate the role of this receptor subtype in influencing both short- and long-term synaptic plasticity (adaptive changes to the synapse affecting the efficacy of neurotransmission) in the CNS.

Metabotropic Glutamate Receptors

Another class of EAA receptors are the G protein–coupled metabotropic receptors (m), which are categorized into one of three groups based on their pharmacology, sequence similarity, and intracellular effector signaling systems. Group I, which includes mGlu1 and mGlu5, are positively coupled to PLC via $G_{q/11}$, whereas Group II, which includes mGlu2 and mGlu3, and Group III, which includes mGlu4, mGlu6, mGlu7, and mGlu8, are negatively coupled via $G_{i/o}$ to adenylyl cyclase (17). The term “metabotropic” is used to indicate that activation of these receptors results in alterations in metabolic processes within the cell. All of the metabotropic receptors are activated by Glu and ibotenate, but none is activated by NMDA, AMPA, or kainate.



Few useful selective agonists or antagonists are available for these receptors subtypes, but some researchers have used knockout mice to explore the role of a particular metabotropic receptor. For instance, mice lacking the mGlu5 receptor fail to display the reinforcing and locomotor stimulant effects of cocaine, suggesting that an agent that is selective at antagonizing the mGlu5 receptor might find utility in treating patients dependent on cocaine (18). Additionally, because the mGlu5 receptor is located in areas of the brain thought to be involved with anxiety, compounds that negatively modulate this receptor subtype have been shown to be anxiolytic in animal studies. The Group II mGlu receptors also are highly concentrated in areas involved with anxiety such that agents that are selective positive modulators for this receptor subtype are found to act as anxiolytics. Finally, positive modulators of the mGlu4 receptor subtype have been suggested as an approach for treating Parkinson's disease (19). As more information is revealed about the distribution, function, binding characteristics, and trafficking of the metabotropic receptor subtypes in the CNS, advances in the therapy of disease states such as Parkinson's, schizophrenia, chronic pain, epilepsy, depression, and drug dependence may be realized (20).

A steady accumulation of evidence supports a role for Glu and its mGlu1 and mGlu5 receptors in depression and antidepressant activity. Furthermore, evidence also implicates Glu release, which can result in activation of NMDA and mGlu1 and mGlu5 receptors, an underlying cause for depression and anxiety. Studies with NMDA receptor antagonists of mGlu1 and mGlu5 receptors as well as positive modulators of AMPA receptors have antidepressant-like activity in a variety of preclinical models. The concept of NMDA antagonists as antidepressants has generated considerable interest in the NMDA receptor as a target for new antidepressant therapies (see Chapter 21). Several studies have shown that chronic antidepressant treatment can modulate NMDA receptor expression and function. Preclinical studies with NMDA receptor antagonists have demonstrated their potential antidepressant properties.

Inhibitory Amino Acid Neurotransmitters

γ-Aminobutyric Acid

The major IAA neurotransmitter in the mammalian CNS is GABA (Fig. 15.2). Initially found to be involved with neuromuscular transmission in the lobster, GABA has since been well characterized as a neurotransmitter in the brain and spinal cord of mammals. In the periphery, in tissues such as the liver, spleen, sympathetic ganglia, and splenic nerve, GABA and its receptors also are found. The levels are very low, however, and their function in these non-CNS tissues is poorly understood. While levels of GABA in the CNS are very high (millimoles per gram tissue) compared to those of the classical monoamine neurotransmitters (nanomoles per gram tissue), the distribution of GABA in the CNS is unique, with an unequal distribution, thus supporting a neurotransmitter role. Unlike many of the other putative amino acid neurotransmitters that also are components of CNS proteins, GABA is not known to be incorporated into proteins, thus making it easier to support a role for GABA as a neurotransmitter.

The synthesis of GABA uses Glu and the enzyme glutamic acid decarboxylase (GAD), the levels of which closely parallel those of GABA (Fig. 15.3). Although Glu itself functions as an important neurotransmitter, the control of GABA synthesis appears to be dependent on the activity of GAD and its cofactor, pyridoxal phosphate. Glutamic acid can be synthesized from α-oxoglutaric acid, α-ketoglutarate, and glutamine (Fig. 15.3). Glucose and pyruvate also can be converted to Glu via metabolism involving the Krebs cycle. Two isoforms of GAD derived from different genes have been characterized: GAD-65, and GAD-67. The lower-molecular-weight GAD-65 has a much higher affinity for its pyridoxal cofactor than does the larger GAD-67. Additionally, there appears to be different cellular and subcellular distribution patterns between the two GAD isoforms, but the significance of their unique roles in GABAergic neurotransmission is not fully understood (21).

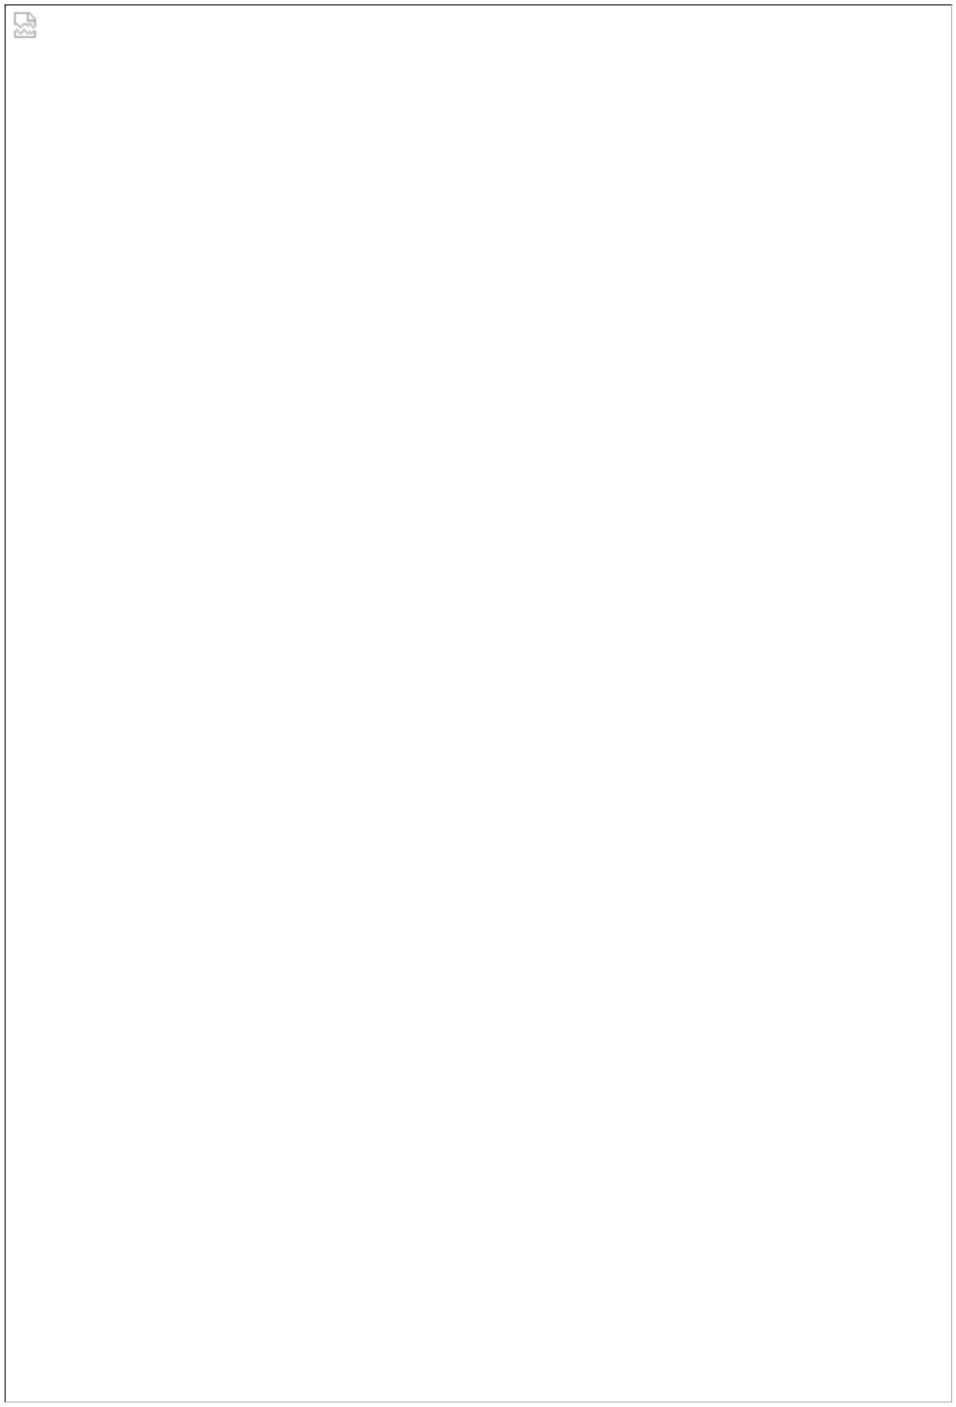


Fig. 15.8. The GABA neuron, showing the formation of GABA, ionotropic and metabotropic receptors, and reuptake transporters.

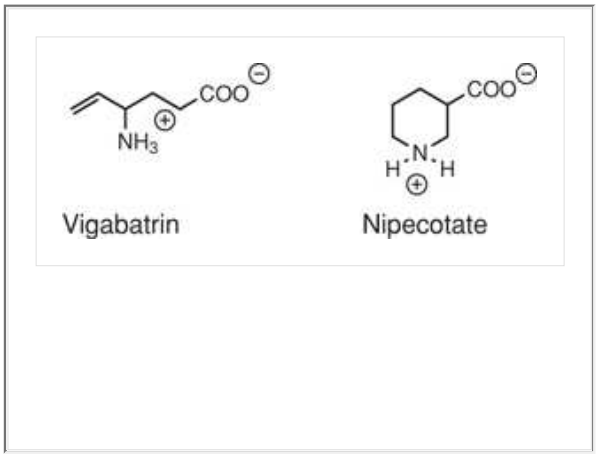
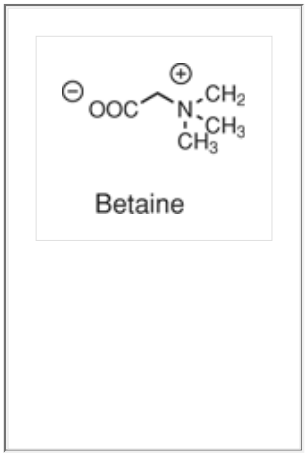
In a similar manner to most other classical neurotransmitters, GABA, once synthesized, is stored in vesicles located in the presynaptic nerve terminals, as shown in Figure 15.8. A specific vesicular transporter protein (VGAT) has been identified that transports largely GABA into the storage vesicles (22). The VGAT lacks complete selectivity, because the other major IAA neurotransmitter glycine also appears to be a substrate for VGAT, which has been shown to be present in glycinergic terminals. Unlike the well-defined vesicular transporters for the monoamine neurotransmitters, which are characterized by 12 transmembrane-spanning segments, VGAT only contains 10 such transmembrane-spanning segments. Similar to the monoamine vesicular

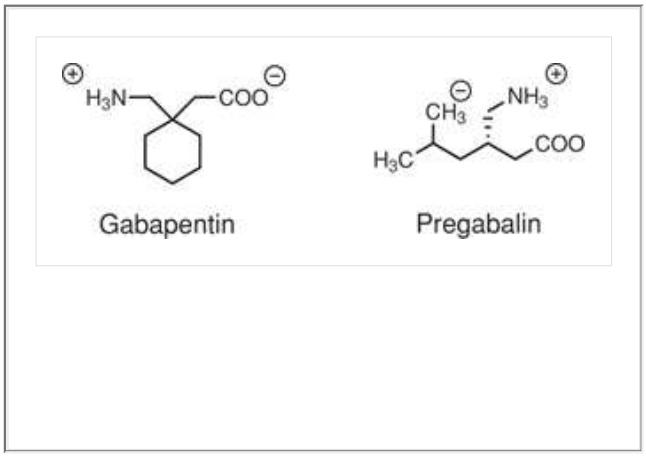
transporters, however, VGAT appears to be driven by a H^+ electrochemical gradient generated by an ATP-dependent H^+ pump in the vesicle plasma membrane. Whereas vigabatrin potently inhibits and nipecotic acid weakly inhibits VGAT, the role of VGAT inhibition in the overall pharmacological actions of these agents is not known, because both agents probably act largely via other mechanisms involving GABA.



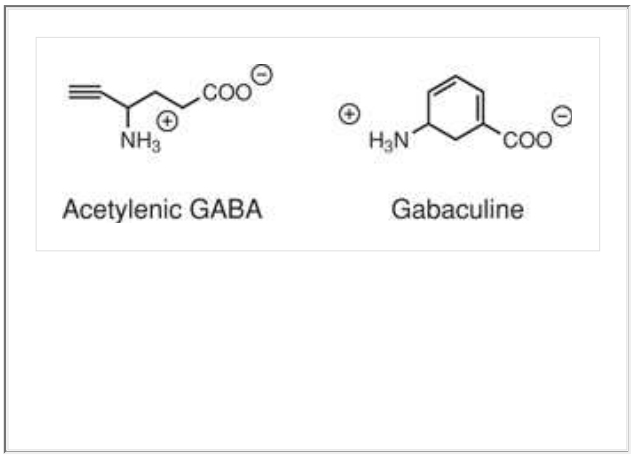
P.454

Nerve stimulation leading to depolarization of GABAergic presynaptic terminals cause the Ca^{2+}-mediated exocytosis of vesicles containing GABA. Once released, GABA diffuses across the synapse to the postsynaptic side, where interaction with GABA receptors takes place, leading to hyperpolarization of the postsynaptic neuron, as shown in Figure 15.8 (these receptor subtypes are described in detail below). Some regulation of GABA release occurs via presynaptic $GABA_B$ autoreceptors that decrease subsequent neurotransmitter release. The termination of the GABA-mediated signal takes place as a result of reuptake transporter systems that transport GABA back into the presynaptic neuron or into surrounding glial cells and astrocytes. This dual neuronal–glial reuptake process is distinct from that observed with the classical monoamines, for which neuronal reuptake predominates. Four transporters with 12 transmembrane-spanning segments have been identified and cloned: GAT-1, GAT-2, GAT-3, and BGT-1 (23). All four are capable of transporting GABA, but they also can transport other IAAs, particularly glycine, β-alanine, and taurine (Fig. 15.2). One of the transporters, BGT-1, is capable of transporting the dimethylated glycine derivative betaine and also is known as the betaine transporter. A number of inhibitors of these transporters are known, but only one currently is available for therapeutic use. Tiagabine, by selectively inhibiting GAT-1, which may be the major GABA neuronal reuptake transporter, is an approved agent for the treatment of partial seizures (see Chapter 20). Clinical trials are underway for its use in the treatment of anxiety, neuropathic pain, and insomnia (24). Two GABA analogues that have been shown to interact with GAT-1 include gabapentin and pregabalin. The concentrations required to inhibit GAT, however, are very high, and a GABAergic mechanism of action most likely does not explain their anticonvulsant activity (25). Despite their close structural similarity to GABA, inhibition of a voltage-gated calcium channel containing the $\alpha_2\delta_1$ subunit is believed to be responsible for their pharmacological actions.





Metabolism of GABA occurs via a series of enzymatic steps starting with GABA transaminase (GABA-T), as shown in Figure 15.3. This reversible mitochondrial enzyme uses pyridoxal phosphate as a cofactor and is widely distributed throughout the CNS. Transamination results in the formation of succinic semialdehyde (SSA), which can be further metabolized to succinate via SSA dehydrogenase (SSADH) or, alternatively, reduced to γ-hydroxybutyrate (GHB). Other metabolites of unknown significance include carnitine, homoanserine, homopantothenic acid, and a number of γ-butyryl derivatives, including γ-butyryllysine, γ-butyrylhistidine, and γ-butyrylcholine. Vigabatrin (γ-vinyl-GABA), an irreversible inhibitor of GABA-T, increases the levels of GABA by inhibiting its metabolism and is used for the treatment of seizure disorders in some countries. Other inhibitors of GABA-T include gabaculline and acetylenic GABA. These agents display anticonvulsant activity in experimental animal models of epilepsy.



$GABA_A$ Receptors

The initial observations that application of GABA was capable of hyperpolarizing neurons, as well as the lack of activity of structurally related amino acids and other compounds, suggested that a receptor likely mediated this response. At least three different families of GABA receptors have been identified to date: $GABA_A$, $GABA_B$, and $GABA_C$ (Fig. 15.9). The $GABA_A$ receptor was the first to be identified and was found to be a neurotransmitter-gated ion channel (ionotropic) that, when activated, allows the entry of chloride ion into the cell, thereby hyperpolarizing the neuron and making cell firing less likely to occur. The $GABA_A$ receptor (Fig. 15.9) is a member of the Cys-loop (cysteine–cysteine loop located on the N-terminal region) family of receptors that also include the strychnine-sensitive glycine, nicotinic acetylcholine, and serotonin 5-HT_3 receptors. The pentameric $GABA_A$ receptor is composed of various combinations of subunits (α, β, γ, δ, ε, π, ρ, and θ). Various subunit isoforms have been identified with 6α, 3β, 3γ, and 3ρ subunits (some have suggested that the ρ subunits are found only in the $GABA_C$ receptor). Each subunit is a four transmembrane-spanning protein that, when arranged in a circle, forms the ion channel with a diameter of approximately 8 nm that remains closed until GABA binds to its ligand recognition site. One of the most common $GABA_A$ receptor conformations in the mammalian CNS consists of a pair of α_1 subunits, a pair of β subunits, and a single γ_2 subunit, as shown in Figure 15.10. Other commonly identified receptors contain α_1, α_2, α_3, and α_5 as well as forms of the β subunit and, typically, the γ_2 subunit, and always in a 2:2:1 stoichiometry (26). The binding of two molecules of GABA, as shown in

Figure 15.11, probably to the individual β subunits near the α–β interface, is believed to be required for normal receptor activation. In fact, among $GABA_A$ receptors, 17 different

combinations of subunits have been identified. Having a family of receptors that all share the same basic structure but that differ in specific subunit composition allows greater levels of functional diversity. Each of the receptor varieties vary in binding affinity, channel activity, and the degree to which GABA binding is affected by different endogenous modulators. As a result, inhibitory neurotransmission can be more finely controlled. Such receptor heterogeneity also allows more control at the genomic level, in turn allowing postsynpatic cells to respond to changing environmental needs or variable activity at the synapse (plasticity).

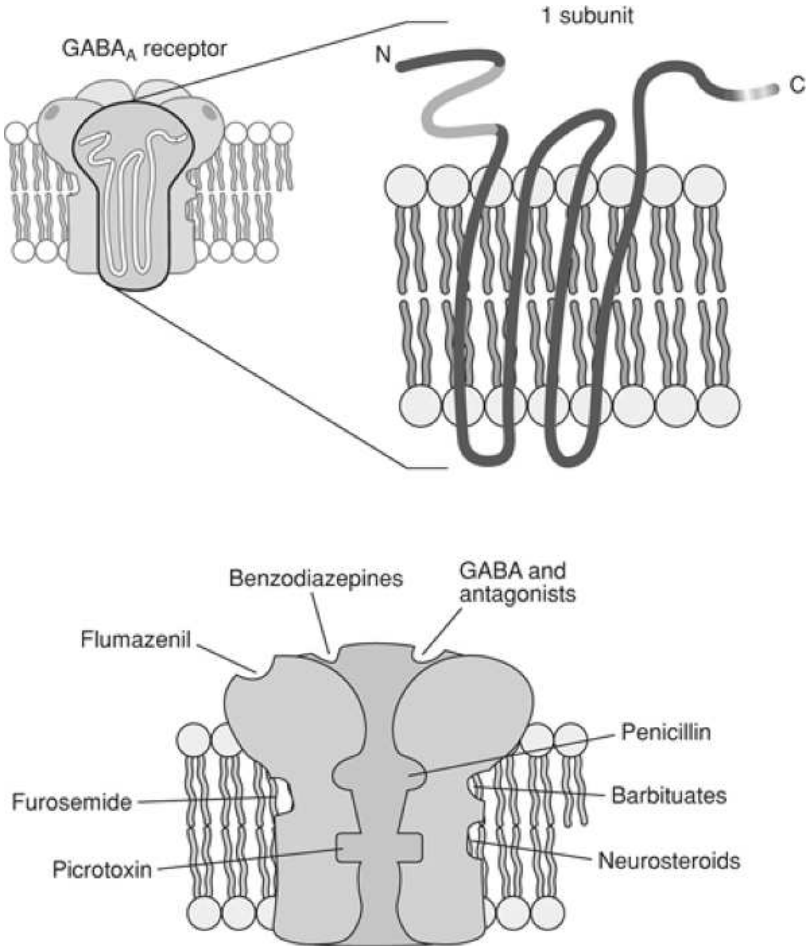


Fig. 15.9. $GABA_A$ receptor. (A) The structure of the $GABA_A$ receptor, showing the N- and C-terminal regions of the four membrane-spanning regions for each of the five subunits. (B) The major binding sites on the $GABA_A$ receptor. (From Chou J, Strichartz GR, Lo EH. Pharmacology of excitatory and inhibitory neurotransmitters, Chapter 10. In: Golan DE, Tashjian A, Tashjian A, et al. Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott, Williams & Wilkins, Baltimore, 2004: pp139-160; with permission.)

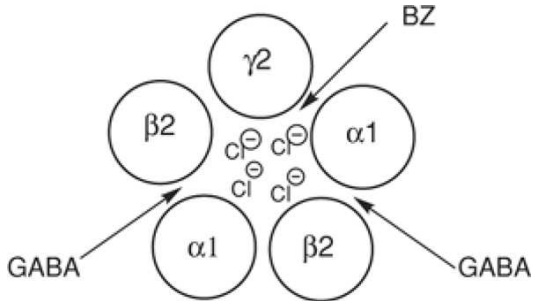

Fig. 15.10. Extracellular view of the $GABA_A$ receptor showing the location of benzodiazepine (BZ) and low-affinity GABA binding sites.

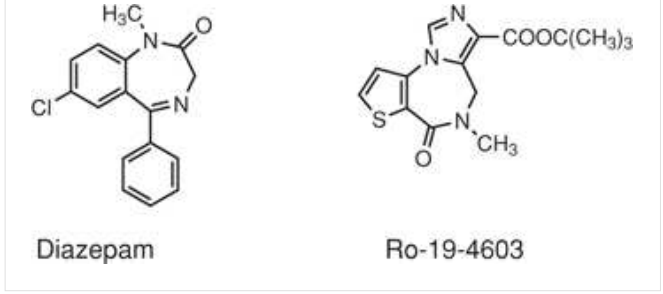
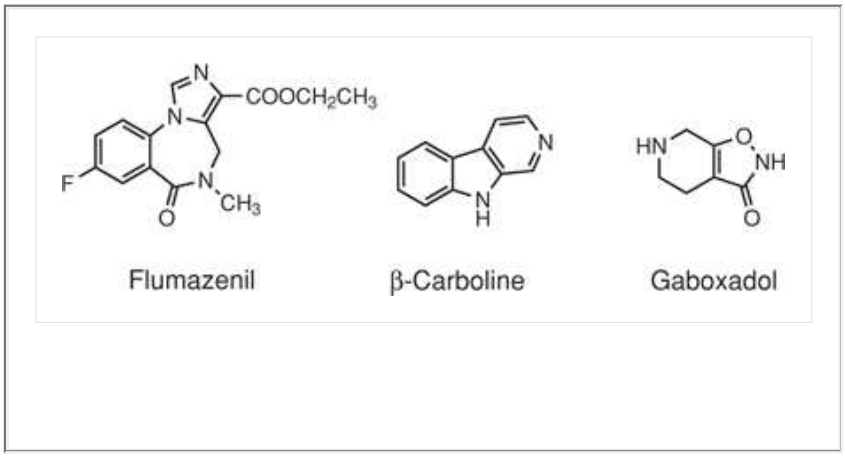
A major class of compounds that modulate $GABA_A$ receptor function is that of the benzodiazepines (e.g., diazepam). The binding site for benzodiazepines likely is the α subunit in proximity to the β subunit, as shown in Figure 15.11. The form of the γ subunit appears to help to determine the affinity of the individual benzodiazepine to the receptor. The benzodiazepines appear to bind better to receptors containing γ_2 than to the γ_1 subunit, as shown in Table 15.3. Similarly, very low-affinity binding is observed if a receptor contains the α_6 subunit. In fact, the α_6 subunit seems to confer binding preference to inverse agonists (agents that stabilize the inactive/resting receptor), such as Ro194603. The benzodiazepines do not bind to the GABA (ligand-recognition) site on the receptor and can only produce effects if presynaptic GABA has been released and is present at the receptors. Benzodiazepines are allosteric modulators, or ligands that bind at a secondary binding site on a receptor that is distinct from the primary ligand binding site, resulting in conformational changes in the structure of the receptor that either activates or, sometimes, inhibits the receptor. Thus, the benzodiazepines allosterically modulate the $GABA_A$ receptor, increasing the frequency of the chloride channel opening when GABA is bound, thus potentiating the response of exogenously released GABA. The benzodiazepines are very safe when used alone in the absence of CNS depressants, because they are not active on GABA receptors alone. This is in contrast to the barbiturates that can directly activate the $GABA_A$ receptor when present at higher concentration and, thus, have a much lower therapeutic index. Flumazenil, a benzodiazepine receptor antagonist, is used for the treatment of severe overdoses of benzodiazepines. Flumazenil competitively antagonizes the binding and allosteric effects of benzodiazepine agonists as well as benzodiazepine inverse agonists, such as the β-carbolines.





P.456

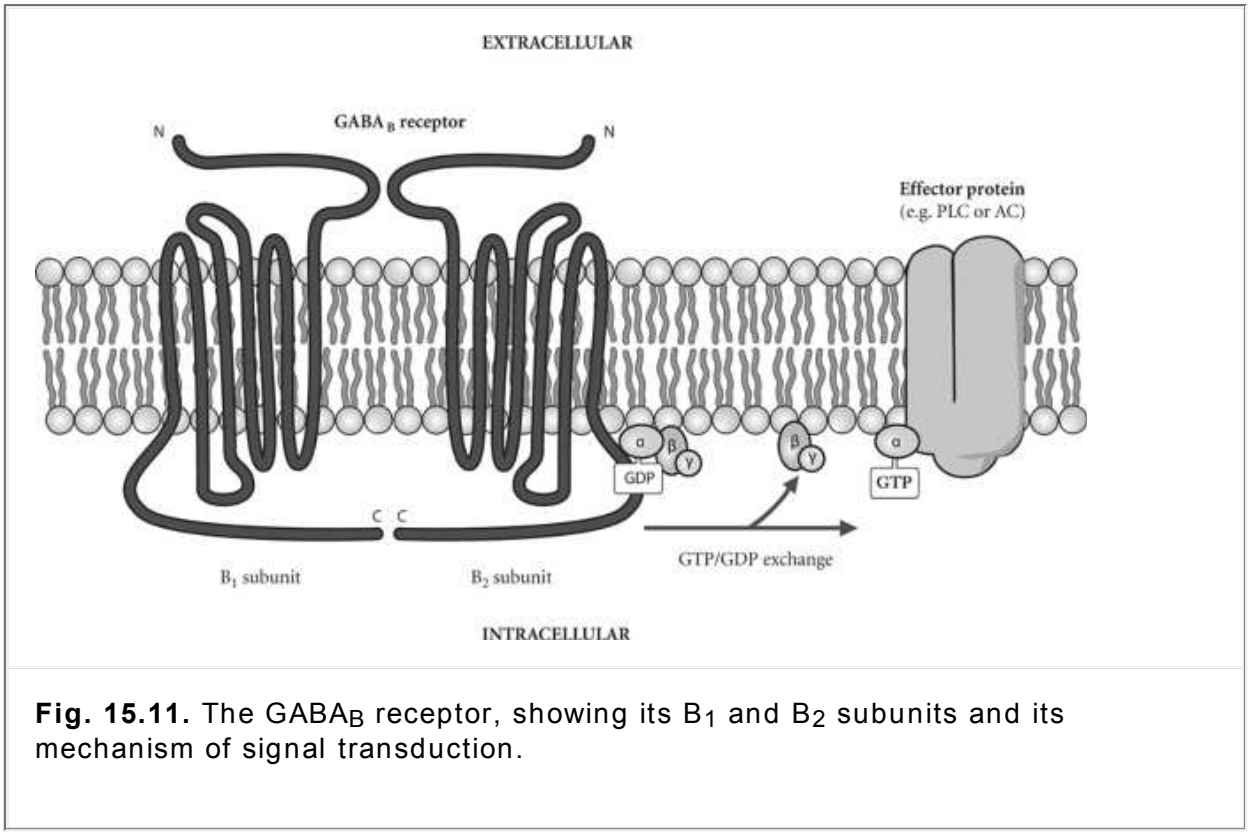


Fig. 15.11. The $GABA_B$ receptor, showing its B_1 and B_2 subunits and its mechanism of signal transduction.

Using molecular biological techniques, point mutations of the α subunits have revealed that the sedative effects of the benzodiazepines likely result from an interaction with the α_1 subunit, whereas the anxiolytic effects result from an interaction at the α_2 subunit (27,28), as shown in Figure 15.10 and Table 15.3. Nonbenzodiazepine receptor agonists, such as the sedative-hypnotics indiplon, zaleplon, zolpicone, and zolpidem (see Chapter 19), are α_1 subunit–preferring ligands, as shown in Table 15.3 (29).

An agent that acts on the $GABA_A$ receptor that does not interact with the benzodiazepine binding site is gaboxadol (previously called THIP). This sedative-hypnotic binds with high affinity to the extrasynaptic $\alpha_4\beta_x\delta$ $GABA_A$ receptor and does not alter sleep onset or REM sleep as do the benzodiazepines. On the other hand, gaboxadol increases slow-wave sleep (30).

Table 15.3. A Comparison of the Binding Affinities (nM) of Benzodiazepine and Nonbenzodiazepine Ligands for $GABA_A$ Receptor Subtypes (45)

	$GABA_A$ Receptor Subtypes

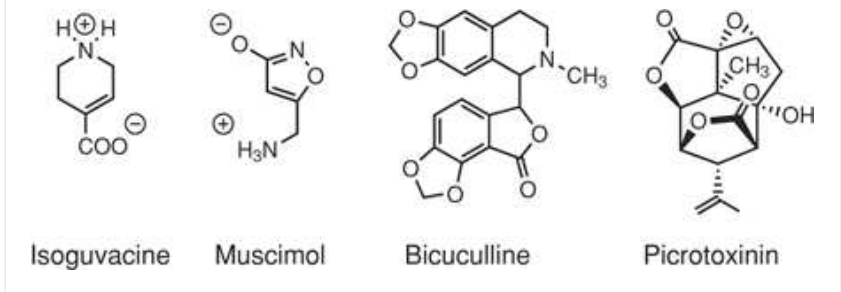
Compound	$\alpha_1\beta\gamma_2$	$\alpha_2\beta\gamma_2$	$\alpha_3\beta\gamma_2$	$\alpha_4\beta\gamma_2$	$\alpha_5\beta\gamma_2$	$\alpha_6\beta\gamma_2$
Benzodiazepines						
Diazepam	16	17	17	>10,000	15	>10,000
Clonazepam	1.3	1.7	2.0	—	—	>10,000
Triazolam	1.8	1.2	3.0	—	1.2	—
Flumazenil	1.0	1.1	1.5	107	2.4	90
Nonbenzodiazepines						
Zaleplon	130	1,820	1,530	>10,000	490	>10,000
Zolpidem	17	290	357	—	>15,000	—
Zoplicone	19	33	—	—	—	—

The barbiturates bind to a different portion of the $GABA_A$ receptor and, similar to the benzodiazepines, enhance the activity of GABA. The binding of a barbiturate leads to an increase in the duration of ion channel opening. Higher concentrations of the barbiturates can directly open the chloride channel; thus, overdoses of barbiturates can lead to life-threatening, CNS-mediated respiratory and cardiovascular depression.

A number of compounds are known to directly activate the $GABA_A$ receptor. Of these compounds, muscimol, the decarboxylated metabolite of ibotenate, and

P.457

isoguvacine are the most well known. Unlike GABA, which does not cross the blood-brain barrier, these agents do cross the blood-brain barrier and display GABA-mimetic activity following peripheral administration. Additionally, a number of compounds can bind to the $GABA_A$ receptor and antagonize the actions of GABA. Bicuculline, by binding to the GABA recognition site and preventing GABA from binding, produces convulsions in experimental animals. Picrotoxin, via its active metabolite picrotoxinin, binds in the chloride channel to prevent ion flow when the receptor is activated by GABA. Picrotoxin does not alter GABA binding but, instead, prevents ions from flowing and is a potent convulsant.

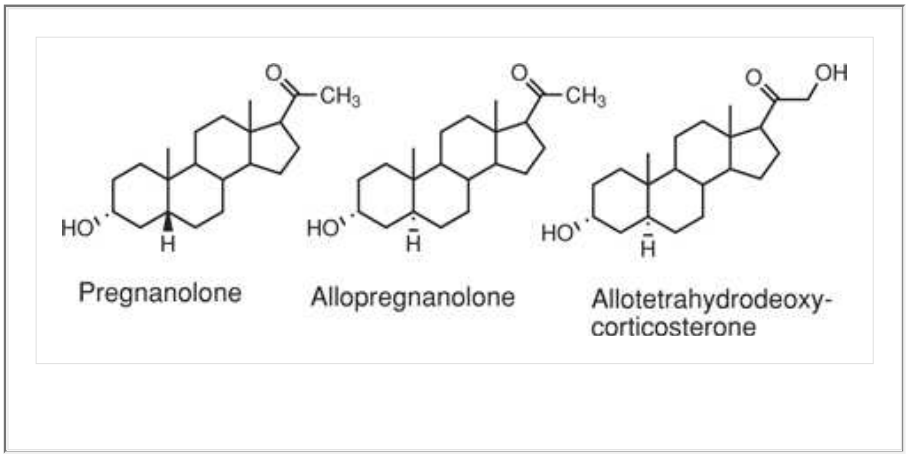


With the many possible subunit assembly sequences of $GABA_A$ receptors, advances in medicinal chemistry may

someday lead to the design of compounds that target specific pentameric subunit assemblies to preferentially produce specific effects (31). For instance, located on the base of the dendritic spines of hippocampal pyramidal cells are $GABA_A$ receptors with an α_5 subunit composition. These receptors are thought to counteract the excitatory input because of glutamatergic NMDA receptor activation involved in learning and memory. Activation of $GABA_A$ receptors in this area disrupt learning and memory, whereas NMDA receptor activation improves learning and memory. Administration of an inverse agonist of the $GABA_A$ receptor with selectivity for the α_5 subunit improves memory performance in experimental animals (32). Additionally, α_3-selective agonists may be useful in treating schizophrenia, because this subtype of $GABA_A$ receptor appears to play a role in decreasing the release of dopamine from overactive neurons in the mesolimbic system (33).

General anesthetics (see Chapter 18) also appear to have interactions with the $GABA_A$ receptor in producing their various anesthetic effects, including immobilization, respiratory depression, and hypnosis via binding to hydrophobic pockets within the receptor. Using point-mutated knock-in mice, general anesthetic agents, such as enflurane, etomidate, and propofol, have been found to interact with the β_3 subunit of the $GABA_A$ receptor to produce immobilization and hypnosis (33). The heart rate and body temperature depressant effects of etomidate and propofol, however, do not appear to be mediated by the sub-β_3 subunit. Studies are underway to improve our understanding of the molecular mechanisms of this chemically varied group of agents used as general anesthetics.

Neurosteroids also are capable of modulating the activity of GABA at the $GABA_A$ receptor by binding to a site distinct from that used by GABA, benzodiazepines, and barbiturates. These steroids, including the progesterone metabolites pregnanolone, allopregnanolone, and allotetrahydrodeoxycorticosterone, enhance GABA- mediated inhibitory activity. The presence of the δ subunit in the pentameric $GABA_A$ receptor greatly increases the affinity of steroid binding and efficacy. High concentrations of these steroids also can result in direct activation of the receptor.



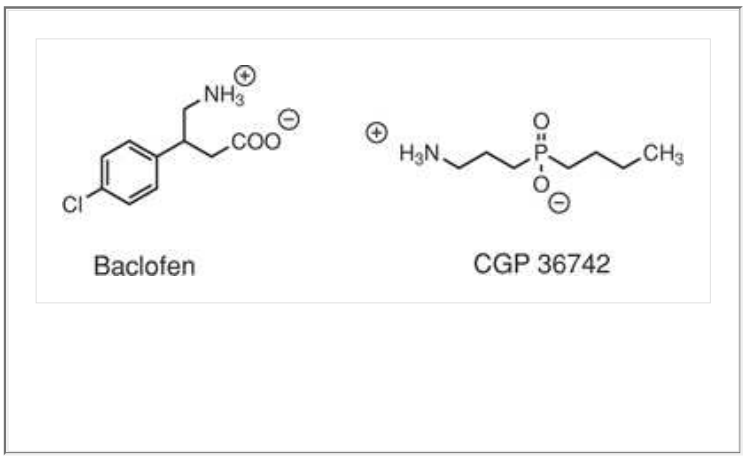
Thus, it may be possible in the future to selectively target the various modulatory sites on the $GABA_A$ receptor to produce preferential pharmacological effects—for example, benzodiazepines that are anxiolytic without sedative effects, antischizophrenic agents that lack sedation and extrapyramidal side effects, and general anesthetics that do not alter respiratory and/or heart rates.

$GABA_B$ Receptors

As studies continued, the application of GABA to cells occasionally was found to produce effects that were not blocked by the standard GABA receptor antagonist bicuculline. Additionally, standard GABA agonists, such as muscimol and isoguvacine, were ineffective as agonists in such systems. This led to the suggestion that a different subtype of GABA receptor mediated these observed effects. In 1998, the structure of the $GABA_B$ receptor was elucidated and found to be a GPCR heterodimer comprised of $GABA_{B1}$ and $GABA_{B2}$ subunits (Fig. 15.11). Each subunit had a 7-membrane spanning segment, which allowed their intracellular C-termini to connect in a 1:1 stoichiometric fashion (34). The $GABA_{B1}$ subunit also was found to exist in two isoforms, $GABA_{B1a}$ and $GABA_{B1b}$. Some have suggested that the $GABA_{B1a}$ subunit is preferentially located presynaptically, whereas the $GABA_{B1b}$ subunit is located postsynaptically. Within this metabotropic receptor, the $GABA_{B1}$ subunits contain the GABA binding domain extracellularly, whereas the $GABA_{B2}$ subunit couples to the G-protein mechanism intracellularly. Both subunits are required for normal receptor function, as shown in Figure 15.11. Knockout mice lacking either of these subunits typically display epileptiform seizures, hyperalgesia, hyperlocomotion, and impaired memory function (35). Besides the normal endogenous agonist GABA, a structural analogue,

(–)-baclofen, acts stereoselectively as an agonist at the $GABA_B$

receptor. (±)-Baclofen, which enters the brain via a selective transporter, has been approved for therapeutic use since 1972 for the treatment of spasticity as a muscle relaxant (36). Besides relaxing skeletal muscles, baclofen is capable of exacerbating absence seizures, decreasing cognitive function, increasing food intake, and decreasing drug-seeking behaviors. Drug development of selective $GABA_B$ receptor antagonists may someday lead to therapeutically useful agents for the treatment of absence seizures, depression, anxiety, and cognitive impairments. One such compound currently undergoing clinical trials is the orally bioavailable $GABA_B$ receptor antagonist CGP-36742, which is in clinical trials for the treatment of mild cognitive impairment and Alzheimer's disease. The inhibition of $GABA_B$ receptors is believed to cause disinhibition of somatostatin (a peptide neurotransmitter in the CNS) release, which then allows activation of NMDA receptors in the hippocampus that normally are required for memory and cognitive functions (37).



γ-Hydroxybutyrate

Another endogenous compound that binds to and weakly activates the $GABA_B$ receptor is GHB (38). This compound, which can be formed as a result of the metabolism of GABA, has a unique distribution in the CNS, but it does not parallel closely that of GABA, as shown in Figure 15.12. Levels of GHB are increased significantly in patients and knockout mice lacking the enzyme SSADH, which is responsible for the conversion of SSA to succinic acid, with eventual entry into the citric acid cycle. A deficiency of this enzyme in patients is caused by a rare, autosomal recessive inheritance and is termed “GHB aciduria” (39).

Endogenous GHB likely interacts with a recently discovered GHB receptor, but the function of GHB in the CNS is not completely understood. A specific GHB receptor was reportedly cloned in 2003 and found to have no sequence homology with the $GABA_B$ receptor—or with any other known GPCR (40). This putative receptor is a member of the GPCR family and is distributed in most brain regions known to bind GHB. The association is not perfect, however, because high levels of mRNA for the GHB receptor are found in the cerebellum even though little GHB normally binds here.

In the United States, GHB is approved for the treatment of cataplexy associated with the sleeping disorder narcolepsy (41). Narcolepsy usually is characterized by a lack of the CNS 11-amino-acid polypeptide orexin (also known as hypocretin) or, possibly, its receptors. Patients with narcolepsy experience excessive bouts of sudden-onset daytime sleepiness and have been treated in the past with stimulants, such as methylphenidate and amphetamine, or with modafinil (see Chapter 23) or antidepressants. The use of GHB in narcolepsy takes a different approach in that dosing is at bedtime and, being a CNS depressant, it acts to enhance sleep quality. Patients then awake the following morning and experience a rebound insomnia, which counteracts any propensity for daytime sleepiness. Exogenously administered GHB appears to produce its clinical and toxic effects via interaction with $GABA_B$ receptors, because most studies have been able to block its effects with $GABA_B$ receptor antagonists but not with the GHB receptor antagonist NCS-382 (although NCS-382 is not an ideal antagonist as it can function as a partial agonist).

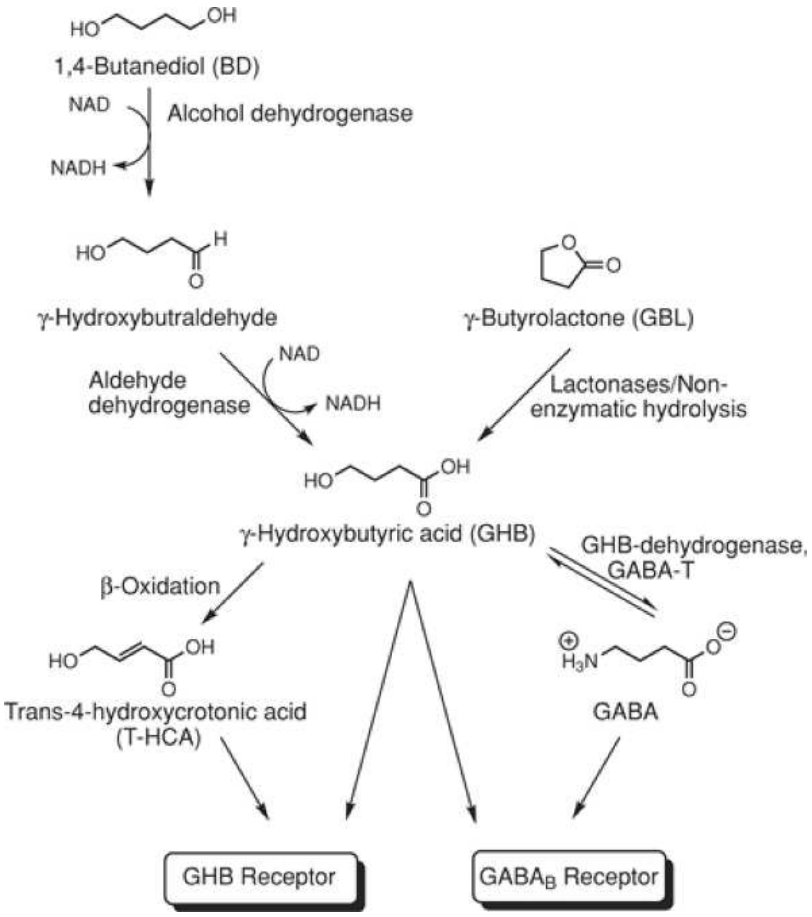


Fig. 15.12. The Biotransformation of 1,4-butanediol (BD) and γ-butyrolactone (GBL) and the receptor sites for their metabolites, γ-hydroxybutyrate (GHB), GABA, and trans-4-hydroxycrotonic acid (T-HCA).

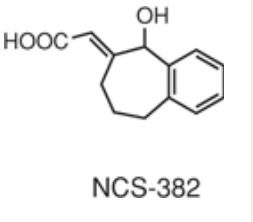


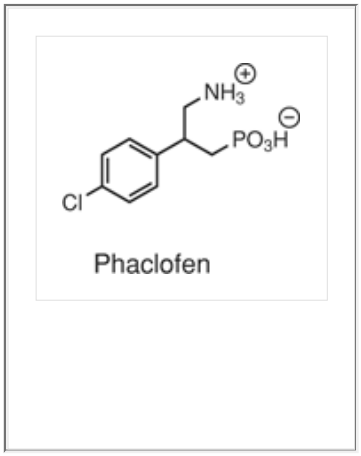
Additionally, GHB has been used for illicit purposes. Because GHB produces CNS sedation with amnesia, some have used this compound for drug-facilitated sexual assault (e.g., “date rape”). As regulations on the availability of GHB became tighter, the use of GHB

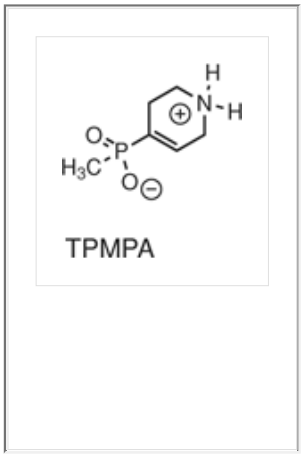
precursors, such as γ-butyrolactone and 1,4-butanediol, became popular (42). Figure 15.12 shows the biotransformation of γ-butyrolactone and 1,4-butanediol to GHB and GABA, explaining their relationship to GHB and $GABA_B$ receptors. They are popular as drugs-of-abuse because they are readily available as solvents.

Furthermore, GHB can be further metabolized by β-oxidation to trans-4-hydroxycrotonic acid, which also can bind to the GHB receptor. Body builders use these compounds as well in an attempt to enhance the release of growth hormone. Usually, however, chronic abuse leads to tolerance, with a need to increase dosing and a propensity to produce physical dependence (43). A serious and difficult-to-treat withdrawal syndrome from GHB abuse has been documented.

$GABA_C$ Receptor

Another receptor that binds GABA but is not antagonized by bicuculline ($GABA_A$) or phaclofen ($GABA_B$) and is not influenced by either the benzodiazepines or barbiturates is known as the $GABA_C$ receptor. The endogenous neurotransmitter GABA is an order of magnitude more potent on the $GABA_C$ receptor as compared with the $GABA_A$ receptor, and the responses to activation of the $GABA_C$ receptor are much slower and sustained as compared with the rapid and brief responses following $GABA_A$ receptor activation. The $GABA_C$ receptor is most abundant in the retina, with significant levels in the spinal cord and pituitary gland. This ligand-gated ion chloride channel is a pentamer of subunits that form the ion channel. Some have suggested that the ρ subunit is unique to the $GABA_C$ receptor (44). On the extracellular domain are binding sites for zinc, which is a potent modulator of receptor activity. The most well-described antagonist is TPMPA. Interestingly, isoguvacine, an agonist at the $GABA_A$ receptors, acts as an antagonist at the $GABA_C$ receptor. Much information regarding the location, function, and pharmacology of the $GABA_C$ receptor is needed to begin to take advantage of this receptor for therapeutic purposes.

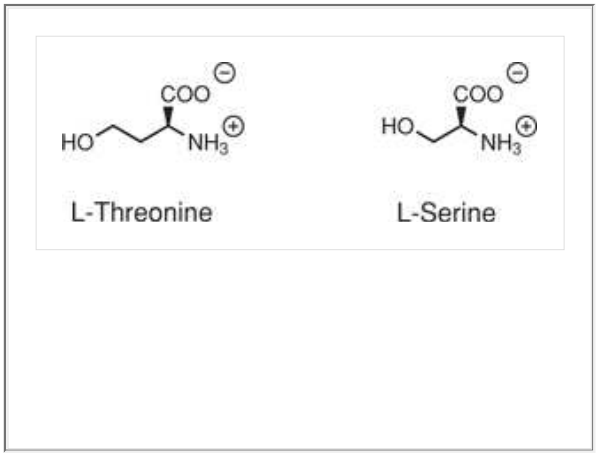




Glycine

The simplest of all amino acids, glycine, which classically causes hyperpolarization of neurons in the CNS, satisfies all the required criteria for neurotransmitter candidacy (45). Glycine in the CNS is unevenly distributed, with the highest concentrations found in the ventral gray areas of the spinal cord and in the medulla oblongata in the brainstem (46). The retina also is a structure with high concentrations of glycine (47). The synthesis of glycine in glycinergic neurons appears to be from L-serine and to be regulated by the enzyme serine hydroxymethyltransferase (SHMT), the concentrations of which in the CNS parallel those of glycine. Another

substrate of SHMT, however, is L-threonine, which also can serve as a precursor of glycine. Administration of large doses of L-serine to animals fails to alter CNS glycine levels, but administration of L-threonine, which passes the blood-brain barrier much better than L-serine does, increase CNS glycine levels (48). L-Threonine has been used to treat a rare form of spasticity, familial spastic paraparesis in humans (49). The synthesis of glycine also could occur via a transamination reaction involving Glu in which glycine and α-ketoglutarate are produced. The understanding of the synthesis of glycine in the CNS for its neurotransmitter functions has been a difficult hurdle to overcome, likely because of the varied roles of glycine in the synthesis of protein, porphyrin, bile salts, and nucleic acids in addition to intermediary metabolic processes involving one-carbon fragments.

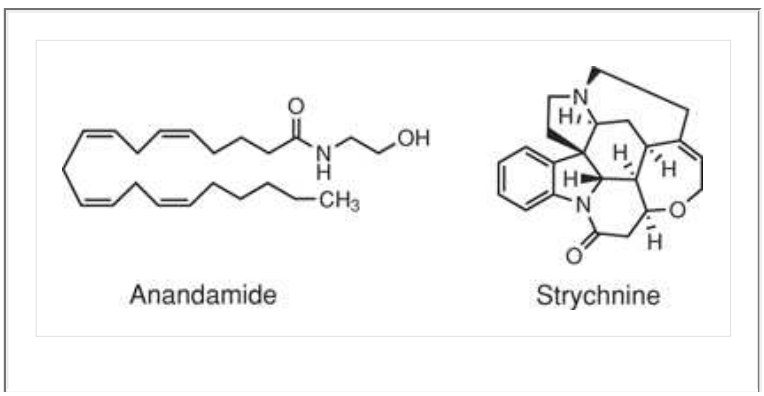


Glycine is stored in vesicles, and its uptake is mediated via VGAT, which also is capable of transporting GABA. Release of glycine occurs from presynaptic terminals in a Ca^{2+}-dependent fashion and, similarly, is taken back up into these terminals and, possibly, nearby glial cells (50,51). Reuptake is via Na^{+}/Cl^{-}-dependent neurotransmitter transporters known as GLYT-1 and GLYT-2. These 12 transmembrane-spanning transporters are located in areas where glycine is believed to act as a neurotransmitter. Few pharmacological tools are available to examine the role of either form of the membrane transporters.

The glycine receptor mediating the inhibitory actions of glycine is similar to the $GABA_A$ receptor and other members of the Cys-loop family in being a pentameric, circular ion channel that allows the conduction of chloride (52). Unlike the GABA receptor, however, the inhibitory glycine receptor can be a homopentamer of α subunits or a heteropentamer comprised of two α subunits and three β subunits. Four isoforms of the α subunits have been identified, whereas only one β subunit is known. The neurotransmitter glycine, in addition to taurine, D-alanine, L-alanine, β-alanine, hypotaurine, serine, and β-aminobutyric acid can bind to any of three sites on the receptor to lead to activation. Positive modulators of the inhibitory glycine receptor include zinc, neurosteroids,

propofol, ethanol, and volatile anesthetics, such as isoflurane (53,54).

The best-described antagonist of the inhibitory glycine receptor is the convulsant strychnine. Strychnine binds to a different site than that which recognizes glycine. Sometimes, the inhibitory glycine receptor is referred to as the “strychnine-sensitive” glycine receptor to distinguish it from the glycine modulatory site on the glutamatergic NMDA receptor. The $GABA_A$ receptor antagonist picrotoxin also can inhibit the glycine receptor. More recently, the endocannabinoids, such as anandamide and 2-arachidonylglycerol, also have been shown to antagonize the activity of glycine at this receptor. Agents that act as agonists at the IAA glycine receptor may find utility as anticonvulsants, muscle relaxants, sedatives, and general anesthetics.



As more information regarding the control of the synthesis of the neurotransmitter pool of glycine becomes available and the development of compounds with selectivity for the IAA glycine receptor are discovered, useful therapeutic agents that take advantage of modulating the glycinergic neurotransmitter system may be realized.

Future Directions

The amino acids play an essential role in the normal control of neurotransmission in the CNS, but during pathological conditions, these same amino acids may mediate a number of the adverse effects that are observed. Many desired agents are available that take advantage of one or more aspects of amino acidergic neurotransmission to produce their pharmacological effects. As agents are developed that are more specific for a particular isoform configuration of an amino acid receptor, the more effectively the treatment of various diseases likely will become. Additionally, associations between disease states and receptor isoform configurations, transporter density, and activity of enzymes involved in the synthesis and degradation of amino acid neurotransmitters may help to improve our understanding of the pathology of these diseases and lead to improved therapies.

Chapter 16

Inhibitors of Nerve Conduction: Local Anesthetics

Matthias C. Lu

Drugs covered in this chapter:

- Articaine
- Benzocaine
- Bupivacaine
- Chloroprocaine
- Mepivacaine
- Levobupivacaine
- Lidocaine
- Ropivacaine

Introduction

A local anesthetic agent is a drug that, when given either topically or parenterally to a localized area, produces a state of local anesthesia by reversibly blocking the nerve conductances that transmit the feeling of pain from this locus to the brain. The term “anesthesia” is defined as a loss of sensation with or without loss of consciousness. According to this definition, wide ranges of drugs with diverse chemical structures are anesthetics. The list includes not only the classic anesthetic agents, such as the general and local anesthetics, but also many central nervous system (CNS) depressants, such as analgesics, barbiturates, benzodiazepines, anticonvulsants, and muscle relaxants.

What Is the Difference between a Local Anesthetic and Other Anesthetic Drugs?

Both general and local anesthetic drugs produce anesthesia by blocking nerve conductance in both sensory and motor neurons. This blockade of nerve conduction leads to a loss of pain sensation as well as to impairment of motor functions. Generally, however, the anesthesia produced by local anesthetics is without loss of consciousness or impairment of vital central functions. It is accepted that a local anesthetic blocks nerve conductance by binding to selective sites on the sodium channels in the excitable membranes, thereby reducing sodium passage through the pores and, thus, interfering with the action potentials. Therefore, a local anesthetic decreases the excitability of nerve membranes without affecting the resting potential. By contrast, a general anesthetic agent alters physical properties of nerve membranes through rather nonspecific interactions with the lipid bilayer or the receptor/ionic channel proteins. These, in turn, reduce membrane excitability through a number of possible mechanisms, including changes in membrane fluidity, permeability, and receptor/channel functions. Furthermore, local anesthetics, in contrast to analgesic compounds, do not interact with the pain receptors or inhibit the release or the biosynthesis of pain mediators.

The Discovery of Local Anesthetics

Similar to many modern drugs, the initial leads for the design of clinically useful local anesthetics were derived from natural sources. As early as 1532, the anesthetic properties of coca leaves (*Erythroxylon coca* Lam) became known to Europeans from the natives of Peru, who chewed the leaves for a general feeling of well-being and to prevent hunger. Saliva from chewing the leaves often was used by the natives to relieve painful wounds. The active principle of the coca leaf, however, was not discovered until 1860 by Niemann, who obtained a crystalline alkaloid from the leaves, to which he gave the name cocaine, and who noted the anesthetic effect on the tongue. Although Moréno y Maiz in 1868 first asked the question of whether cocaine could be used as a local anesthetic, it was Von Anrep in 1880 who, after many animal experiments, recommended that cocaine be used clinically as a local anesthetic. The first report of successful surgical use of cocaine appeared in 1884 by Koller, an Austrian ophthalmologist. This discovery led to an explosive development of new anesthetic techniques and local anesthetic agents (1).

Although the structure of cocaine was not known until 1924, many attempts were made to prepare new analogues of cocaine without its addicting liability and other therapeutic shortcomings, such as allergic reactions, tissue irritations, and poor stability in aqueous solution. Also, cocaine is easily decomposed when the solution is sterilized (Fig. 16.1).

Initially, analogues of ecgonine and benzoic acid, the hydrolysis products of cocaine, were prepared. When the chemical structure of ecgonine became known, the preparation of active compounds accelerated. It was soon realized that a variety of benzoyl esters of amino alcohols, including benzoyltropine, exhibited strong local anesthetic properties without any addicting liability. Thus, removal of the 2-carbomethoxy group of cocaine also abolished the addicting liability. This discovery eventually led to the synthesis of procaine (N,N-diethylaminoethyl ester of *p*-aminobenzoic acid [PABA]) in 1905, which became the prototype for local anesthetics for nearly half a century, largely because it did not have the severe local and systemic toxicities of cocaine.

Clinical Significance

Local anesthetics are widely used clinically in surgery, dentistry, ophthalmology, and in other clinical procedures in which temporary relief of pain is warranted. Some local anesthetics also can be used to treat or prevent cardiac arrhythmias because of their action on cardiac sodium channels.

Before using a local anesthetic, clinicians must take into account the physical properties of the drug, such as its lipid solubility and protein binding as well as the degree of vascularization, the rate of blood flow at the site of application, and the total dosage administered, because these factors govern local anesthetic activity and its associated toxicities. For example, increasing the lipid solubility of an anesthetic may produce an increased penetration into a nerve membrane, but it also can enhance the ability of the drug to pass through a blood vessel wall. This then leads to reduction in anesthetic potency because of the more rapid removal of the agent from the site, which thereby increases its systemic toxicity. Another complicating factor affecting local anesthetic action is distribution of the drug into adipose tissue, because this reduces local anesthetic activity. Additionally, if the protein binding affinity of the local anesthetic is too great, the ability of the drug to reach its target site can be impeded.

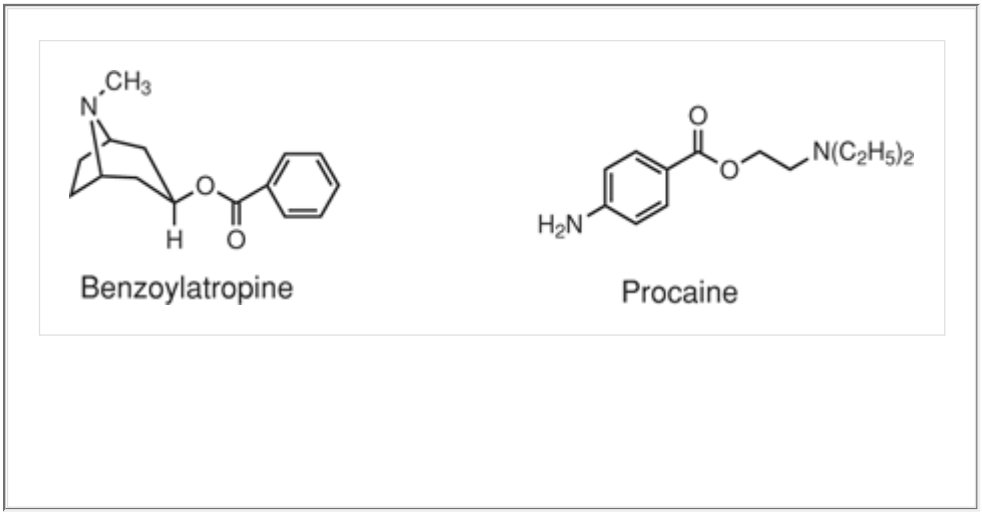
Extraneuronal blood vessels near the site of drug application affect the amount of drug that reaches the nerve trunk to establish anesthesia; thus, a larger dosage is required to elicit local anesthesia, which also contributes to toxicity. After the establishment of anesthesia, a

contributing factor to loss of the drug from the nerve may be caused by the intraneuronal blood vessels. Finally, a reduction in local blood flow also slows systemic uptake of the drug from the injection site and, thus, minimizes any potential toxicity, but it increases the amount of drug available to the nerve and, thus, the duration of anesthesia

Therefore, a sound understanding of how local anesthetics work as well as their relative potencies, duration of action, metabolism, and excretion, along with their relative central nervous system and cardiovascular toxicities, significantly affects clinical practice in which local anesthetics are administered.

Matthias C. Lu

University of Illinois at Chicago, Professor, Assistant Head for Curricular Affairs, Department of Medicinal Chemistry and Pharmacognosy



Although the intrinsic potency of procaine was low and its duration of action relatively short compared with that of cocaine, it was found that these deficiencies could be remedied when procaine was combined with a vasoconstrictor, such as epinephrine. Apparently, a vasoconstrictor agent reduces the local blood supply and, thereby, prolongs the residence time of the local anesthetic.

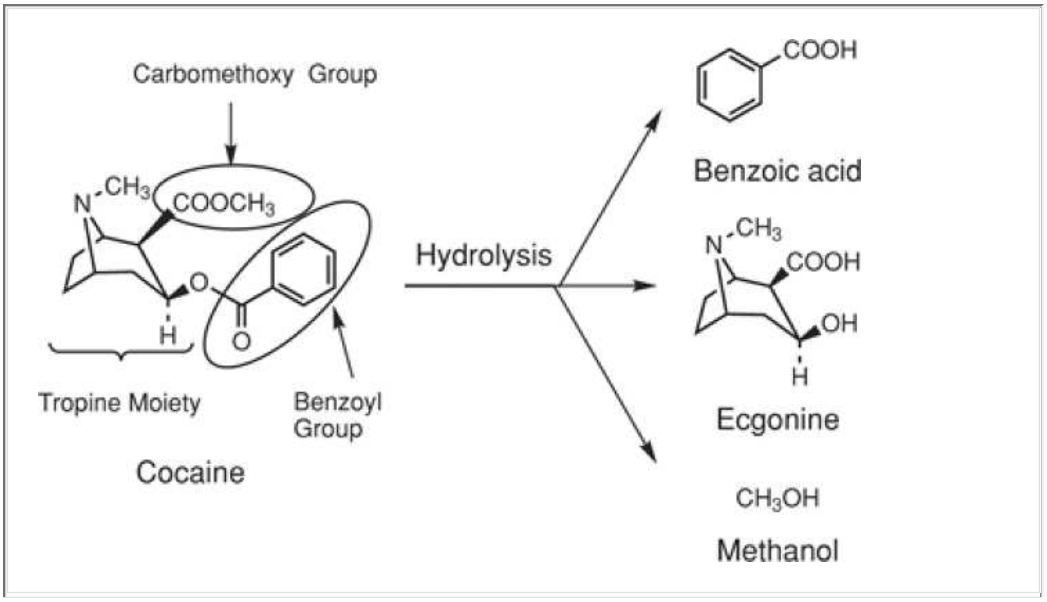


Fig. 16.1. Structures of cocaine and its hydrolysis products.

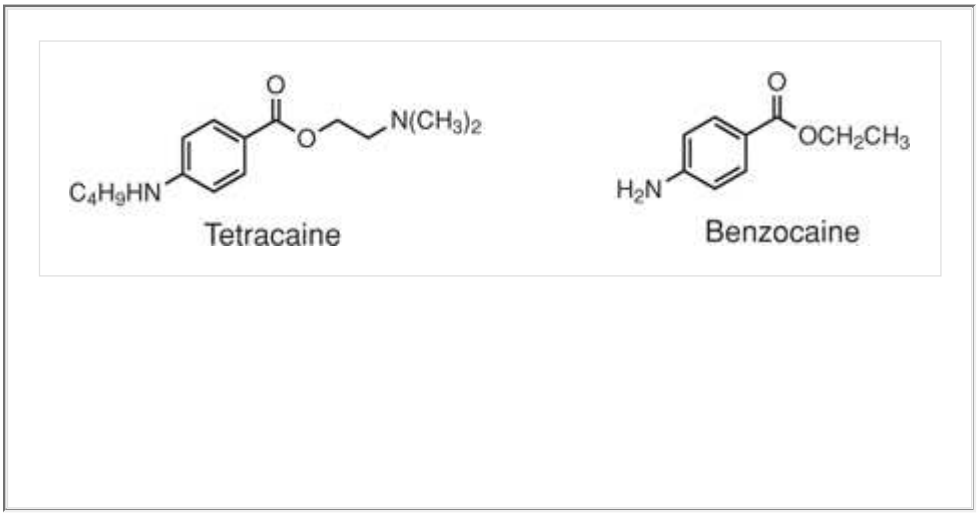
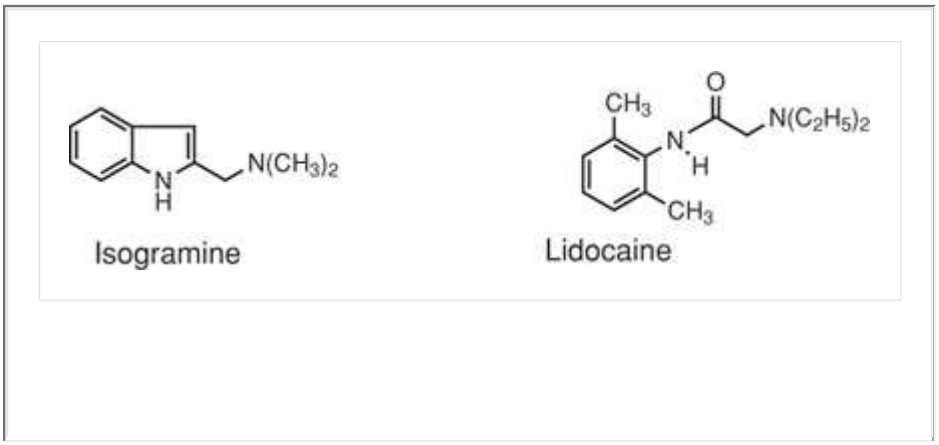
Following the introduction of procaine, hundreds of structurally related analogues were prepared and their local anesthetic properties examined. Most of these compounds were prepared for the purposes of enhancing the intrinsic potency and the duration of action of procaine. Among these compounds, tetracaine remains the most potent, long-acting ester-type local anesthetic agents used in spinal anesthesia.

Benzocaine, an effective topical anesthetic agent, was synthesized by Ritsert in 1890 and was found to have good anesthetizing properties and low toxicity. Benzocaine, however, has limited water solubility except at low pH values because of the lack of a basic aliphatic amino group, thereby disallowing the preparation of pharmaceutically acceptable parenteral solutions.



The next major turning point in the development of clinically useful local anesthetic agents was the serendipitous discovery of the local anesthetic activity of another natural alkaloidal product, isogramine, in 1935 by von Euler and Erdtman. This observation led to the synthesis of lidocaine (Xylocaine) by Löfgren in 1946; lidocaine was the first nonirritating, amide-type local anesthetic agent with good local anesthetic properties yet less prone to allergenic reactions than procaine analogues. A further

practical advantage of lidocaine was its stability in aqueous solution because of the more stable amide functionality. Structurally, lidocaine can be viewed as an open-chain analogue of isogramine and, thus, is a bio-isoteric analogue of isogramine.



In the years since 1948, extensive progress has been achieved primarily in the fields of neurophysiology and neuropharmacology rather than that of synthetic medicinal chemistry. Most of this research has significantly increased our understanding of how nerve conduction occurs and how compounds interact with the neuronal membranes to produce local anesthesia. It should be noted, however, that although a number of current clinically useful local anesthetic agents have been introduced into the market, an ideal local anesthetic drug has, unfortunately, not been realized.

Characteristics for an Ideal Local Anesthetic

An ideal local anesthetic should produce reversible blockade of sensory nerve fibers with a minimal effect on the motor fibers. It also should possess a rapid onset and have a sufficient duration of action for the completion of major surgical procedures without any systemic toxicity.

This goal, however, can be attained only through further structure–activity relationship studies, particularly with regard to their selective actions on the voltage-gated sodium channels. Additional leads for the design of ideal local anesthetics also could come from a more systematic metabolic and toxicity study of currently available agents. To understand the chemical aspects of local anesthetics and, thus, to provide a proper background for practical uses of these compounds, it is necessary to have a working knowledge of basic neuroanatomy and electrophysiology of the nervous system.

Neuroanatomy and Electrophysiology of the Nervous System

Neuroanatomy

As can be seen in Figure 16.2, the sensory fibers (afferent neurons) course together in bundles with the motor fibers (efferent neurons) from the periphery to the spinal cord (2). The cell bodies of the sensory fibers are found at the point at which the nerve enters the vertebra, and they are seen as enlargements on the nerve bundles. The cell bodies of the motor fibers are found within the spinal cord. The bundles of sensory and motor fibers outside the spinal cord are wrapped in a connective tissue sheath, the epineurium. Groups of fibers are found within this “nerve'' in small bundles, each of which is surrounded by connective tissue known as perineurium and, in even smaller tubes of connective tissue, called endoneurium.

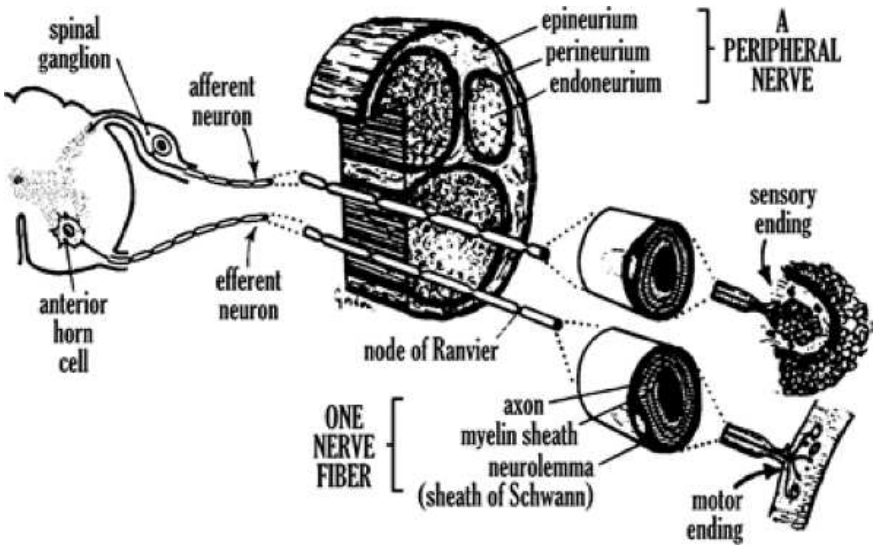


Fig. 16.2. Diagram showing the various parts of a peripheral nerve. (Adapted from Ham AW. Histology, 6th Ed. Philadelphia: JB Lippincott, 1969: p. 524; with permission.)

Figures 16.2 and 16.3 also show that each nerve axon has its own membranous covering, often called the nerve membrane, tightly surrounded by a myelin sheath called a Schwann cell covering. The myelin is not continuous along the fiber. The interruptions are the nodes of Ranvier, which are of great importance for nerve functioning.

Electrophysiology of Nerve Membrane

Resting Potential

Most nerves have resting membrane potentials of approximately -70 to -90 mV as a result of a slight imbalance of electrolytes across the nerve membranes (i.e., between the cytoplasm and the extracellular fluid) (3). The origin of this membrane potential has been of great interest to neurophysiologists. The main electrolytes in nerve axons and cell bodies are sodium, potassium, calcium, magnesium, and chloride.

At resting potential, the nerve membrane was believed to be impermeable to sodium because of the low sodium ion concentration in the excitable cell. Potassium ions may flow in and out of the cell with ease, indicating that the membrane is highly permeable to potassium ions. A high potassium ion concentration is retained intracellularly by the attractive forces provided by the negative charges on the protein molecules. Thus,

the predominant intracellular cation is potassium (~110 to 170 mmol/L), and the predominant extracellular ions are sodium (~140 mmol/L) and chloride (~110 mmol/L).

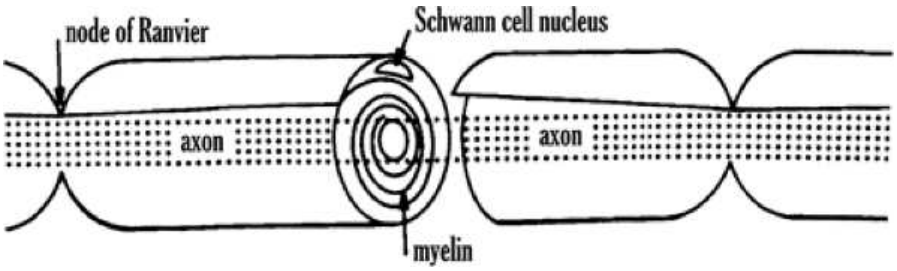

Fig. 16.3. Single myelinated nerve fiber.

It would appear that changes in the intracellular or extracellular concentration of potassium ions markedly alter the resting membrane potential. For this reason, neurophysiologists treated an excitable cell as if it were an electrochemical, or Nernst, cell. The resting potential for one permeant species could therefore be explained by the familiar Nernst equation:

$E = -RT/zF \ln [K^+]_i/[K^+]_o$

in which E = membrane potential, inside minus outside; R = gas constant; T = temperature; z = valence of ion; F = Faraday's constant; $[K^+]_i$ = activity of potassium intracellularly, and $[K^+]_o$ = activity of potassium extracellularly.

Action Potential

Action potentials are transient membrane depolarizations that result from the influx of sodium ions through a brief opening of the voltage-gated sodium channels on excitation of the cell (3). The transmembrane potential during an action potential goes from -70 to approximately +40 mV (a total net change of 110 mV) and promptly returns to the resting potential; the event lasts approximately 1 millisecond (Fig. 16.4).

The transmembrane potential at the peak of the action potential can be predicted from the Nernst equation by substituting appropriate sodium ion concentrations for those of potassium ions. Thus, it appears that the excitable membrane can be transformed from a potassium electrode to a sodium electrode during the active process (4).

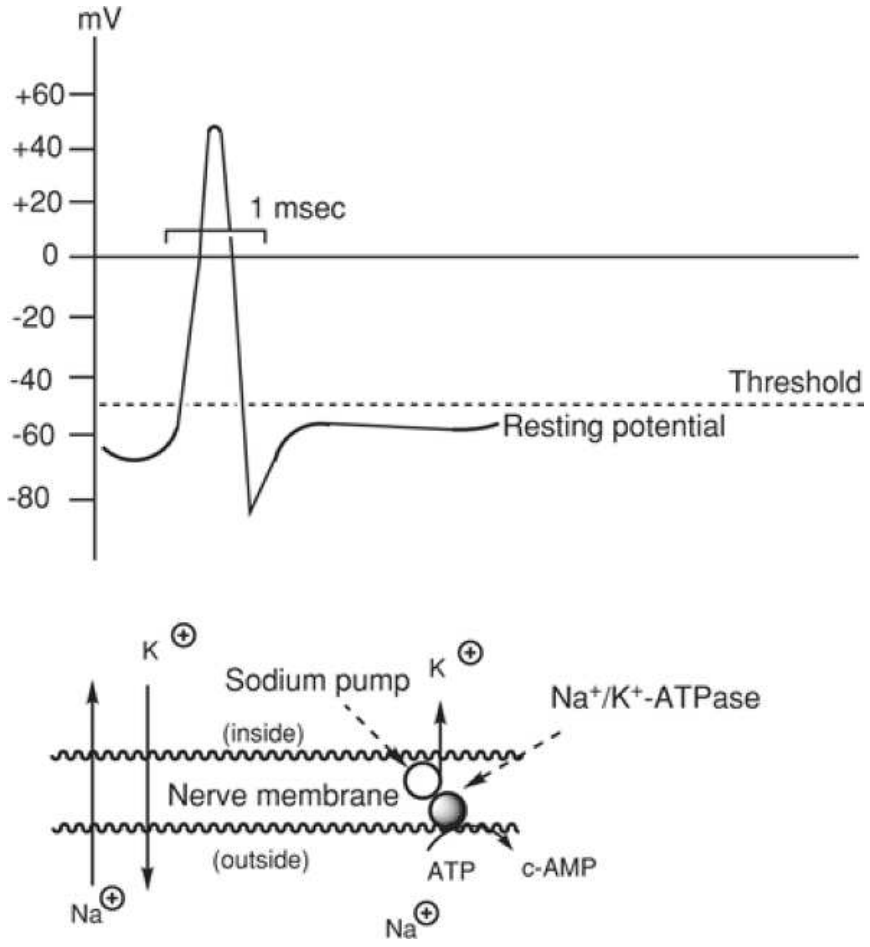

Fig. 16.4. Relationship between membrane action potential and ionic flux across the nerve membrane.

As the cell approaches its peak action potential, the permeability to sodium again decreases (sodium inactivation or repolarization). If no other event occurred, this cell would slowly return to its resting potential, but the cell again becomes highly permeable to potassium ions, allowing potassium ions to flow out and quickly restore the membrane potential. After an action potential, the cell would therefore be left with a small increase in sodium ions and a decrease in potassium ions. To explain how the nerve is restored to its original electrolyte composition at the resting potential, it was necessary to postulate a mechanism by which sodium ions could be extruded and potassium ions could probably be accumulated. It has been suggested that by using the energy derived from splitting adenosine triphosphate, an adenosine triphosphatase system could serve this function and act as a sodium pump (5). Other investigators believe that during excitation, the membrane goes from one stable state to another, functioning more like an ion exchanger (6). Koketsu (7) suggests that during excitation, the membrane goes from a calcium-associated to a calcium-dissociated state, triggered by the depolarizing pulse, and that during recovery, the membrane returns to the resting state by the reassociation as a result of outward movement of potassium ions.

Threshold

An electrical stimulus of less than a certain voltage can result in only local electronegativity and

cannot elicit a propagated action potential. The voltage necessary to change localized electronegativity into a propagated action potential is called the threshold voltage, which is closely related to the stimulus duration—the longer the stimulus, the lower the threshold voltage.

Refractoriness

Immediately after an impulse has been propagated, the axon is absolutely refractory, or completely inexcitable, and no stimulus, no matter how strong or long, can excite it. Shortly thereafter, the axon becomes relatively refractory; it responds with a propagated impulse only to stimulation that is greater than the normal threshold. The length of the refractory period is affected by the frequency of stimulation and by many drugs (Fig. 16.5).

Conductance Velocity

The conductance velocity is the velocity at which an impulse is conducted along the nerve and is proportional to the diameter of the fiber.

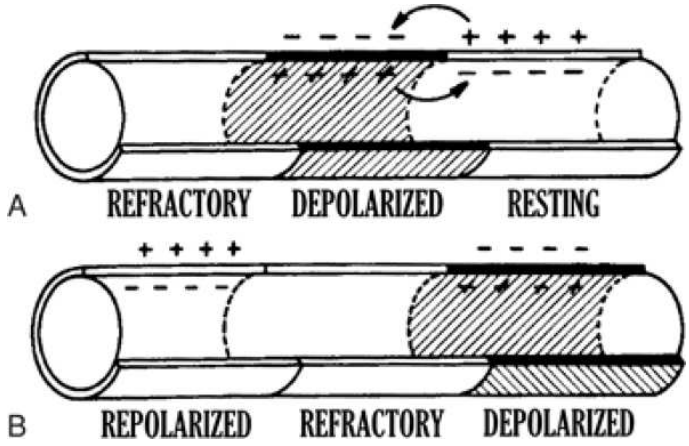

Fig. 16.5. Impulse propagation. (A) The wave of depolarization passes down the nerve, followed by a wave of refractoriness. (B) The wave of refractoriness is followed by a wave of repolarization. (Adapted from De Jong RH, Freund FG. Physiology of peripheral nerve and local anesthesia. Int Anesthesiol Clin 1970;8:35–53; with permission.)

Nodal Conduction

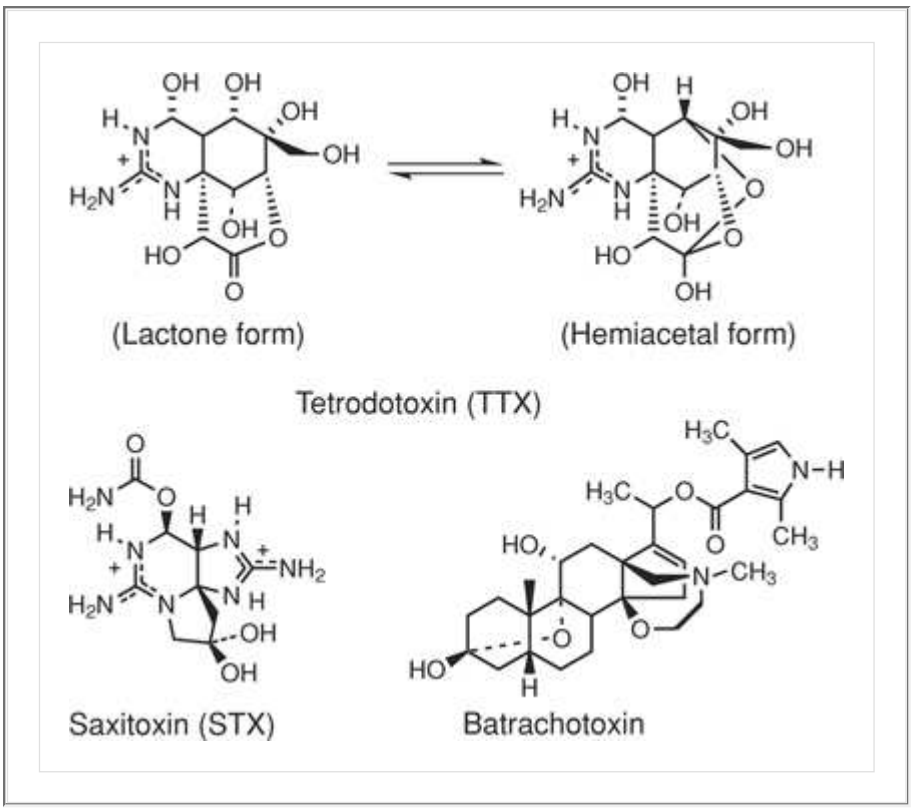
Because longitudinal resistance is inversely proportional to cross-sectional area, impulses are conducted faster in large-diameter fibers. The squid axon is unmyelinated and exceptionally large (~800 μμ); therefore, impulses are conducted rapidly along it. Contraction of the mantle of a squid, however, is an uncomplicated procedure that does not require a complex sensorimotor system. Perhaps, during evolution, vertebrates developed a complicated input–output system of many fibers collected in bundles, as shown in Figure 16.2.

Conduction in these fibers would be slow if they were not insulated with a myelin coat, interrupted at intervals by the nodes of Ranvier, where current enters and exits. Ionic fluxes occur at these nodes. The impulse jumps along the fiber from node to node faster than in

unmyelinated fiber (8).

Sodium Channel

The voltage-gated sodium channels are discrete, membrane-bound glycoproteins that mediate sodium permeability and, thus, are responsible for the generation of action potentials in skeletal muscle, nerve, and cardiac tissues (9,10,11,12,13,14,15,16). Our understanding of the structural domains and binding sites on voltage-gated sodium channels have evolved considerably since the first cloning and expression studies of the channel protein by Noda (9). The channel gating kinetics have been extensively studied with the use of selective blockers of sodium channels, such as tetrodotoxin (TTX) and saxitoxin (STX), and by site-directed mutagenesis (15). Both TTX and STX bind stoichiometrically to the outer opening of the channels and are detected with patch-clamp electrophysiological techniques on the cut-open squid giant axon (16). Neher and Sakmann, two German scientists, were awarded the 1991 Nobel Prize in physiology and medicine for their work on ion channels with these neurotoxins (16).



Recent mapping of receptor binding sites within the channel protein for lipid soluble neurotoxins, such as batrachotoxin (BTX), and for local anesthetics using site-directed mutagenesis has provided further insight regarding these channels (15). For example, mammalian voltage-gated sodium channel contain one large α subunit and one or two smaller β subunits (15). The primary structure of the α subunit is composed of four homologous domains (D1–D4), each with six transmembrane segments (S1–S6) and a hydrophobic loop thought to dip into the membrane to line the aqueous pore in a pseudotetrameric arrangement (Fig. 16.6) (13,14,15).

Furthermore, the voltage sensor for activation gating and the structure for fast inactivation gating have been delineated to involve the positively charged S4 segments of each domain (also known as the ion selectivity filter, because it contains positively charged amino acid residues). The selective filter is needed to discriminate sodium ions from other ions (i.e., sodium ions pass

through this pore approximately 12-fold faster than the potassium ions). Sodium channels open

and close as they switch between several conformational states: the resting/closed form (nonconducting state), the open channel (conducting), and the inactivated form (nonconducting state).

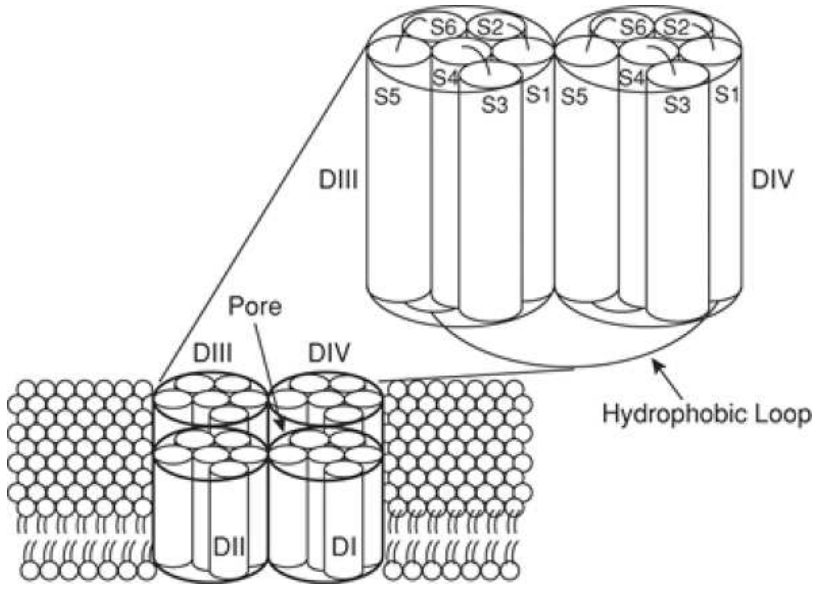


Fig. 16.6. A schematic representation of the α subunit of the sodium channel and the pore-forming unit. (From Anger T, Madge DJ, Mulla M, et al. Medicinal chemistry of neuronal voltage-gated sodium channel blockers. J Med Chem 2001;44:115–137; with permission.)

What Are the Sources of These Neurotoxins?

Tetradotoxin is a potent neurotoxin isolated from the ovaries and liver of many species of Tetradodontidae, especially the Japanese fugu (or puffer fish). Saxitoxin is a mussel or clam poison produced by certain marine dinoflagellates, *Gonyaulax catenella* or *G. tamarensis*, the consumption of which cause the mussels or clams to become poisonous. These poisonous shellfish were connected to a toxic "red tide" environmental condition on the coastal region of California in early 1970. Batrachotoxin is a cardiotoxic and neurotoxic steroid isolated originally from the poison dart frog, *Phyllobates terribilis*. It is a lipid soluble neurotoxin that is at least 10-fold more toxic than tetradotoxin.

It generally is agreed that at resting potential, the sodium channels are in a rest/closed state and are impermeable to the passage of sodium ions. On activation, the channels undergo conformational changes to an open state, allowing rapid influx of sodium ions across the axonal membrane.

Table 16.1. Clinically Available Local Anesthetics

Generic Name	Trade Name	Recommended Application

Articainea	Septocaine, Septanest	Parenteral (dental)
Benoxinateb	Oxybuprocaine	Mainly in ophthalmology
Benzocaine[ab]	Americaine, Anbesol, Benzodent, Orajel, Oratect, Rid-A-Pain, Hurricaine	Topical
Bupivacaine[ab]	Marcaine, Sensorcaine	Parenteral
Butamben[ab]	Butesin	Topical
Chloroprocaine[ab]	Nesacaine	Parenteral
Dibucaine[ab]	Nupercainal, Cinchocaine	Topical
Dyclonine[ab]	Sucrets	Topical (mucosal only)
Etidocainea	Duranest	Parenteral
Levobupivacinea	Chirocaine	Parenteral
Lidocaine[ab]	Xylocaine, L-Caine, DermaFlex, Dilocaine, Lidoject, Lignocaine, Octocaine,	Parenteral, topical
Mepivacaine[ab]	Carbocaine, Polocaine, Isocaine	Parenteral, topical
Pramoxine[ab]	Prax, Tronothane	Topical

Prilocaine[ab]	Citanest	Parenteral, topical
Procaine[ab]	Novocain	Parenteral
Proparacaine[ab]	Alcaine, Ophthaine, Ak-Taine	Mainly in ophthalmology
Propoxycaineb	Blockaine, Ravocaine	Parenteral
Ropivacaine[ab]	Naropin	Parenteral
Tetracaine[ab]	Pontocaine, Amethocaine, Prax	Parenteral, topical
Benzyl alcoholb		Topical, mainly in combination with pramoxine
Eugenolb		Topical, especially in dentistry
Menthol[ab]	Chloraseptic lozenges, Dermoplast,	Topical, mainly in combination with benzocaine or
	Pramegel, Pontacaine ointment	pramoxine or tetracaine
Phenol[ab]	Anbesol	Topical, mainly in combination with benzocaine
Ethyl chlorideb		Extracutaneous, temperature decreasing

Thus, when threshold potential is exceeded, most of the sodium channels are in an open, or conducting, state. At the peak of the action potential, the open channels spontaneously convert to an inactivated state (i.e., nonconducting and nonactivatable), leading to a decrease in sodium permeability. When a sodium channel is in the inactivated state, it cannot be opened without first transforming to the normal resting/closed form.

Therapeutic Considerations for Using Local Anesthetic Drugs

Since the discovery of cocaine in 1880 as a surgical local anesthetic, several thousand new compounds have been tested and found to produce anesthesia by blocking nerve conductance. Among these agents, only approximately 20 are clinically available in the United States as local anesthetic preparations (Table 16.1). Table 16.2 contains chemical structures of the different types of agents in current or recent use.

Pharmaceutical Preparations

Local anesthetic agents generally are prepared in various dosage forms: aqueous solutions for parenteral injection, and creams and ointments for topical applications. Thus, chemical stability and aqueous solubility become primary factors in the preparations of suitable pharmaceutical dosage forms.

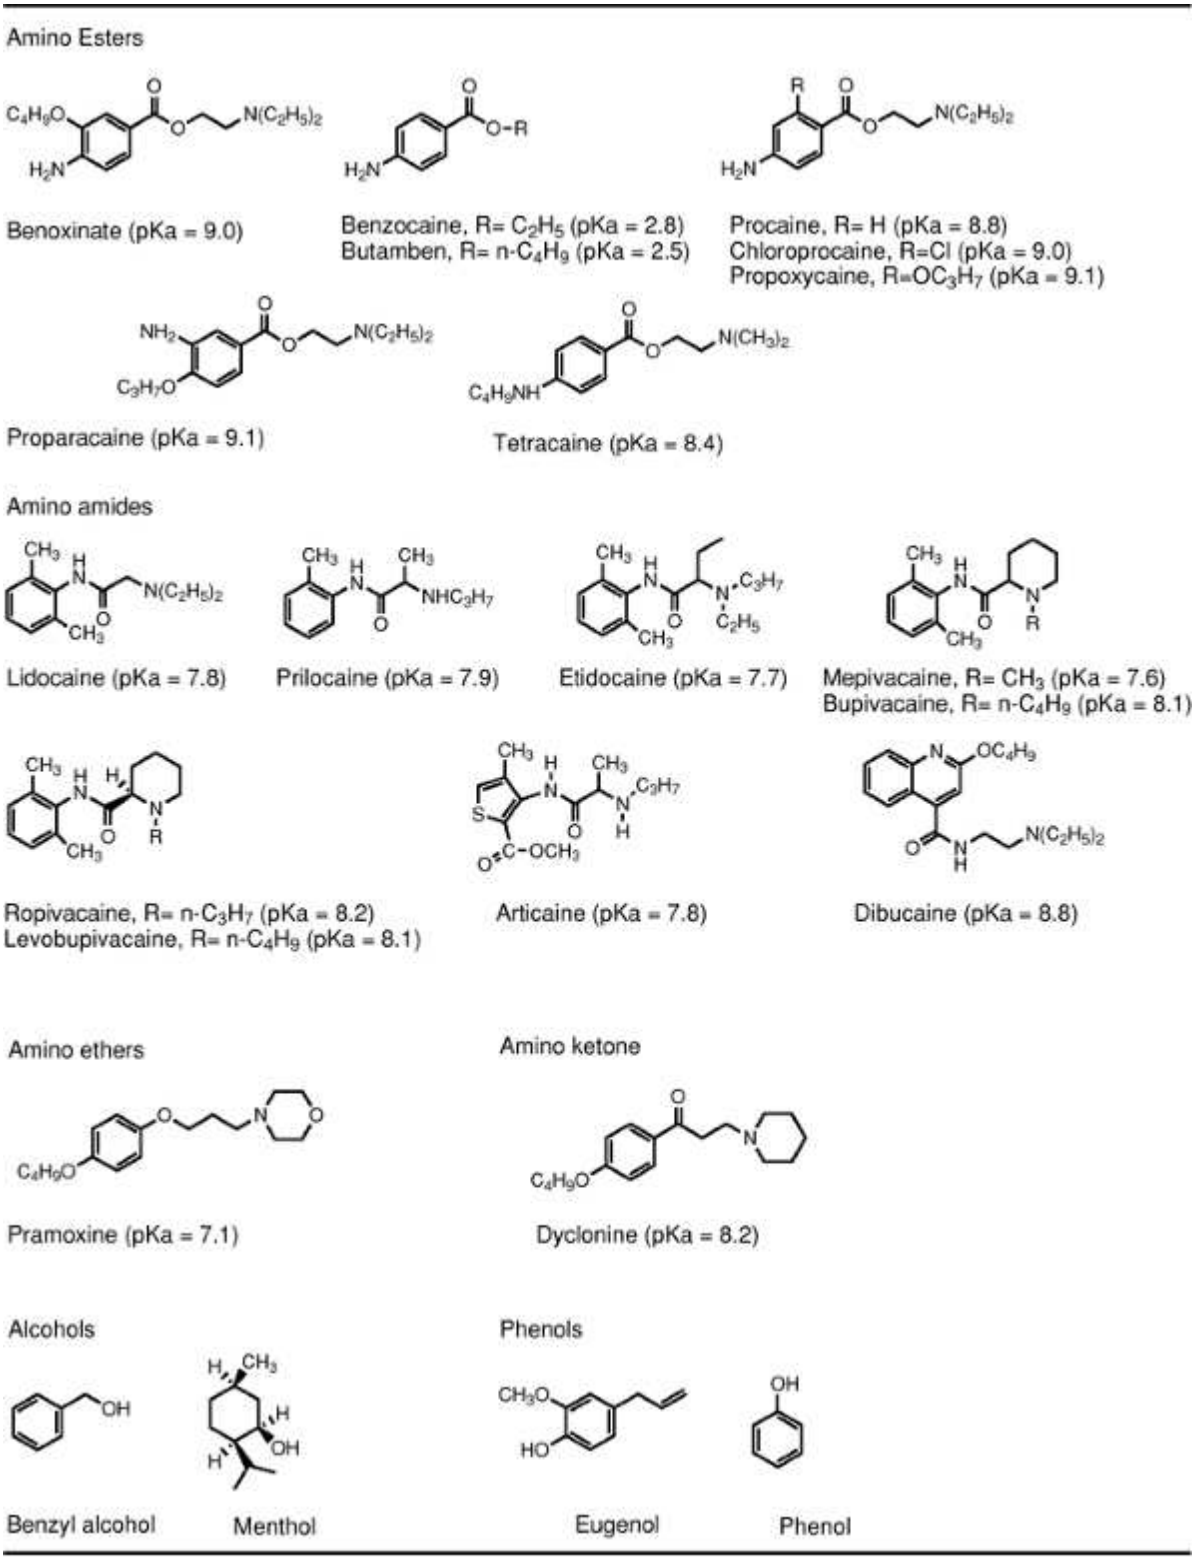

Table 16.2. Structures of Local Anesthetics

As a rule, compounds containing an amide linkage have greater chemical stability than the ester types do. In this regard, an aqueous solution of an amino ester-type local anesthetic is more likely to decompose under normal conditions and cannot withstand heat sterilization because of

base-catalyzed hydrolysis of the ester.

Local anesthetic activity usually increases with increasing lipid solubility. Unfortunately, this increase in lipid solubility is often inversely related to water solubility. For this reason, a suitable parenteral dosage form may not be available for these agents because of poor water solubility under acceptable conditions. For example, benzocaine, which lacks a sufficiently basic aliphatic amino group needed for salt formation, is practically insoluble in water at a neutral pH. Protonation of the aromatic amino group in benzocaine results in a salt with a pK_a of 2.78,

which is too acidic and, therefore, unsuitable for the preparation of a parenteral dosage form for injection. For this reason, benzocaine and its closely related analogue, butamben, are used mostly in creams or ointments to provide topical anesthesia of accessible mucous membranes or skin for burns, cuts, or inflamed mucous surfaces.

Study Question 1

Question: What is the biochemical and pharmacological basis for the observation that coadministration of epinephrine with procaine leads to an increase in the duration of action as well as a decrease in systemic toxicity of procaine?

Many attempts have been made to substitute oils, fats, or fluid polymers for the aqueous vehicle commonly used in injectable local anesthetics. Unfortunately, the pharmacological results of these experiments have been quite disappointing, often as a result of the undesirable toxicity of the nonaqueous vehicle.

The only commonly accepted organic additives to local anesthetics are vasoconstrictors, such as epinephrine. These compounds often increase the frequency of successful anesthesia and, to a limited degree, increase the duration of activity by reducing the rate of drug loss from the injection site. These agents are believed to function by constricting arterioles that supply blood to the area of the injection.

The effect of these vasoconstrictors is less pronounced if the agents are added to a local anesthetic solution that is to be injected in an area that has profuse venous drainage but is remote from an arterial supply.

Administration of a local anesthetic in a carbonic acid–carbon dioxide aqueous solution rather than the usual solution of a hydrochloride salt appreciably improves the time of onset and duration of action. This change in solution form is apparently not associated with local or systemic toxicity.

Current theories suggest that carbon dioxide potentiates the action of local anesthetics by initial indirect depression of the axon, followed by diffusion trapping of the active form of the local anesthetic within the nerve. Use of the carbonate salt appears to be one pharmaceutical modification of the classic local anesthetic agents that may result in significant clinical advantages.

A eutectic mixture of a local anesthetic cream (EMLA cream) containing 2.5% lidocaine and 2.5% prilocaine (or etidocaine) also is available for topical application of local anesthetic through the keratinized layer of the intact skin to provide dermal or epidermal analgesia. This mode of administration allows the use of higher concentrations with minimal local irritation and lower systemic toxicity. The use of EMLA creams, especially those containing prilocaine, on mucous membranes is not recommended, however, because of the faster absorption of the drugs and, therefore, the increasing risk of systemic toxicity, such as methemoglobinemia (17).

Study Question 2

Question: Why is the alkalinization of local anesthetics to improve onset time theoretically sound but clinically impractical?

Toxicity and Side Effects

The side effects and toxicity of local anesthetics seem to be related to their actions on other excitable membrane proteins, such as in the sodium and potassium channels in the heart, the nicotinic acetylcholine receptors in the neuromuscular junctions, and the nerve cells in the CNS. In general, neuromuscular junctions and the CNS are more susceptible than the cardiovascular system to the toxic effects of local anesthetics.

The actions on skeletal muscles are transient and reversible, whereas the CNS side effects can be deleterious. The primary effect of the toxicity seems to be convulsions, followed by severe CNS depression, particularly of the respiratory and cardiovascular centers. This may be related to an initial depression of inhibitory neurons, such as GABAergic systems, causing convulsions, followed by depression of other neurons, leading to general depression of the CNS.

Amino amide-type local anesthetics (i.e., lidocaine derivatives) are, in general, more likely to produce CNS side effects than the amino ester-type compounds (procaine analogues). It should be noted, however, that the toxic effects observed depend heavily on the route and site of administration as well as on the lipid solubility and metabolic stability of a given local anesthetic molecule. For example, most amide-type local anesthetics, such as lidocaine, are first degraded via N-dealkylations by the hepatic enzymes (see Fig. 16.10). Unlike lidocaine, however, the initial metabolic degradation of prilocaine in humans is hydrolysis of the amide linkage to give o-toluidine and N-propylalanine. Formation of o-toluidine and its metabolites are said to cause methemoglobinemia in some patients (17). For this reason, prilocaine is more likely than other local anesthetics to cause methemoglobinemia.

In contrast, allergic reactions to local anesthetics, although rare, are known to occur exclusively with *p*-aminobenzoic ester-type local anesthetics (18). Whether the formation of PABA on ester hydrolysis is solely responsible for this hypersensitivity remains to be investigated. However, the preservative compounds, such as methyparaben, used in the preparation of amide-type local anesthetics are metabolized to PABA-like substance, *p*-hydroxybenzoic acid. Thus, patients who are allergic to amino ester-type local anesthetics should be treated with a preservative-free amino amide-type local anesthetic.

Amide-type local anesthetics (e.g., procainamide and lidocaine) also possess antiarrhythmic activity when given parenterally and at a subanesthetic dosage. Although this action can be attributed to their actions on sodium channels in cardiac tissues, current evidence suggests a distinctly different mechanism of action with respect to the modulation of channel receptors and the location of binding sites for these compounds (19,20).

Chemical and Pharmacodynamic Aspects of Local Anesthetics

Mechanism of Action

Local anesthetics decrease the excitability of nerve cells without affecting the resting potential. Because the action potential, or the ability of nerve cells to be excited, seems to be associated with the movement of sodium ions across the nerve membranes, anything that interferes with the movement of these ions interferes with cell excitability. For this reason, many hypotheses have been suggested to explain how local anesthetics regulate the changes in sodium permeability that underlie the nerve impulse. These hypotheses include direct action on ionic channels that interferes with ionic fluxes and interaction with phospholipids and calcium that reduces

membrane flexibility and responsiveness to changes in electrical fields.

The nonspecific membrane actions of local anesthetics can be easily ruled out, because most clinically useful agents, in contrast to general anesthetics, possess a defined set of structure–activity relationships. As mentioned earlier, local anesthetic agents block nerve conductance and produce anesthesia as a result of their selective actions on membrane-bound sodium channels. It should be pointed out that at much higher drug concentrations, local anesthetics also bind and block potassium channels.

Interaction with Phospholipids and Calcium

Calcium exists in the membrane in a bound state. Many investigators believe that the release of the bound calcium is the first step in membrane depolarization and that this release leads to the changes in ionic permeability described previously. It has been suggested that local anesthetics displace the bound calcium from these sites and form more stable bonds, thereby inhibiting ionic fluxes. The following evidence has been offered in support of this theory: Both calcium and local anesthetics bind to phospholipids in vitro, reducing their flexibility and responsiveness to changes in electrical fields (21,22,23). Also, membrane excitability and instability increase in calcium-deficient solutions. Local anesthetics counteract this abnormal increase in excitability, and more local anesthetic is necessary to block excitation in calcium-poor solutions (24). Direct proof of this hypothesis, however, is lacking because of the difficulty in measuring calcium movements in vivo. It also is possible that the aforementioned cause-and-effect relationship between intracellular free calcium and membrane excitability is the result of a sodium-calcium exchange reaction; that is, the influx of sodium ions displaces the membrane-bound calcium, which leads to an increase of intracellular free calcium and, thereby, increases cellular excitability.

Local anesthetics interact differently, however, with neuronal phospholipids with or without the presence of cholesterol. Thus, the interactions of local anesthetics with the cellular membranes actually may contribute to their observed differences in toxicity (25).

Action on Voltage-Sensitive Sodium Channels

As mentioned, the voltage-sensitive sodium channels are membrane-bound glycoproteins that mediate sodium permeability. On excitation, these channels undergo conformational changes from a closed to an open state, thus allowing a rapid influx of sodium. The movement of sodium ions is blocked by the neurotoxins TTX and STX and by local anesthetics (26). Most electrophysiologists and neuropharmacologists now agree that the mechanism of action of local anesthetics results primarily from their binding to one or more sites within the sodium channels, thus blocking the sodium conductance (27). The exact location of these binding sites, however, and whether all local anesthetics interact with a common site remain matters of dispute.

Action on Sodium Conductance

Local anesthetics block sodium conductance by two possible modes of action: tonic inhibition, and phasic inhibition (28,29). Tonic inhibition results from the binding of local anesthetics to nonactivated closed channels and, thus, is independent of channel activation. Phasic inhibition may be accomplished when local anesthetics bind to activated, open states (conducting) or to inactivated states (nonconducting) of the channels. Thus, it is not surprising that a greater phasic inhibition usually is obtained with repetitive depolarization.

Two reasons have been suggested to explain this observation. First, channel inactivation during depolarization increases the number of binding sites that normally are inaccessible to local anesthetics at resting potential. Second, both the open and the inactivated channels possess binding sites with a higher affinity; therefore, local anesthetics bind more tightly and result in

stronger nerve block.

Furthermore, it generally is agreed that most of the clinically useful local anesthetics exert their actions by binding to the inactivated forms of the channels and, thus, prevent their transition to the original rest state (29). Because most of these drugs exhibit both tonic and phasic inhibitions, however, whether tonic and phasic block results from drug interaction at the same or different sites remains unclear.

Local Anesthetics Binding to Sodium Channels

Most of the clinically useful local anesthetics are tertiary amines with a pK_a of 7.0 to 9.0. Thus, under physiological

conditions, both protonated forms (onium ions) and the un-ionized, molecular forms are available for binding to the channel proteins. In fact, the ratio between the onium ions [BH^+] and the un-ionized molecules [B] can be easily calculated based on the pH of the medium and the pK_a of the drug molecule by the Henderson-Hasselbach equation:

$$pH = pK_a - \log [BH^+]/[B]$$

The effect of pH changes on the potency of local anesthetics has been extensively investigated (30). Based on these studies, it was concluded that local anesthetics block the action potential by first penetrating the nerve membrane in their un-ionized forms and then binding to a site within the channels in their onium forms. Perhaps the most direct support for this hypothesis comes from the experimental results of Narahashi et al. (31,32), who studied the effects of internal and external perfusion of local anesthetics (both tertiary amines and quaternary ammonium compounds), at different pH values, on the sodium conductance of the squid axon. The observation that both tertiary amines and quaternary ammonium compounds produce greater nerve blockage when applied internally indicates an axoplasmic site for these compounds.

Furthermore, only the tertiary amines exhibit a reduction in their local anesthetic activities when the internal pH is raised from 7.0 to 8.0. Because the increase of internal pH to 8.0 favors the existence of the un-ionized forms, this result again suggests that the onium ions are required for binding to the channel receptors. Narahashi and Frazier (33) further estimated that approximately 90% of the blocking actions of lidocaine may be attributed to onium forms of the drug molecule, whereas only approximately 10% may result from un-ionized molecule and, perhaps, at a hydrophobic binding site other than the primary binding site. Benzocaine, because of its lack of a basic amine group (pK_a = 2.78), and other neutral anesthetics, such as benzyl alcohol, have been suggested to bind to this hydrophobic binding site.

In 1984, Hille (34) proposed a unified theory involving a single receptor in the sodium channels for both onium ions (protonated tertiary amines and quaternary ammonium compounds) and un-ionized forms of local anesthetics. As depicted in Figure 16.7, a number of pathways are available, depending on the size, pK_a, and lipid solubility of the drug molecules as well as the voltage and frequency-dependent modulation of the channel states, for a drug to reach its receptor binding sites. Protonated anesthetic molecules [BH^+] and quaternary ammonium compounds reach their target sites via the hydrophilic pathway externally (pathway b in Fig. 16.7), which is available only during channel activation.

The lipid-soluble anesthetic molecules, on the other hand, diffuse across the neuronal membrane in their un-ionized forms. They can interact with the same receptors from either the hydrophilic pathway (pathway b′ in Fig. 16.7) on reprotonation to their onium ions [BH+] or via the hydrophobic pathway (pathway a in Fig. 16.7) in their un-ionized forms [B]. Benzocaine and other nonbasic local anesthetic molecules use this hydrophobic pathway and, thus, bind to the same receptor, although at the hydrophobic site of the receptor, to produce their actions. Again, this

hypothesis is purely speculative, and its acceptance remains open for further debate. Recent site-directed mutagenesis studies (35,36,37,38) suggest that local anesthetics bind to the hydrophobic amino acid residues near the center and the intracellular end of the S6 segment in the domain D4, whereas the BTX receptor is within segment S6 in domain D1, of the α subunit of the sodium channels (Fig. 16.7) (15).

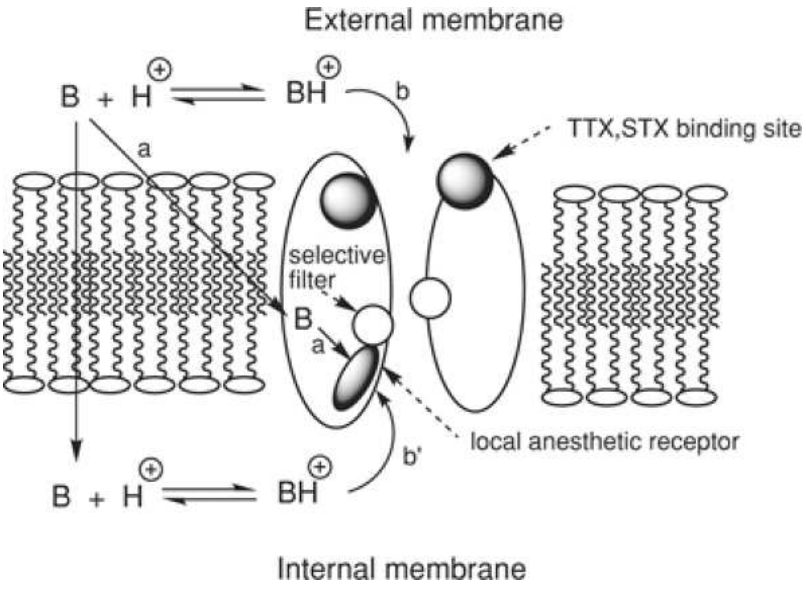

Fig. 16.7. Model of a sodium channel, as suggested by Hille (34), depicting a hydrophilic pathway (denoted by b and b′) and a hydrophobic pathway (denoted by a) by which local anesthetics may reach their receptor sites.

Structure–Activity Relationships

A quick perusal of Table 16.2 reveals that many diverse chemical structures possess local anesthetic properties: amino esters (procaine analogues), amino amides (lidocaine analogues), amino ethers (pramoxine), amino ketones (dyclonine), alcohols (benzyl alcohol and menthol), and phenols (eugenol and phenol). It would seem that there is no obvious structure–activity relationship among these agents. Most of the clinically useful local anesthetics, however, are tertiary amines with pK_a values of 7.0 to 9.0. These compounds exhibit their local anesthetic properties by virtue of the binding of the onium ions to a selective site within the sodium channels (Fig. 16.7). For this reason, any structural modifications that alter the lipid solubility, pK_a, and metabolic inactivation have a pronounced effect on the ability of a drug molecule to reach or bind to the hypothetical receptor sites, thus modifying its local anesthetic properties.

Lipophilic Portion

The lipophilic portion of the molecule is essential for local anesthetic activity. For most of the clinically useful local

anesthetics, this portion of the molecule consists of either an aromatic group directly attached to a carbonyl function (the amino ester series) or a 2,6-dimethylphenyl group attached to a carbonyl function through an —NH— group (the amino amide series)(Fig. 16.8).

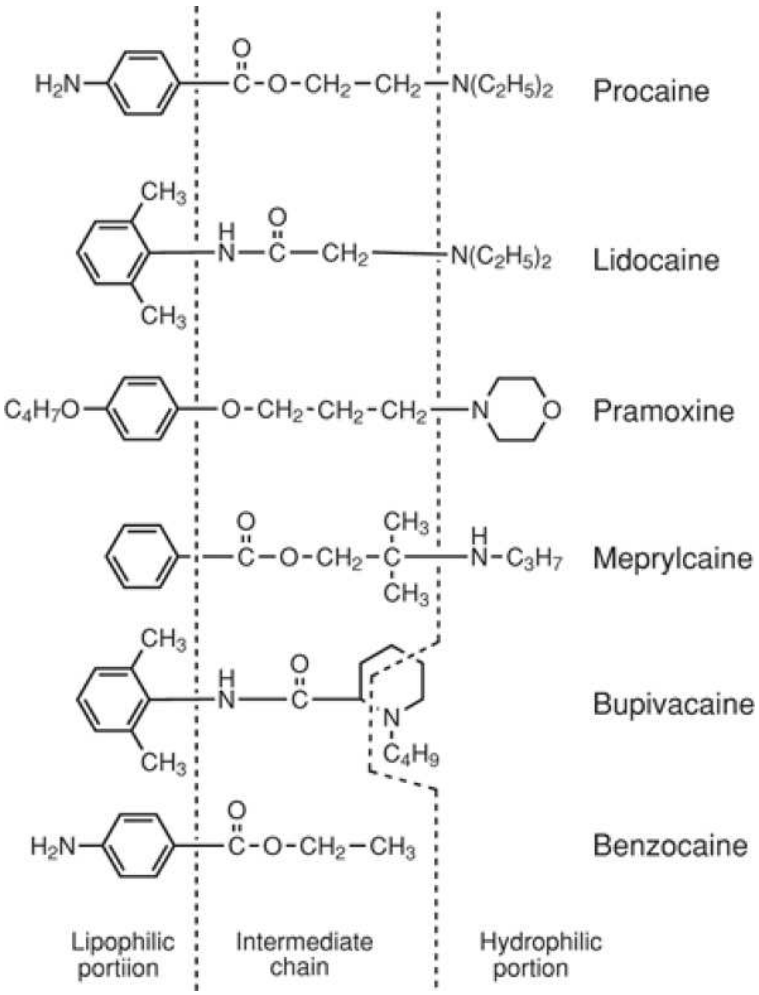

Fig. 16.8. Structure–activity relationship comparison of local anesthetics.

Both of these groups are highly lipophilic and appear to play an important role in the binding of local anesthetics to the channel receptor proteins. Structural modification of this portion of the molecule has a profound effect on its physical and chemical properties, which in turn alters its local anesthetic properties.

In the amino ester series, an electron-donating substituent in the ortho or para (or both) positions increases local anesthetic potency. Such groups as an amino (procaine, chloroprocaine, and propoxycaine), an alkylamino (tetracaine), or an alkoxy (proparacaine and propoxycaine) group can contribute electron density to the aromatic ring by both resonance and inductive effects, thereby enhancing local anesthetic potency over nonsubstituted analogue (meprylcaine).

As illustrated in Figure 16.9, resonance is expected to give rise to a zwitterionic form; (i.e., the electrons from the amino group can be resonance delocalized onto the carbonyl oxygen). Although neither drawn structure of procaine in Figure 16.9 may accurately represent the structure of procaine when it binds to the local anesthetic receptors, it is reasonable to assume that the greater the resemblance to the zwitterionic form, the greater the affinity for the receptor (i.e., binding from both the hydrophilic pathway b′ and hydrophobic pathway a in Fig. 16.7). This is particularly true for the binding of benzocaine to its receptors, because it lacks a basic amine

group. Therefore, it can only bind from the hydrophobic pathway a. Thus, addition of any aromatic substitution that can enhance the formation of the resonance form through electron donation or inductive effects will produce more potent local anesthetic agents. Electron-withdrawing groups, such as nitro (—NO_2), reduce the local anesthetic activity.

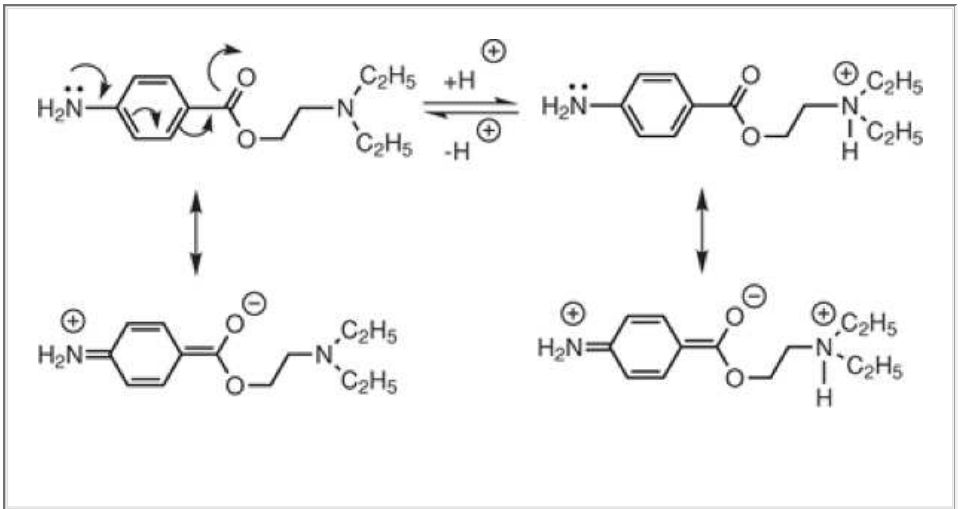

Fig. 16.9. Possible zwitterionic forms for procaine.

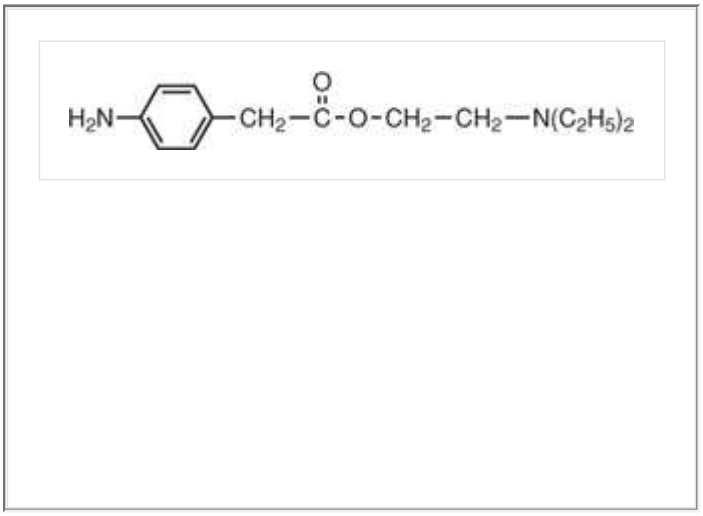
Insertion of a methylene group between the aromatic moiety and the carbonyl function in the procaine molecule, which prohibits the formation of the zwitterionic form, has led to a procaine analogue with greatly reduced anesthetic potency. This observation lends further support for the involvement of the resonance form when an ester-type local anesthetic binds to the receptor. When an amino or an alkoxy group is attached to the meta position of the aromatic ring, however, no resonance delocalization of their electrons is possible. The addition of this function only increases (alkoxy group) or decreases (amino group) the lipophilicity of the molecule (e.g., benoxinate and proparacaine).



Furthermore, tetracaine is approximately 50-fold more potent than procaine. Experimentally, this increase in potency cannot be correlated solely with the increase of lipid solubility of the n-butyl group. Perhaps part of this potentiation of local anesthetic activity can be attributed to the electron-releasing property of the n-butyl group via the inductive effect, which indirectly enhances the electron density of the *p*-amino group, which in turn increases the formation of the

zwitterionic form available for binding to the receptor proteins via both the hydrophobic and the hydrophilic pathways of the receptor.

Another important aspect of aromatic substitution has been observed from structure–activity relationship studies. In the amino amides (lidocaine analogues), the o,o′-dimethyl groups are required to provide suitable protection from amide hydrolysis to ensure a desirable duration of action. Similar conclusions can be made to rationalize the increase in the duration of action of propoxycaine by the o-propoxy group. The shorter duration of action, however,

observed with chloroprocaine when compared with that of procaine can only be explained by the inductive effect of the o-chloro group, which pulls the electron density away from the carbonyl function, thus making it more susceptible for nucleophilic attack by the plasma cholinesterases.

Intermediate Chain

The intermediate chain almost always contains a short alkylene chain of one to three carbons in length linked to the aromatic ring via several possible organic functional groups. The nature of this intermediate chain determines the chemical stability of the drug. It also influences the duration of action and relative toxicity. In general, amino amides are more resistant to metabolic inactivation than the amino esters and, thus, are longer-acting local anesthetics. The placement of small alkyl groups (i.e., branching), especially around the ester function (e.g., meprylcaine) or the amide function (e.g., bupivacaine, etidocaine, prilocaine, and ropivacaine), also hinders esterase- or amidase-catalyzed hydrolysis, prolonging the duration of action (Fig. 16.8 and Table 16.2). It should be mentioned, however, that prolonging the duration of action of a compound usually also increases its systemic toxicities unless it is more selective toward local anesthetic receptor, as in the case of levobupivacaine (39,40).

In the lidocaine series, lengthening of the alkylene chain from one to two or three increases the pK_a of the terminal tertiary amino group from 7.7 to 9.0 or 9.5, respectively. Thus, lengthening of the intermediate chain effectively reduces local anesthetic potency as a result of a reduction of onium ions under physiological conditions. As mentioned earlier, the onium ions are required for effective binding of the amino amide-type local anesthetics to the channel receptors.

Hydrophilic Portion

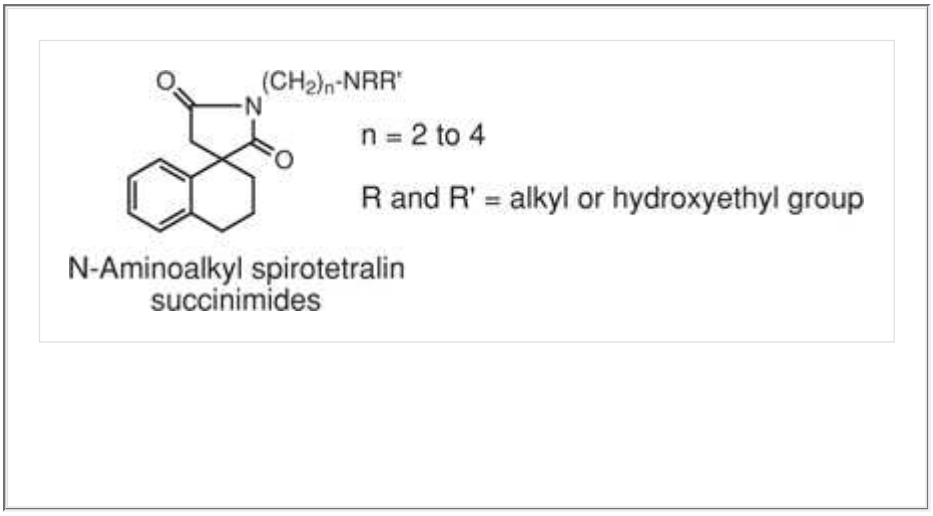
Most clinically useful local anesthetics have a tertiary alkylamine, which readily forms water-soluble salts with mineral acids, and this portion commonly is considered to be the hydrophilic portion of the molecule (Fig. 16.9). The necessity of this portion of the molecule for amino ester-type local anesthetics remains a matter of debate. The strongest opposition for requiring a basic amino group for local anesthetic action comes from the observation that benzocaine, which lacks the basic aliphatic amine function, has potent local anesthetic activity. For this reason, it often is suggested that the tertiary amine function in procaine analogues is needed only for the formation of water-soluble salts suitable for pharmaceutical preparations. With the understanding of the voltage-activated sodium channel and the possible mechanism of action of local anesthetics discussed previously, however, it is quite conceivable that the onium ions produced by protonation of the tertiary amine group also are required for binding to the receptors (Fig. 16.7).

From Table 16.2, the hydrophilic group in most of the clinically useful drugs can be in the form of a secondary or tertiary alkyl amine or part of a nitrogen heterocycle (e.g., pyrrolidine, piperidine, and morpholine). As mentioned earlier, most of the clinically useful local anesthetics have pK_a values of 7.5 to 9.0. As we learned in organic chemistry, the effects of an alkyl substituent on the pK_a depend on the size, length, and hydrophobicity of the group; it is difficult to see a clear structure–activity relationship among these structures. Generally, however, it is accepted that

local anesthetics with higher lipid solubility and lower pK_a values appear to exhibit more rapid onset and lower toxicity.

Stereochemistry

Are there any stereochemical requirements of local anesthetic compounds when they bind to the sodium channel receptors? A number of clinically used local anesthetics do contain a chiral center (i.e., bupivacaine, etidocaine, mepivacaine, and prilocaine) (Table 16.2), but in contrast to cholinergic drugs, the effect of optical isomerism on isolated nerve preparations revealed a lack of stereospecificity. In a few cases (e.g., prilocaine, bupivacaine, and etidocaine), however, small differences in the total pharmacological profile of optical isomers have been noted when administered in vivo (41,42,43). Whether these differences result from differences in uptake, distribution, and metabolism or from direct binding to the receptor has not been determined. When structural rigidity has been imposed on the molecule, however, as in the case of some aminoalkyl spirotetralin succinimides (44), differences in local anesthetic potency of the enantiomers have been observed (range, 1:2 to 1:10). Although these differences in enantiomers clearly are not as pronounced as those in other pharmacological agents, such as adrenergic blocking agents or anticholinergic drugs, steric requirements are necessary for effective interaction between a local anesthetic agent and its proposed channel receptors.



Stereochemistry of the local anesthetics, however, plays an important role in their observed toxicity and pharmacokinetic properties. For example, ropivacaine and levobupivacaine, the only optically active local anesthetics currently being marketed, have considerably lower cardiac toxicities than their close structural analogue, bupivacaine (45). Furthermore, the degree of separation between motor and sensory blockade is more apparent with ropivacaine and levobupivacaine relative to bupivacaine at a lower end of the dosage scale (46). Thus, the observed cardiac toxicity of bupivacaine has been attributed to the *R*-(+)-bupivacaine enantiomer (41,42,43). The exact mechanisms for this enantiomeric

difference remain unknown. Longobardo and colleagues observed a stereoselective blockade on the cardiac hKv1.5 channels by the *R*-(+)-enantiomers of bupivacaine, ropivacaine, and mepivacaine (47,48). It should be noted that the *S*-(–)-bupivacaine, which was recently approved by the U.S. Food and Drug Administration (FDA) and is marketed under the name of Chirocaine, has even less CNS toxicity than ropivacaine.

Study Question 3

Question: Patients who are dibucaine-resistant homozygotes or heterozygotes are more likely to experience toxic reactions to amino ester-type local anesthetics. Explain.

Metabolism of Local Anesthetics

An understanding of the metabolism of local anesthetics is important in clinical practice, because the overall toxicity of a drug depends not only on its uptake and tissue distribution but also on how it is deactivated in vivo. The amino ester-type local anesthetics are rapidly hydrolyzed by plasma cholinesterase (also known as pseudocholinesterase), which is widely distributed in body tissues. These compounds can therefore be metabolized in the blood, kidneys, and liver and, to a lesser extent, at the site of administration. For example, both procaine and benzocaine are easily hydrolyzed by cholinesterase into PABA and the corresponding N,N′-diethylaminoethyl alcohol.

It is not surprising that potential drug interactions exist between the amino ester-type local anesthetics and other clinically important drugs, such as cholinesterase inhibitors or atropine-like anticholinergic drugs. These compounds either inhibit or compete with local anesthetics for cholinesterases, therefore prolonging local anesthetic activity or toxicity. Another potential drug interaction with clinical significance may be envisioned between benzocaine and sulfonamides; that is, the hydrolysis of benzocaine to PABA may antagonize the antibacterial activity of sulfonamides.

Study Question 4

Question: The metabolism of ropivacaine in human is mediated by CYP1A2 and, to a minor extent, by CYP3A4 (50). The major metabolite is 3-hydroxyropivacaine, and the minor metabolite is (S)-2′,6′-pipecoloxylidide (a N-dealkylated product). Explain, based on your knowledge of drug metabolism, why severe drug–drug interactions between ropivacaine and fluvoxamine, a serotonin reuptake inhibitor, were observed whereas ketoconazole, a known hepatic enzyme inhibitor, causes only a minor decrease in ropivacaine renal clearance.

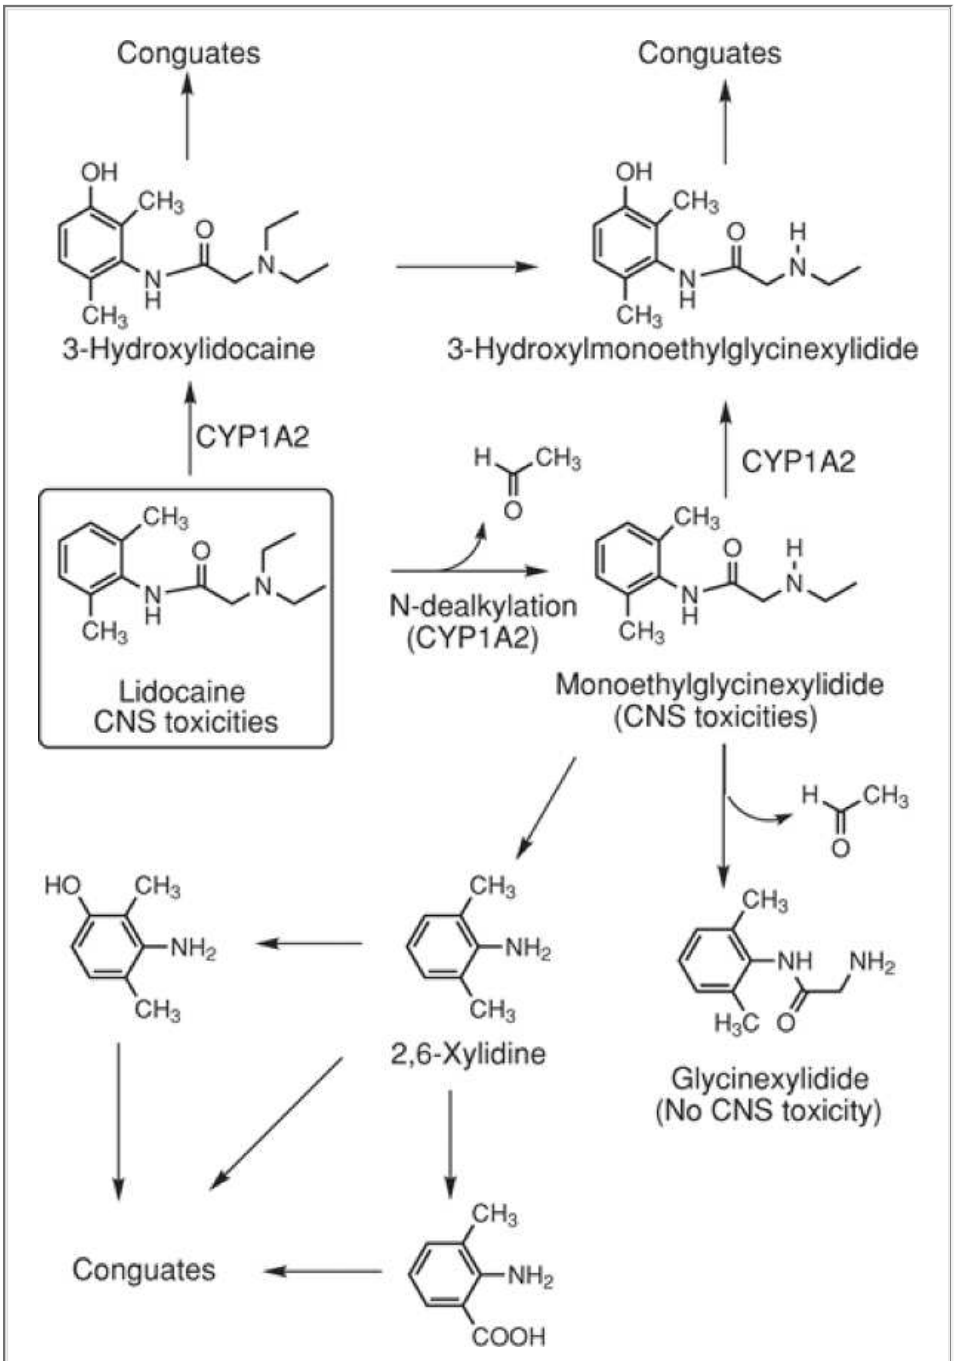


Fig. 16.10. Metabolic scheme for lidocaine.

The amino amide-type local anesthetics, however, are metabolized primarily in the liver, involving CYP1A2 isozymes (49). A general metabolic scheme for lidocaine is shown in Figure 16.10.

Marked species variations occur in the quantitative urinary excretion of these metabolites. For example, rats produce large quantities of the 3-hydroxy derivatives of both lidocaine and monoethylglycinexylidide, which subsequently are conjugated and recycled in the bile. Significant quantities of these two metabolites, however, are not produced by guinea pigs, dogs, or humans. It therefore is unlikely that biliary excretion is a major pathway for excretion in these species. Species variability is important primarily when the acute and chronic toxicity of nonester-type

local anesthetic agents is being evaluated.

Although the exact mechanism for the CNS toxicity of lidocaine remains unclear, the metabolic studies of lidocaine provide some insight for future studies. Of all the metabolites of lidocaine, only monoethylglycinexylidide (and not glycinexylidide) contributes to some of the CNS side effects of lidocaine. This observation suggests that the toxicities of lidocaine are, perhaps, related to the removal of the N-ethyl groups of lidocaine after crossing

the blood-brain barrier. Support for this hypothesis can be obtained from the fact that reaction of a tryptophan derivative with formaldehyde under physiological conditions will give a β-carboline derivative, which is a CNS convulsant (Fig. 16.11). Recent advances in the $GABA_A$ receptor–benzodiazepine receptor–chloride ion channels and their role in the mechanism of action of benzodiazepine anticonvulsants lends further support to this hypothesis (i.e., β-carbolines are inverse agonists of benzodiazepines).

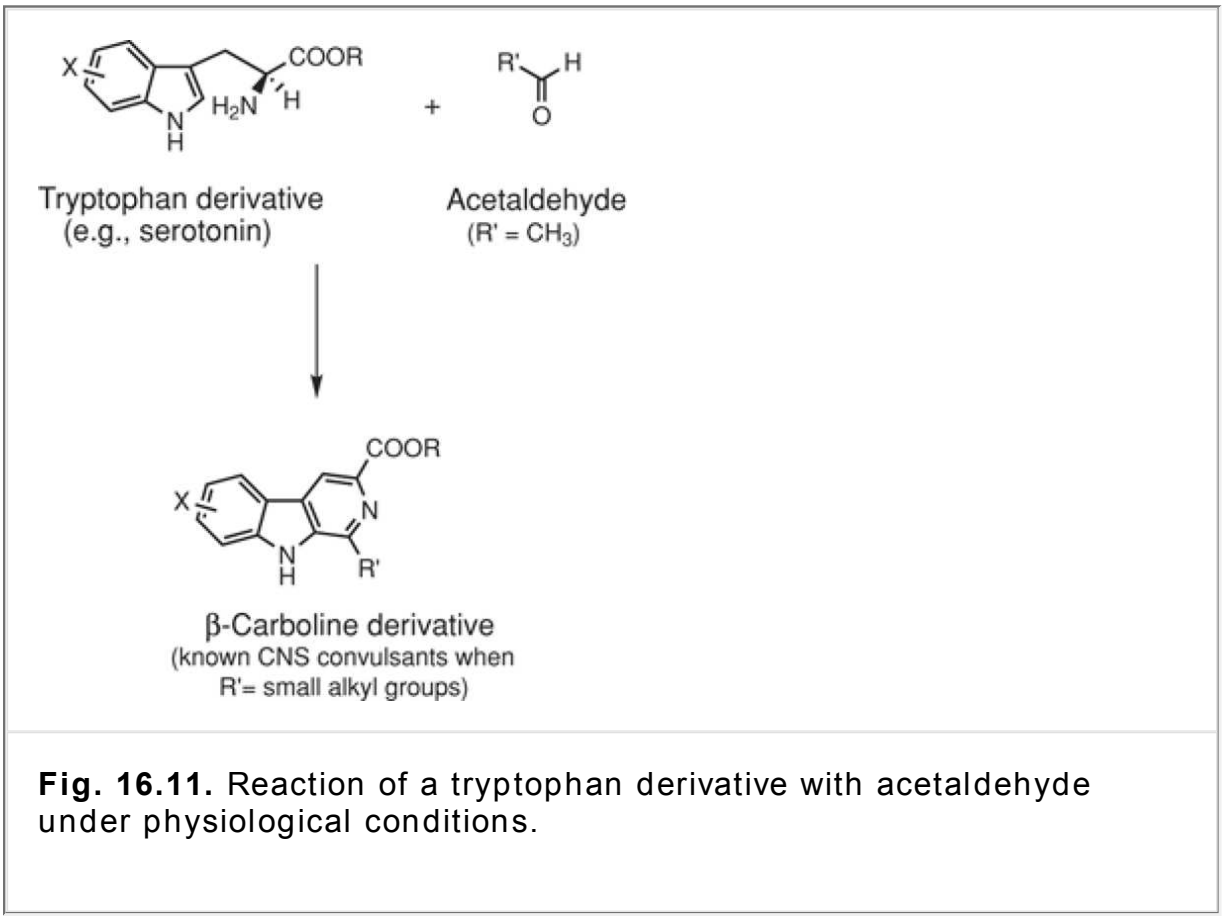

Fig. 16.11. Reaction of a tryptophan derivative with acetaldehyde under physiological conditions.

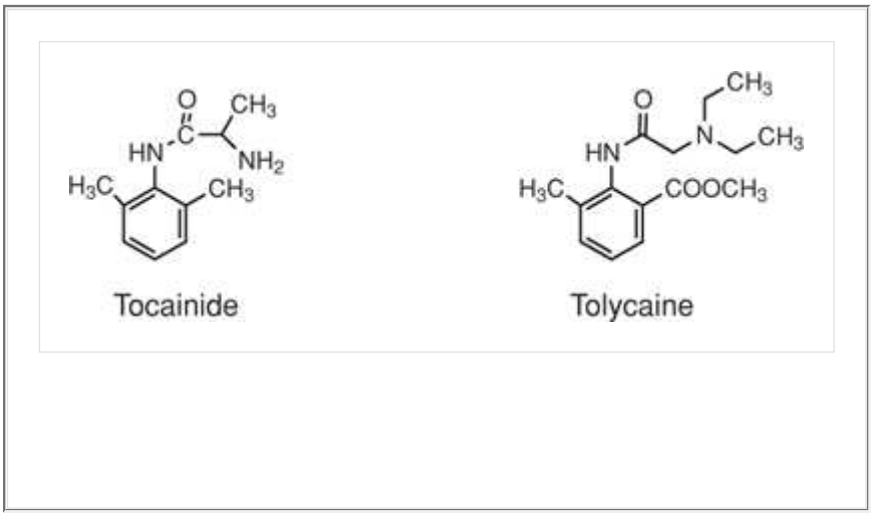
To minimize these unwanted side effects of lidocaine, tocainide and tolycaine have been prepared and found to possess good local anesthetic activity without any appreciable CNS side effects. Tocainide, which lacks the vulnerable N-ethyl group but has a α-methyl group to prevent degradation of the primary amine group from amine oxidase, has desirable local anesthetic properties. Tolycaine has an o-carbomethoxy substituted for one of the o-methyl group of lidocaine. The carbomethoxy group is fairly stable in tissues but is rapidly hydrolyzed in the blood to the polar carboxylic function and, thus, is unable to cross the blood-brain barrier.

For this reason, tolycaine lacks any CNS side effects, even though it still contains the N-ethyl groups. It should be noted, however, that both tocainide and tolycaine are primarily used clinically as antiarrhythmic agents.



Furthermore, nonester-type drugs, especially lidocaine derivatives, also are known to be more prone to enzyme induction or inhibition of other medications (e.g., cimetidine and barbiturates).

Common Agents Used for Local Anesthesia

Local anesthetics are widely used in many primary care settings. Techniques for their administration in these settings include topical application, local infiltration, field block, and peripheral nerve block. Their use can be maximized by an understanding of their potencies, durations of action, routes of administration, and their pharmacokinetic and side effect profiles. The generic, trade name, and recommended application are given in Table 16.1, and the chemical structures of these agents can be found in Table 16.2.

Articaine

Articaine [4-methyl-3-(2-propylaminopropionamido) thiophene-2-carboxylic acid methyl ester hydrochloride] has been widely used in dentistry since its approval by the U.S. FDA in the year 2000 because of its quick onset and short duration of action. The structure of articaine differs from those of all other amino amide-type local anesthetics in that it contains a thiophene ring instead of a benzene ring and a carbomethoxy group. This renders the molecule more lipophilic and, thus, easier to cross any lipoidal membranes.

Its local anesthetic potency is approximately 1.5-fold that of lidocaine, even though it has similar pK_a (7.8) and plasma protein binding (76%) properties. Articaine also is metabolized primarily by plasma cholinesterases because of the presence of an ester group and, therefore, has a much shorter duration of action than lidocaine (i.e., only approximately one-fourth that of lidocaine). Articaine undergoes rapid hydrolysis of the carbomethoxy group to give articainic acid, which is eliminated either unchanged (75%) or as its glucuronides (25%). Compared with to other short-acting, amino amide-type local anesthetics, such as mepivacaine, lidocaine, or prilocaine, articaine is said to be a much safer drug for regional anesthesia and is the drug of choice for dental procedures.

Benzocaine

Benzocaine (ethyl *p*-aminobenzoate) is used topically by itself or in combination with menthol or phenol in nonprescription dosage forms such as gels, creams, ointments, lotions, aerosols, and lozenges to relieve pain or irritation caused by such conditions as sunburn, insect bites, toothache, teething, cold sores or canker sores in or around the mouth, and fever blisters. Benzocaine is a lipophilic local anesthetic agent with a short duration of action.

Like most amino ester-type local anesthetics, it is easily hydrolyzed by plasma cholinesterase. Because of its low

pK_a, however, it is un-ionized under most physiological conditions and, therefore, can only bind to the lipid side of the local anesthetic receptor (Fig. 16.7). It also can easily cross membranes into systemic circulation to cause systemic toxicities. Furthermore, being a PABA derivative, it has similar allergenic properties to procaine and is contraindicated with sulfonamide antibacterial agents.

Study Question 5

Articaine, a dental anesthetic, is said to lack the CNS and cardiovascular toxicity associated with lidocaine and other amide-type local anesthetics. Explain.

Study Question 6

Question: Explain, with your knowledge of acid-base chemistry, why benzocaine can only be used for topical applications.

Chloroprocaine

Chloroprocaine (N,N′-diethylaminoethyl 4-amino-2-chlorobenzoate) is a very short-acting, amino ester-type local anesthetic used to provide regional anesthesia by infiltration as well as by peripheral and central nerve block, including lumbar and caudal epidural blocks. The presence of a chlorine atom ortho to the carbonyl of the ester function increases its rate of hydrolysis by plasma cholinesterase at least threefold compared to procaine and benzocaine. Thus, chloroprocaine may be used in maternal and neonatal patients with minimal placental passage of chloroprocaine. The lower plasma cholinesterase activity in the maternal epidural space must still have sufficient activity for degrading chloroprocaine and, thus, not allowing it to cross the placenta barrier.

Like PABA, the hydrolysis product of chloroprocaine, 4-amino-2-chlorobenzoic acid, also inhibits the action of sulfonamides. Therefore, its use with sulfonamides should be avoided.

Lidocaine

Lidocaine [2-(diethylamino)-N-(2, 6-dimethylphenyl) acetamide monohydrochloride] is the most commonly used amino amide-type local anesthetic. Lidocaine is very lipid soluble and, thus, has a more rapid onset and a longer duration of action than most amino ester-type local anesthetics, such as procaine and tetracaine. It can be administered parenterally (with or without epinephrine) or topically either by itself or in combination with prilocaine or etidocaine as a eutectic mixture that is very popular with pediatric patients. The use of lidocaine–epinephrine mixtures should be avoided, however, in areas with limited vascular supply to prevent tissue necrosis. Lidocaine also frequently is used as a class IB antiarrhythmic agent for the treatment of ventricular arrhythmias, both because it binds and inhibits sodium channels in the cardiac muscle and because of its longer duration of action than amino ester-type local anesthetics.

Central nervous system changes are the most frequently observed systemic toxicities of lidocaine. The initial manifestations are restlessness, vertigo, tinnitus, slurred speech, and eventually, seizures. Subsequent manifestations include CNS depression with a cessation of convulsions and the onset of unconsciousness and respiratory depression or cardiac arrest. This biphasic effect occurs because local anesthetics initially block the inhibitory GABAergic pathways, resulting in stimulation, and eventually block both inhibitory and excitatory pathways

(i.e., block the sodium channels associated with the NMDA receptors, resulting in overall CNS inhibition) (51).

Lidocaine is extensively metabolized in the liver by N-dealkylation and aromatic hydroxylations catalyzed by CYP1A2 isozymes (Fig. 16.10). Lidocaine also possesses a weak inhibitory activity toward the CYP1A2 isozymes and, therefore, may interfere with metabolism of other medications (52).

Mepivacaine

Mepivacaine hydrochloride [N-(2, 6-dimethylphenyl)-1-methyl 2-piperidinecarboxamide monohydrochloride] is an amino amide-type local anesthetic agent widely used to provide regional analgesia and anesthesia by local infiltration, peripheral nerve block, and epidural and caudal blocks. The pharmacological and toxicological profile of mepivacaine is quite similar to that of lidocaine, except that mepivacaine has a slightly longer duration of action and lacks the vasodilator activity of lidocaine. For this reason, it serves as an alternate choice for lidocaine when addition of epinephrine is not recommended in patients with hypertensive vascular disease.

Mepivacaine undergoes extensive hepatic metabolism catalyzed by CYP1A2, with only a small percentage of the administered dosage (<10%) being excreted unchanged in the urine. The major metabolic biotransformations of mepivacaine are N-dealkylation (to give the N-demethylated compound 2′,6′-pipecoloxylidide) and aromatic hydroxylations. These metabolites are excreted as their corresponding glucuronides.

Bupivacaine and Levobupivacaine

Bupivacaine hydrochloride [N-(2,6-dimethylphenyl)-1-n-butyl 2-piperidinecarboxamide monohydrochloride] contains a racemic mixture of the S-(–)- and R-(+)-enantiomers. Bupivacaine has higher lipid solubility and a much decreased rate of hepatic degradation compared with lidocaine. For this reason, bupivacaine has greater tendency than lidocaine to produce cardiotoxicity. Because of its greater affinity for voltage-gated sodium channels, the R-(+)-enantiomer confers greater cardiotoxicity to racemic bupivacaine.

It was not surprising to see the approval of levobupivacaine, the S-(-)-enantiomer of (±)-bupivacaine, as the second optically active, amino amide-type local anesthetic for parenteral applications. Like ropivacaine, levobupivacaine has a lower cardiotoxicity than bupivacaine, but it also has a lower CNS toxicity than both ropivacaine and lidocaine.

Answer for Study Question 1

Answer: With the exception of cocaine (itself a vasoconstrictor), all local anesthetics are associated with arteriolar dilatation. Thus, to decrease the rate of removal of local anesthetics from the site of administration and to maintain an effective drug concentration at the site of action, a vasoconstrictor, such as epinephrine, frequently is used to reduce regional blood supply. Epinephrine is a potent adrenergic agonist at the α- and β-adrenergic receptors; however, its vasoconstricting action results primarily from its action on the α1-adrenergic receptors. A reduction of regional blood flow into and out of the site of action greatly reduces the systemic toxicity of procaine. Furthermore, as procaine and other ester-type local anesthetics are inactivated predominantly by plasma esterase, a reduction of local blood flow also lowers the plasma esterase concentrations and, thereby, prolongs the duration of action of the local anesthetic.

Answer for Study Question 2

Answer: Many in vitro studies have demonstrated that addition of sodium bicarbonate to

solutions of local anesthetics decreases the ratio of ionized to un-ionized molecules, thereby allowing more rapid penetration of the local anesthetic through the lipid membrane (Fig. 16.7) and, thus, shortening the onset time. Addition of too much bicarbonate, however, will cause precipitation of the drug molecules, and this may result in the injection of particulate un-ionized drug along with the solution. For this reason, routine alkalization of local anesthetics is not desirable.

Answer for Study Question 3

Answer: Patients with genetic anomalies of plasma cholinesterase in so-called dibucaine-resistant homozygotes (lacks one such gene) or heterozygotes (lacks both genes) are unable to efficiently hydrolyze local anesthetics. Thus, an increased drug level in the blood circulation would lead to increased cardiac and CNS toxicity. For this reason, an individual with atypical plasma cholinesterase should wear a Medic-Alert bracelet so that complications can be avoided.

Answer for Study Question 4

Answer: 3-Hydroxyropivacaine is produced via the microsomal aromatic hydroxylation catalyzed by CYP1A2 isozymes. This enzymatic reaction introduces a hydroxy group ortho to one of the methyl group of ropivacaine. Because CYP1A2 is the most important isozyme for the degradation of ropivacaine, a potent inhibitor of this isozyme, such as fluvoxamine, will greatly reduce the renal plasma clearance of ropivacaine. On the other hand, (S)-2′,6′-pipecoloxylidide is formed by removal of N-propyl group of ropivacaine by CYP3A4 isozyme. Because this is only a minor metabolite, an inhibitor of CYP3A4, such as ketoconazole, will have no relevance in the total clearance of ropivacaine.

Answer for Study Question 5

Answer: Articaine lacks the CNS and cardiovascular toxicity of lidocaine, because it has a carbomethoxy group instead of a methyl group at the ortho position. It will protect amide hydrolysis at the site of local anesthetic action because of a lower tissue esterase concentration. When articaine is absorbed into the blood circulation, however, this carbomethoxy group is rapidly hydrolyzed to provide a carboxylic acid function. The presence of this carboxylic acid function with a basic amine group in the molecule will greatly decrease the concentration of neural un-ionized molecules needed to cross the lipoidal membranes in heart and the blood-brain barrier. Furthermore, any unprotonated drug molecules in the blood circulation will probably exist as an internal salt similar to that of amino acid, thus greatly reducing their ability to cross lipid membranes.

Answer to Study Question 6

Answer: Benzocaine, which lacks an aliphatic amino group needed for salt formation, is practically insoluble in water. Protonation of the aromatic amino group in benzocaine results in a salt with a pK_a of 2.78, which is too acidic and, therefore, unsuitable for preparation of a parenteral dosage form for injection. Based on the acid-base chemistry principle, an aromatic amino group is a weak base, because its nonbounded elections are delocalized into the aromatic ring. Thus, an aromatic amine salt, such as benzocaine, will not hold onto its proton as tightly as an aliphatic amine salt and, therefore, will readily release the proton when dissolved in water.

Possible pathways for metabolism of bupivacaine include aromatic hydroxylation, N-dealkylation, and to a minor extent, the amide hydrolysis. Only the N-dealkylated product, however, has been

identified in urine after epidural or spinal anesthesia.

Ropivacaine

Ropivacaine hydrochloride [*S*-(–)-N-(2, 6-dimethylphenyl)-1-n-propyl 2-piperidine-carboxamide monohydrochloride] is the first optically active, amino amide-type local anesthetic marketed in recent years. It combines the anesthetic potency and long duration of action of (±)-bupivacaine with a side-effect profile intermediate between those of bupivacaine and lidocaine. Although ropivacaine has a pK_a nearly identical to that of bupivacaine, it is two- to threefold less lipid soluble and has a smaller volume of distribution, a greater clearance, and a shorter elimination half-life than bupivacaine in humans.

The metabolism of ropivacaine in human is mediated by hepatic CYP1A2 isozymes and, to a minor extent, by CYP3A4 (50). The major metabolite is 3-hydroxyropivacaine, and the minor metabolite is (S)-2′,6′-pipecoloxylidide (a N-dealkylated product).

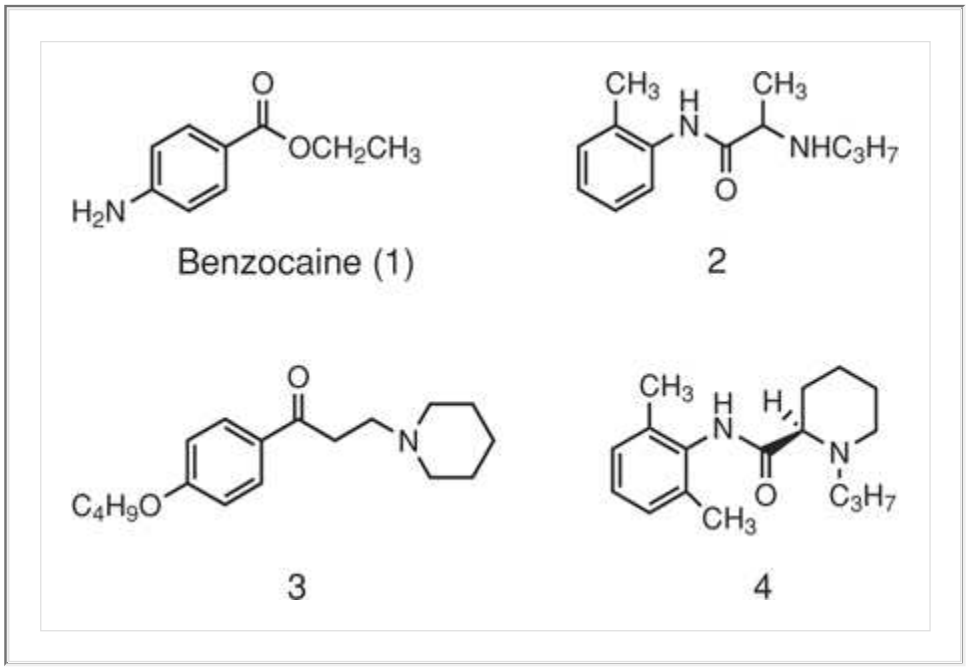
Case Study

Victoria F. Roche

S. William Zito

BJ is a 58-year-old woman who is undergoing the novel method of transesophageal echocardiography in preparation for use in determining the correct placement of a central vein catheter for long-term parenteral nutrition. To assist in the insertion of the tube, BJ's esophagus was sprayed with 20% benzocaine solution, and oxygen was delivered via nasal route (1.5 L/min). During the procedure, BJ's arterial oxygen saturation, as determined by pulse oximetry, dropped from 99 to 88%, and her lips appeared cyanotic. The procedure was stopped and 100% oxygen administered by face mask with no effect. At this point, co-oximetry was used to measure arterial blood gas and hemoglobin with the following results: pH 7.47; partial pressure oxygen, 292 mm Hg; partial pressure of carbon dioxide, 32 mm Hg; bicarbonate, 24 mEq/L; and arterial oxygen saturation, 67%. The diagnosis of methemoglobinemia was confirmed by determination of a methemoglobin level of 31%. BJ was treated with IV methylene blue (1 mg/kg body wt) and recovered promptly. Her physician wants to perform the procedure again with another local anesthetic. Evaluate structures 2 through 4 for possible use in this case.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.



3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 17

Phosphodiesterase Inhibitors

Kevin Dalby

Drugs covered in this chapter:

Phosphodiesterase inhibitor 5

- Sildenafil
- Tadalafil
- Vardenafil

Phosphodiesterase inhibitor 4

- Cilomilast
- Roflumilast

Phosphodiesterase Enzyme System

Cyclic Nucleotide Signaling

The cyclic nucleotides cyclic adenosine 3′,5′-monophosphate (cAMP) and cyclic guanosine 3′,5′-monophosphate (cGMP) play critical roles in mediating cellular signals in response to hormones, neurotransmitters, chemokines, and cytokines (Fig. 17.1) (1,2,3). These signals usually begin through binding of a hormone neurotransmitter to a G protein–coupled receptor with subsequent triggering of adenylyl and guanylyl cyclases* that synthesize cAMP or cGMP, respectively. In turn, these newly synthesized nucleotides bind and activate effectors, such as protein kinase A and protein kinase G. These protein kinases phosphorylate a variety of substrates, including ion channels and transcription factors. The resulting signaling can lead to changes in gene expression and cell metabolism and, ultimately, to the regulation of a wide variety of cellular functions, such as immune responses, cardiac and smooth muscle contraction, visual response, glycogenolysis, apoptosis, and growth control (4).

Phosphodiesterases (PDEs) hydrolyze the cyclic nucleotides to their inactive linear forms (5′-AMP and 5′-GMP) (Fig. 17.1) and may be considered as negative regulators of cyclic nucleotide signaling. Their activity is regulated by multiple signals, however, suggesting a higher level of complexity in function that reflects their roles in compartmentalizing cyclic nucleotide signaling and integrating these signaling events with other pathways (4,5,6,7,8,9,10).

Therapeutic Use of Phosphodiesterase Inhibitors

Nomenclature

Human PDEs comprise a family of 21 genes, the products of which fall into 11 families with as many as 60 isoforms (4,5,6,7,8,9,10). In the most widely accepted nomenclature, the PDE family is indicated by an Arabic numeral, followed by a capital letter indicating the gene within a family and a second Arabic numeral indicating the splicing variant derived from a single gene (e.g., PDE4D2: family 4, gene D, splicing variant 2) (11).

Despite the complexity of cyclic nucleotide signaling pathways, PDE inhibitors have emerged as an attractive drug class with the potential to treat a number of human conditions. For example, PDE inhibitors may potentially serve as anti-inflammatory agents, vasodilators, smooth muscle relaxants, antidepressants, antithrombotics, cardiotonic agents, and agents for improving cognitive functions (12). These enzymes are widely distributed throughout the body, exhibiting isoform-specific tissue concentrations. Thus, therapeutic strategies have focused on targeting specific PDE isoforms in efforts to limit their drug effects on cellular cAMP or cGMP levels within localized tissues.

PDE5 Inhibitors

The most successful area of intervention to date has been in treating erectile dysfunction, in which PDE5 selective competitive inhibitors, such as sildenafil, vardenafil, and the more discriminatory tadalafil (Fig. 17.2), have proven to be highly efficacious (13,14). These drugs work by enhancing and prolonging smooth muscle relaxation and vasodilation as a result of sexual stimulation. Normally, sexual stimulation causes the release of nitric oxide by endothelial cells as well as cavernous nerves, activating the enzyme guanylate cyclase (EC 4.6.1.2), thus stimulating the production of cGMP (13,14). This leads to a decrease in cellular levels of calcium, the relaxation of smooth muscle cells in the cavernosal bodies, and ultimately, erection (15). Erectile dysfunction results from a disruption in this sequence of events and can be the result of a number of different factors, such as hormonal imbalance and neurologic or vascular impairment (14). Because the degradation of cGMP in the penile corpora is catalyzed primarily by PDE5, the inhibition of PDE5 leads to the maintenance of an increased level of cGMP in the corpus cavernosum and an improved ability to obtain or maintain an erection (13).

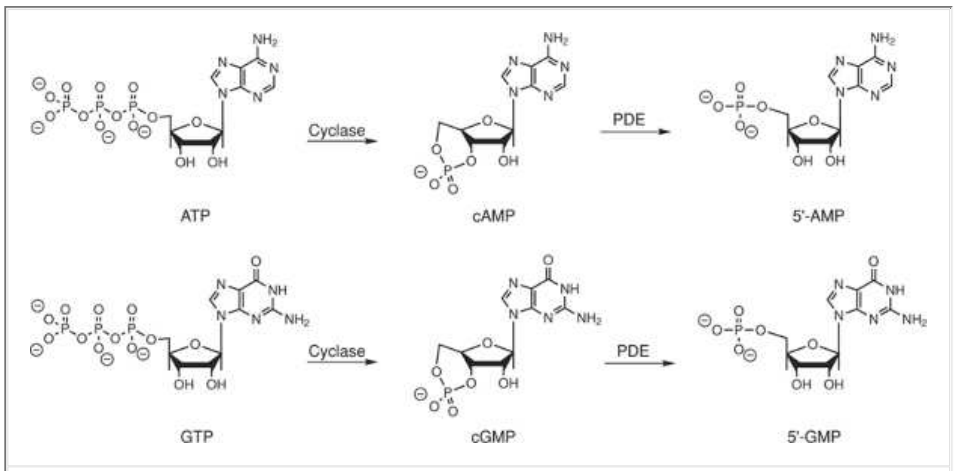

Fig. 17.1. Enzymatic interconversion of cyclic and linear nucleotides.

PDE4 Inhibitors

The PDE4 isozymes have been known since the early 1980s to regulate cAMP signaling pathways that are affected by antidepressants (16). In addition, intracellular elevations of cAMP are associated with broad anti-inflammatory effects, in which the PDE4A, PDE4B, and PDE4D isoforms are thought to be the major cAMP-hydrolyzing PDEs in most inflammatory cells (17,18). Currently, the clinical utility of PDE4 selective inhibitors for the treatment of a number of inflammatory-related conditions is still in development (19,20). It is thought that nausea and emesis, the most common side effects of PDE4 inhibitors, results from the inhibition of PDE4D in the brain (21). Therefore, much research effort currently is directed toward the design of subtype selective inhibitors which might show better profiles.

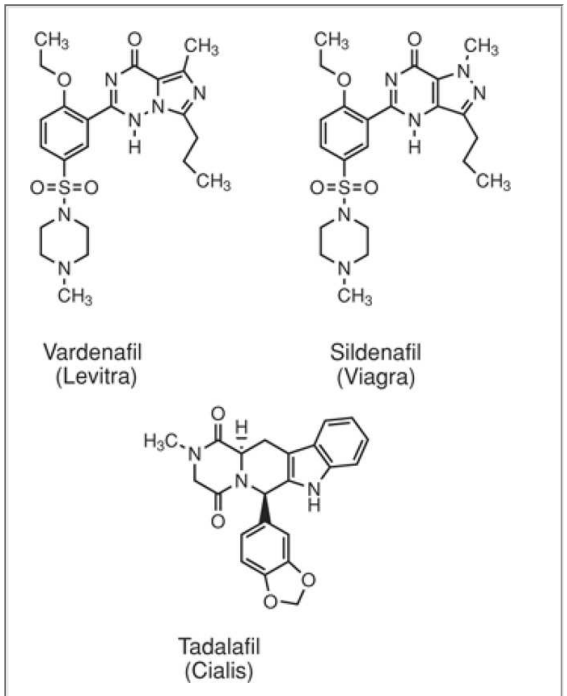

Fig. 17.2. Competitive inhibitors of PDE5.

PDE3 Inhibitors

The inhibition of platelet activation is a critical component in the treatment and prevention of cardiovascular diseases and cerebral ischemia/thrombotic disorders. Nitric oxide and prostacyclins inhibit platelet activation by elevating intracellular levels of both cGMP and cAMP, respectively. In platelets, the most abundant PDE is PDE3A, which lowers the intracellular concentration of cAMP. Inhibitors of PDE3A serve as potential antiplatelet agents by elevating cAMP levels. One PDE3-type selective inhibitor cilostazol, which has both antiplatelet, antithrombotic, and vasodilatory effects, is used for the treatment of intermittent claudication and for the prevention of short- and medium-term vessel closure (22).

Specificity of Cyclic Nucleotide Phosphodiesterases

The PDEs catalyze the hydrolysis of the 3′-phosphate diester bond of the cyclic nucleotides to give the acyclic 5′-phosphate monoesters (Fig. 17.1). They can be distinguished according to their primary structure, tissue distribution, intracellular localization, regulation, and specificity: Families 4, 7, and 8 hydrolyze cAMP; families 5, 6, and 9 hydrolyze cGMP; and families 1, 2, 3, 10, and 11 hydrolyze both cyclic nucleotides (Table 17.1).

All human PDEs are modular (Fig. 17.3) composed of a conserved C-terminal catalytic domain and various signal transduction domains that are thought to be sensors of intracellular signals, the reception of which leads to changes in conformation of the PDE and, thus, its activity (8). The catalytic domain contains a core of 16 α-helices

in a compact arrangement (Fig. 17.4) of three subdomains comprised of αH1-7, αH8-11, and αH12-16, respectively (23). The active site at the intersection of these three domains forms a deep hydrophobic pocket with a narrow opening and a wide inner space (Fig. 17.5). Eleven of 16 invariant amino acids are present in the active site and facilitate recognition and catalysis through four key interactions: 1) the binding of two divalent metal ions, 2) the coordination to the phosphate diester moiety, 3) the hydrophobic clamping of the nucleotide ring by highly conserved hydrophobic residues that sandwich the substrate in the active site, and 4) a hydrogen-bonding network that helps to determine nucleotide specificity (Fig. 17.6A and B).

Table 17.1. Specificity and Potency of PDE Inhibitors

PDE	Specificity	Inhibitor	IC_{50}a (nM)	PDE	Specificity	Inhibitor	IC_{50}a (nM)

[a]Data are from Sutherland and Rall (28) unless stated otherwise. The numbers shown in the table are the 50% inhibition concentration (IC50). The cAMP and cGMP concentrations used were far below the K_m of all the PDEs assayed except for PDE9A, in which case it was close to the K_m. The IC50s obtained are good approximations of the inhibition constant K_i. Selectivities of an inhibitor may be determined by taking ratios of the numbers given in the table.

[b]K_i values are from Card et al. (30).

[c]Value from Hatzelmann and Schudt (34).

Fig. 17.3. Schematic representation of the domain organization of PDEs. The conserved catalytic domain is found toward the C-terminal half of the PDE (8). The number and function of the regulatory domains differ between the different PDE subfamilies. These domains include calcium-sensing domains as well as signaling domains that mediate interactions with other signaling proteins.

Several structures of PDEs complexed to various ligands are available and have been reviewed (24). The structure of 5′-AMP bound to PDE4D2 (25) (Fig. 17.7) reveals direct coordination of the phosphate to two divalent metal ions as well as His-160, Asp-201, and Asp-318. This enzyme product complex is suggestive of a potential catalytic mechanism in which the cyclic phosphate diester undergoes nucleophilic attack from a metal-bound hydroxide ion (Fig. 17.8), which then displaces the 3′-hydroxyl leaving group. According to this mechanism, His-160 is

predicted to serve as a general acid to protonate and, thus, stabilize developing negative charge on the 3′-hydroxyl leaving group. This mechanism is consistent with the observed structure as well as studies on other enzymes that catalyze similar processes using a binuclear strategy.

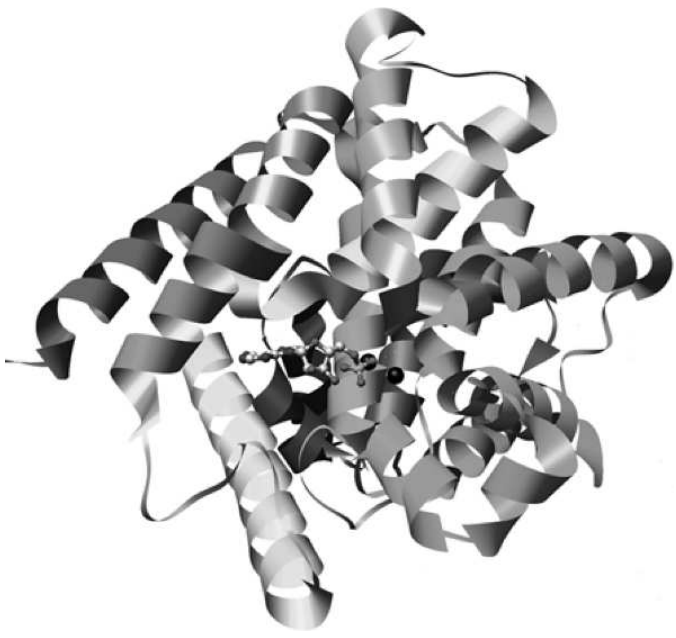

Fig. 17.4. Ribbon diagram of monomeric PDE4D2 (PDB 1PTW). 5′-AMP is shown as balls-and-sticks, whereas two divalent metal icons are shown as solid spheres (24). (See color plate.)

Recognition of the nucleotide base is mediated by π-π interactions with a conserved phenylalanine (Phe-372 in PDE4D2) that shapes the roof of the hydrophobic pocket and van der Waals interactions that line both the roof and the base. Additional hydrophobic interactions to the ribose ring, which has a C3′-endo puckering configuration, contributes to substrate recognition.

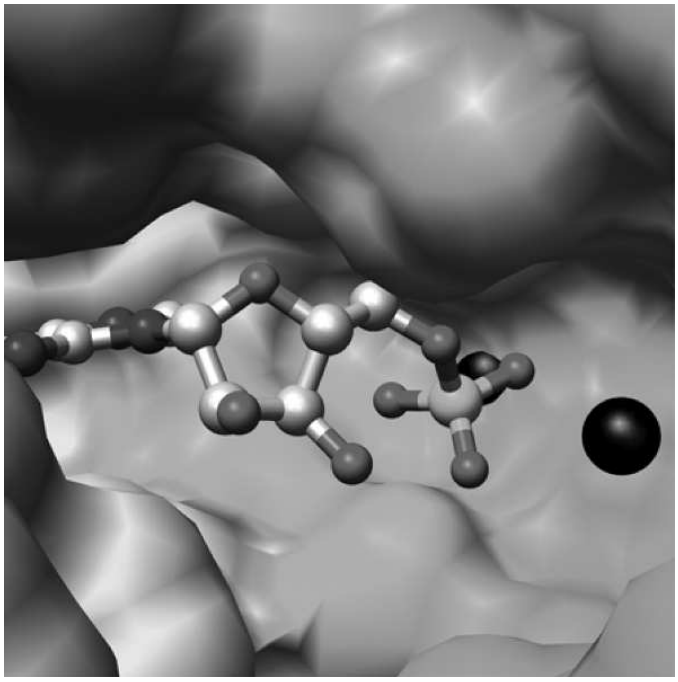

Fig. 17.5. Surface representation showing 5′-AMP in the nucleotide binding pocket of PDE4D2 (PDB 1PTW). 5′-AMP is shown as balls-and-sticks, while two divalent zinc icons are shown as solid spheres (24). (See color plate.)

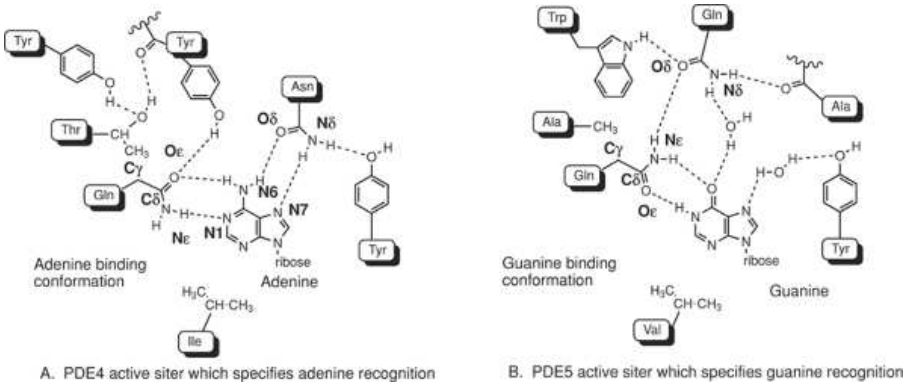

Fig. 17.6. Schematic representation of the hydrogen-bonding network in the active site of PDEs.

An important question, given the high degree of conservation between the PDE active sites, is what determines their substrate specificity (26). Current theory points toward the role of a key glutamine conserved in all PDEs (Gln-369 in PDE4D2), which can adopt either an adenine- or a guanine-specific binding conformation (27). The specificity of the PDEs is thus derived from

hydrogen-bond networks within the active site, which strongly favor either the cAMP-specific (26) or the cGMP-specific (27) conformation (Fig. 17.6A and B). These two conformations differ essentially by rotation about the Cγ-Cδ bond of the glutamine, which switches the positions of the Nε and Oε atoms to accommodate the hydrogen-bonding requirements of either adenine or guanidine (Fig. 17.6). It has been suggested that the ability of PDEs 1, 2, 3, 10, and 11 to hydrolyze both cAMP and cGMP reflects the ability of the glutamine to adopt either conformation.

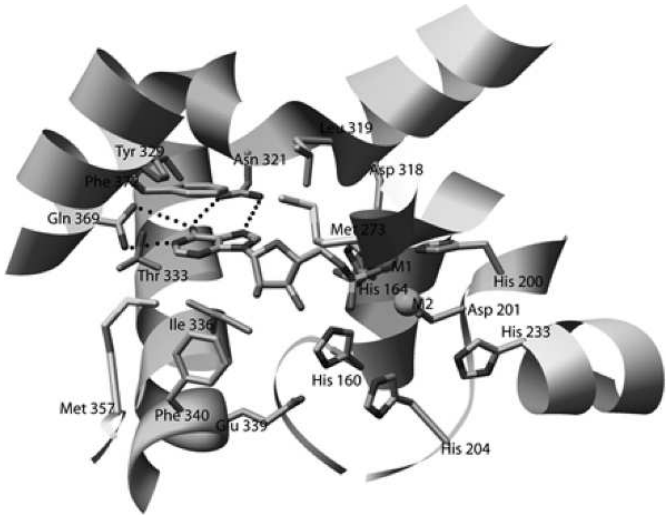

Fig. 17.7. Ribbon diagram of the active site of PDE4D2. The AMP phosphate group binds two divalent zinc icons and forms hydrogen bonds with His-160, Asp-201, and Asp-318. The adenine group of AMP adopts an anticonformation and orients toward the hydrophobic pocket made up of residues Tyr-159 (not shown), Leu-319, Asn-321, Thr-333, Ile-336, Gln-369, and Phe-372. It forms three hydrogen bonds with Gln-369 and Asn-321 and buttresses against Phe-372. The ribose of AMP has a C3′-endo puckering configuration and makes van der Waals contacts with residues His-160, Met-273, Asp-318, Leu-319, Ile-336, Phe-340, and Phe-372 (24). (See color plate.)

Specificity of Phosphodiesterase Inhibitors

The first PDE inhibitor described was theophylline, the activity of which toward PDE was first reported some 50 years ago (28). Like all PDE inhibitors, theophylline and other xanthines, such as 3-isobutyl-1-methylxanthine (IBMX), have a planar structure that mimics the planarity of the cAMP and cGMP bases. They are nonselective, however, and adopt multiple binding modes in the active sites of the PDEs (24).

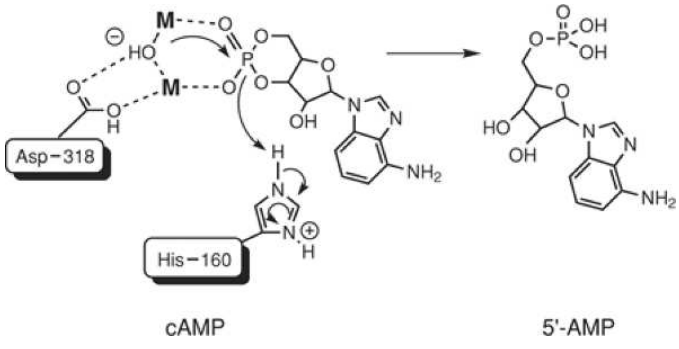

Fig. 17.8. Proposed catalytic mechanisms of PDE4D2 (24).

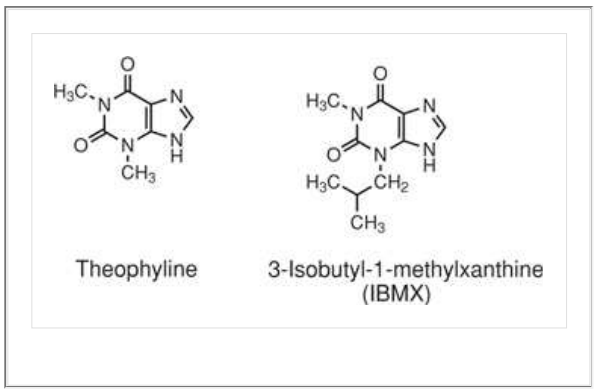

Recent years have seen the development of a number of selective PDE inhibitors that compete with cyclic nucleotides for binding. Notably, the solved structures of a number of PDE inhibitor complexes have been instrumental in allowing researchers to delineate some of the reasons for the selectivity of various inhibitors (29,30). These structures have clearly shown that the uniformly important planar property of PDE inhibitors supports binding in the hydrophobic cleft of the active site that normally is reserved for the nucleotide base. They also allude to further specificity, resulting from an array of hydrogen-bonding interactions and the extension of inhibitors into unique regions of space. Notably, the conformation of the conserved active site glutamine, that specifies nucleotide binding, also is a key determinant of inhibitor selectivity.

PDE5 Selective Inhibitors

Sildenafil (7) and its analogue, vardenafil (Fig. 17.1), are substituted azaguanine analogues, the pyrazolopyrimidinone group of which mimics the binding mode of guanine in cGMP, whereas the 3′-n-propyl substituent binds in a similar region to the ribose ring (Fig. 17.9). The

PDE5/PDE selectivity of sildenafil and vardenafil appears to revolve in part around the conserved glutamine residue (Gln-817), which interacts with the pyrimidine ring of cGMP in the guanine selective conformation. Further specificity may result from the alkylpiperazine ring, which has no overlap with the nucleotide and is exposed at the protein surface through the opening to the active site. Its interactions with surrounding hydrophobic residues are not found in the equivalent regions of PDE4, for example, suggesting that they may contribute to the specificity (24). Whereas sildenafil and vardenafil show good PDE5/PDE selectivity against the cAMP selective PDEs (PDEs 4, 7, and 8), they do inhibit other cGMP selective PDEs (1,6,9,10,11), and their low PDE5/PDE6 selectivity (22- and 11-fold respectively) (Table 17.1) is a particular issue that is thought to be a factor in certain side effects related to transient aberrations in vision. This lack of selectivity can be explained by the high homology between the active sites of PDE5 and PDE6. The basis for the high PDE5/PDE2 and PDE5/PDE3 selectivities of sildenafil and vardenafil are unclear.

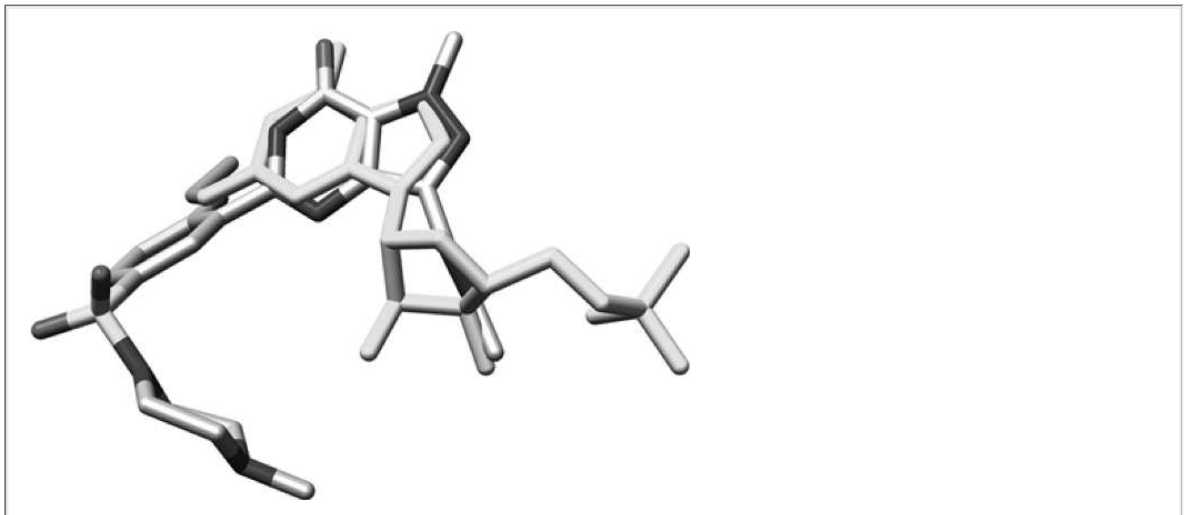

Fig. 17.9. Overlay of sildenafil with 5′-GMP in the active site of PDE5 (35). (See color plate.)

The newer drug tadalafil (Fig. 17.2) is structurally unrelated to sildenafil, and it displays an approximately 1,000-fold PDE5/PDE6 selectivity ratio (Table 17.1). Interestingly, whereas the binding mode of tadalafil clearly is different from that of sildenafil, the reasons for its high PDE5/PDE6 selectivity are currently unclear (24).

PDE4 Selective Inhibitors

The PDE4 is inhibited by rolipram (Fig. 17.10), with a PDE4/PDE (all forms) selectivity of more than 100-fold (Table 17.1) (31). Like all

PDE inhibitors, rolipram adopts a binding mode that resembles the cyclic nucleotide substrate (Fig. 17.11). In the adenosine binding conformation, Gln-369 of PDE4 bisects the two ether oxygens of rolipram, providing a specific binding interaction (32). In addition, the cyclopentyl ring of rolipram interacts with Mrt-357 and Phe-340 of PDE4D. Interestingly, the lactam ring does not make any specific interactions with the binding site. On the basis of Gln-369 binding, the cGMP selective enzymes (PDEs 5, 6, and 9) may be excluded. The high PDE4/PDE selectivities for PDEs 1, 2, 3, 10, and 11, however, in which the conserved glutamine side chain is free to rotate, are difficult to explain on this basis. In this regard, it has been suggested that the selectivity may be the result of a prohibitive cost in freezing the rotation of the glutamine in these PDEs. Similar arguments have been made to explain the high PDE4/PDE7 and PDE4/PDE8 selectivities of rolipram (24).

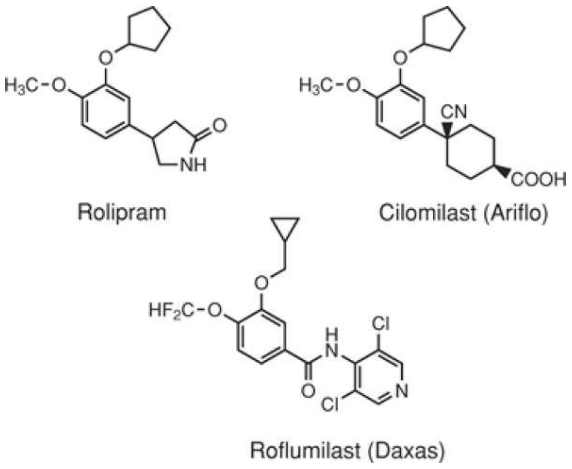

Fig. 17.10. Competitive inhibitors of PDE4.

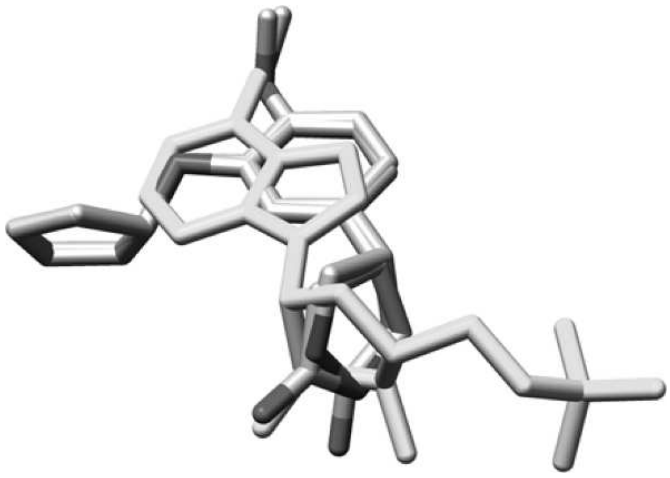

Fig. 17.11. Overlay of (R,S)-rolipram with 5′-AMP in the active site of PDE4D (31). (See color plate.)

Cilomilast (33) and roflumilast (34) are newer PDE4 selective inhibitors that are related to rolipram, but they display enhanced potency toward PDE4 (Fig. 17.10) (Table 17.1). They bind similarly, with the substituted aromatic ring occupying the hydrophobic clamp and the substituents making differential contacts with hydrophobic residues that line the pocket. Interestingly, these inhibitors also interact with the active-site metal ions via a water molecule, a potential source of additional potency (30).

PDE3 Selective Inhibitors

Presently, no structures of cilostazol or dipyridamole are bound to a PDE. Therefore, the precise mechanism of inhibition and the basis for their selectivity are unknown.

Summary

Two common features of inhibitor binding to PDEs define the scaffold for all known PDE inhibitors (29,30). A planar ring structure is held tightly in the active site by interactions with hydrophobic residues that line the nucleotide-binding pocket, facilitating

hydrogen-bond interactions with an invariant glutamine, which is essential for nucleotide recognition and selectivity. In addition to these features, further hydrophobic interactions near the invariant purine selective glutamine also are important for inhibitor binding, and potency also is improved through interactions with residues near the metal ions

and through indirect, water-mediated interactions with the metals. Furthermore, the selectivity of inhibitors is enhanced by exploiting the differences in shape and hydrophobicity of the binding pockets near the invariant glutamine.

Drugs Inhibiting Phosphodiesterases

Clinical Experience

PDE5 Selective Inhibitors

As indicated earlier, the selective PDE5 inhibitors developed for the treatment of male erectile dysfunction resulting from organic or mixed organic-psychogenic origin have been the most successful PDE inhibitors. The three marketed drugs are sildenafil, vardenafil, and tadalafil (Fig. 17.2). In addition to the treatment of erectile dysfunction, sildenafil has been indicated for the treatment of pulmonary hypertension and female sexual dysfunction. These latter uses are unlabeled uses.

Sildenafil

Sildenafil is rapidly absorbed and peaks in concentration (127–560 ng/mL) after 0.5 to 2.0 hours, displaying a half-life of 3 to 4 hours for the full therapeutic dose (25–100 mg). It is 96% bound to plasma proteins and is metabolized by the liver CYP3A4 (13). The metabolite N-desmethylsildenafil possesses approximately 50% of the activity of the parent molecule.

Vardenafil

Vardenafil also is rapidly absorbed and peaks in concentration (9.05 μg/mL after a 10-mg dose) after 0.9 hours, displaying a half-life of 4 to 5 hours. The absorption rate of both sildenafil and vardenafil are reduced when taken with a high-fat diet (13). The drug also is metabolized by hepatic CYP3A4, and a potential for drug–drug interaction with inhibitors or enhancers of CYP3A4 exists. Biochemical studies demonstrate a significant increase in selectivity of vardenafil over sildenafil for PDE5 versus PDE6. Whether this translates into a significant improvement in side effects must await studies in a greater population of patients.

Tadalafil

Tadalafil is different in structure from both sildenafil and vardenafil. It is rapidly absorbed and peaks in concentration (378 μg/L after a 20-mg dose) after 2 hours, displaying a long half-life of 17.5 hours. It also is metabolized by the liver (CYP3A4). Notably, its pharmacokinetics is not clinically influenced by alcohol or food intake or by factors such as diabetes or impaired hepatic or renal function (13).

Adverse effects related to oral therapy for erectile function are primarily concerned with adverse cardiovascular effects, because PDE5 inhibitors promote vasodilation and, therefore, have an inherent potential to cause hypotension. This is a particular concern for elderly patients with a preexisting condition (13).

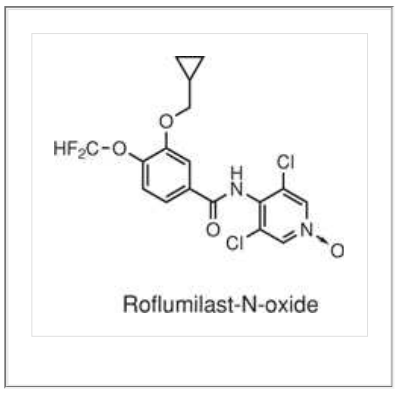
Additional discussion on the pharmacodynamics of the PDE5 inhibitors can be found in Chapter 45.

PDE4 Selective Inhibitors

Considerable interest in PDE4 inhibitors is based on the recognition that of the four gene-produced PDE4s, three (PDE4A, PDE4B, and PDE4D) are abundant in inflammatory and immune cells, which include T and B cells, monocytes, macrophages, neutrophils, and eosinophils. The fourth PDE4 (PDE4C) is localized in testis, skeletal muscle, and brain. Inhibition of PDE4 has been shown to suppress production of cytokines, cell proliferation and chemotaxis, and release of inflammatory mediators. Thus, the interest in PDE4 inhibitors for treatment of asthma, chronic obstructive pulmonary disease (COPD), and the intestinal conditions of Crohn's disease and inflammatory bowel disease (20). Two PDE4 inhibitors are proceeding through clinical studies. Cilomilast is an investigational drug being studied in the United States for use in COPD (asthma studies have been discontinued), and roflumilast is moving forward in Europe for the treatment of asthma and COPD (Fig. 17.10) (see Chapter 44).

Roflumilast

Roflumilast is the more potent of the two drugs, and along with its active metabolite, roflumilast-N-oxide, it is nonselective in its inhibitory action on PDE4B and PDE4D. The PDE4B appears to be the most closely linked to anti-inflammatory effects, whereas the PDE4D receptor subtype is thought to be linked to nausea, possibly through a central effect (21). Roflumilast exhibits 80% oral bioavailability and has an elimination half-life of 10 hours, whereas the N-oxide has an elimination half-life of 20 hours and has shown no drug interactions. Clinical trials in patients with asthma or COPD are quite promising.



Cilomilast

Cilomilast is rapidly absorbed following oral administration (96% bioavailability), has an elimination half-life of 7 hours, and is extensively metabolized, but not by cytochrom P450 enzymes. The drug shows considerably more selectivity than roflumilast toward PDE4D, and this might account for the common side effects of nausea and emesis (20). Studies regarding the benefits of cilomilast versus placebo in the treatment of asthma have not been very encouraging, but significant improvement was seen in clinical trials of cilomilast in the treatment of COPD. The side effects of diarrhea and nausea have been considerably higher with cilomilast versus placebo, but these effects generally are tolerable and self limiting.

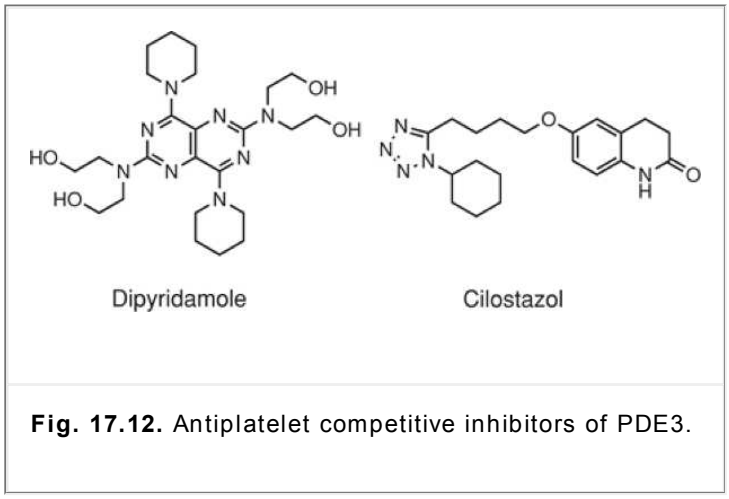


Fig. 17.12. Antiplatelet competitive inhibitors of PDE3.

PDE3 Selective Inhibitors

Antiplatelet drugs

A site for regulating blood coagulation and subsequent thrombus formation is at the level of the platelets. Antiplatelet drugs work by inhibiting platelet activation via a number of different mechanisms. The major role of antiplatelet drugs is in the prevention of ischemic complications in patients with coronary diseases. They also are effective in combination with moderate-intensity anticoagulants for patients with atrial fibrillation (see Chapter 31). Rapid platelet aggregation and thrombus formation at the site of vascular injury is the main mechanism of hemostasis (i.e., stoppage of bleeding, a normal process of wound healing). When platelets are activated on the ruptured atherosclerotic plaques or in regions of restricted blood flow, however, it can lead to thromboembolic complications that contribute to common diseases, such as myocardial infarction or ischemic stroke.

Mechanism of action of antiplatelet drugs

Most of the currently available antiplatelet drugs exert their actions by affecting only the secondary platelet aggregation pathways, and in the case of dipyridamole and cilostazol (Fig. 17.12), interruption of platelet function through increasing cellular concentration of cAMP by inhibiting PDE serves as the mechanism of action. The PDE3 is an enzyme responsible for degradation of cAMP to AMP in platelets and blood vessels. Selective cAMP PDE3 inhibitors, such as dipyridamole and cilostazol, inhibit the degradation of cAMP, thereby increasing cellular concentration of cAMP, leading to inhibition of platelet aggregation and vasodilation.

Dipyridamole and cilostazol

Dipyridamole is a pyrimidopyrimidine derivative with vasodilatory and antiplatelet properties, whereas cilostazol is a quinolinone derivative, which is a potent, orally active antiplatelet with a higher degree of selectivity than dipyridamole for PDE3. The latter drug appears to possess greater therapeutic potential. It is rapidly absorbed following oral administration and is extensively metabolized. Several of the metabolites also possess antiplatelet activity. (For a more in-depth discussion of these drugs, see Chapter 31.)

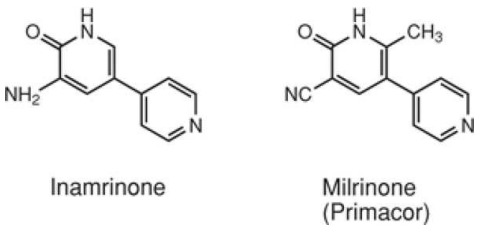

Fig. 17.13. PDE3 inhibitors with cardiac and pulmonary effects.

Cardiac drugs

Inamrinone and milrinone

Inamrinone and milrinone (Fig. 17.13) have been available for some time and have been used for the treatment of cardiac heart failure. Their action is based on a positive inotopic response and a concentration-dependent vasodilatory effect (Chapter 26). These drugs are selective PDE3 inhibitors, resulting in increased levels of cAMP. To what extent this inhibition contributes to the clinical effects of the drugs is not totally clear. Recent studies have shown that milrinone exhibits pulmonary vasodilation, which might prove to be beneficial in the treatment of pulmonary hypertension, although the same studies suggested that the use of zaprinast, a PDE5 inhibitor, has greater potential for such use (35).

Chapter 18

General Anesthetics

Timothy J. Maher

Drugs covered in this chapter:

Inhaled general anesthetics

- Ether
- Halothane
- Desflurane
- Enflurane
- Isoflurane
- Methoxyflurane
- Sevoflurane
- Nitrous oxide

Intravenous general anesthetics

- Etomidate
- Ketamine
- Propofol
- Thiopental

Introduction

Before the mid-1800s, pain-producing surgical and dental procedures typically were undertaken without the aid of acceptable anesthetic agents. Chemical methods available at the time included intoxication with ethanol, hashish, or opium, whereas physical methods included packing a limb in ice, creating ischemic conditions with tourniquets, inducing unconsciousness by a blow to the head, or the most common technique, employing strong-armed assistants to hold down the helpless patient during the entire surgical procedure. Additionally, at this time, many practicing physicians had been taught that pain was a requirement for effective healing; therefore, the observation of a patient in terrible pain was viewed as part of the normal healing process. These factors, along with the lack of knowledge regarding sterile techniques or the availability of suitable infection-fighting agents, made surgical procedures a method of last resort.

There have been many accounts of the first demonstration by the Hartford dentist Horace Wells of the use of nitrous oxide as a surgical anesthetic in 1844. Wells first observed the anesthetic actions of nitrous oxide at a public demonstration of “laughing gas.” One of the volunteers, a pharmacy clerk named Samuel Cooley, injured his leg while under the influence of this gas and appeared to experience no pain. The next day, Wells inhaled the gas himself and, with the aid of a colleague, had one of his own teeth extracted without any sensation of pain. Wells then began routinely using nitrous oxide for dental procedures in his own practice. In 1845, he attempted to demonstrate the anesthetic effects of nitrous oxide at the Massachusetts General Hospital in Boston. This demonstration was considered to be a failure, however, because the patient cried out

during the procedure. Following this unfortunate incident, use of nitrous oxide was minimal until it resurfaced in dental practice during the mid-1860s, when it was combined with oxygen and made available in steel cylinders. This gas is still commonly used today, especially in combination with other anesthetic and analgesic agents.

The anesthetic that gained greatest popularity shortly after the failed demonstration of Wells was diethyl ether. William Morton, a Boston dentist, was familiar at the time with the use of nitrous oxide by Wells. He also had heard of the interesting effects of diethyl ether and began to experiment on animals and himself with this volatile liquid. In 1846, he was allowed an opportunity to demonstrate the anesthetic actions of diethyl ether at, again, Massachusetts General Hospital. In the famed "Ether Dome," which still stands today, Morton administered the diethyl ether with a specially designed delivery device to the nervous patient, and the surgical procedure was performed without apparent pain. Following this demonstration, word of its success spread quickly, and soon, dental and medical practices throughout the United States and Europe were employing diethyl ether as an anesthetic agent. Today, diethyl ether is no longer used in procedures because of its toxicity and dangerous physical properties (e.g., it is flammable and explosive).

Another anesthetic agent that enjoyed some early popularity was cyclopropane. Like diethyl ether, however, it also is explosive and is no longer used. As described below, the inhalational anesthetic agents used today generally are hydrocarbons and ethers with halogen (Cl, Br, or F) substitutions. Nitrous oxide is the exception. Table 18.1 lists the characteristics of the "ideal" general anesthetic agent. Currently, the agent that fulfills all these characteristics is not known.

Stages of Anesthesia

The ideal anesthetic state is characterized by a loss of all sensations and includes analgesia and muscle relaxation. Neuronal depression in specific areas of the central nervous system is believed to be largely responsible for such an anesthetic state. The areas involved include many cortical regions that are represented by excitatory pyramidal

cells and inhibitory/excitatory stellate cells. Excitation of the pyramidal cells helps to maintain consciousness, whereas the degree of inhibition or excitation of stellate cells determines the overall activity level of the pyramidal cells with which they synapse. As the concentration of anesthetic increases in the central nervous system, the degree of overall neuronal depression also increases, resulting in progressively deeper stages of anesthesia. Based on observations using diethylether, Guedel in 1920 originally described this progression into four distinct stages, and Gillespie subsequently further subdivided these stages (Fig. 18.1), as described below.

Table 18.1. Characteristics of the Ideal Anesthetic

Rapid and pleasant induction of surgical anesthesia
Rapid and pleasant withdrawal from anesthesia
Adequate relaxation of skeletal muscles
Potent enough to permit adequate oxygen supply in mixture
Wide margin of safety
Nontoxic
Absence of adverse effects
Nonflammable/nonexplosive
Chemically compatible with anesthetic devices
Nonreactive
Inexpensive

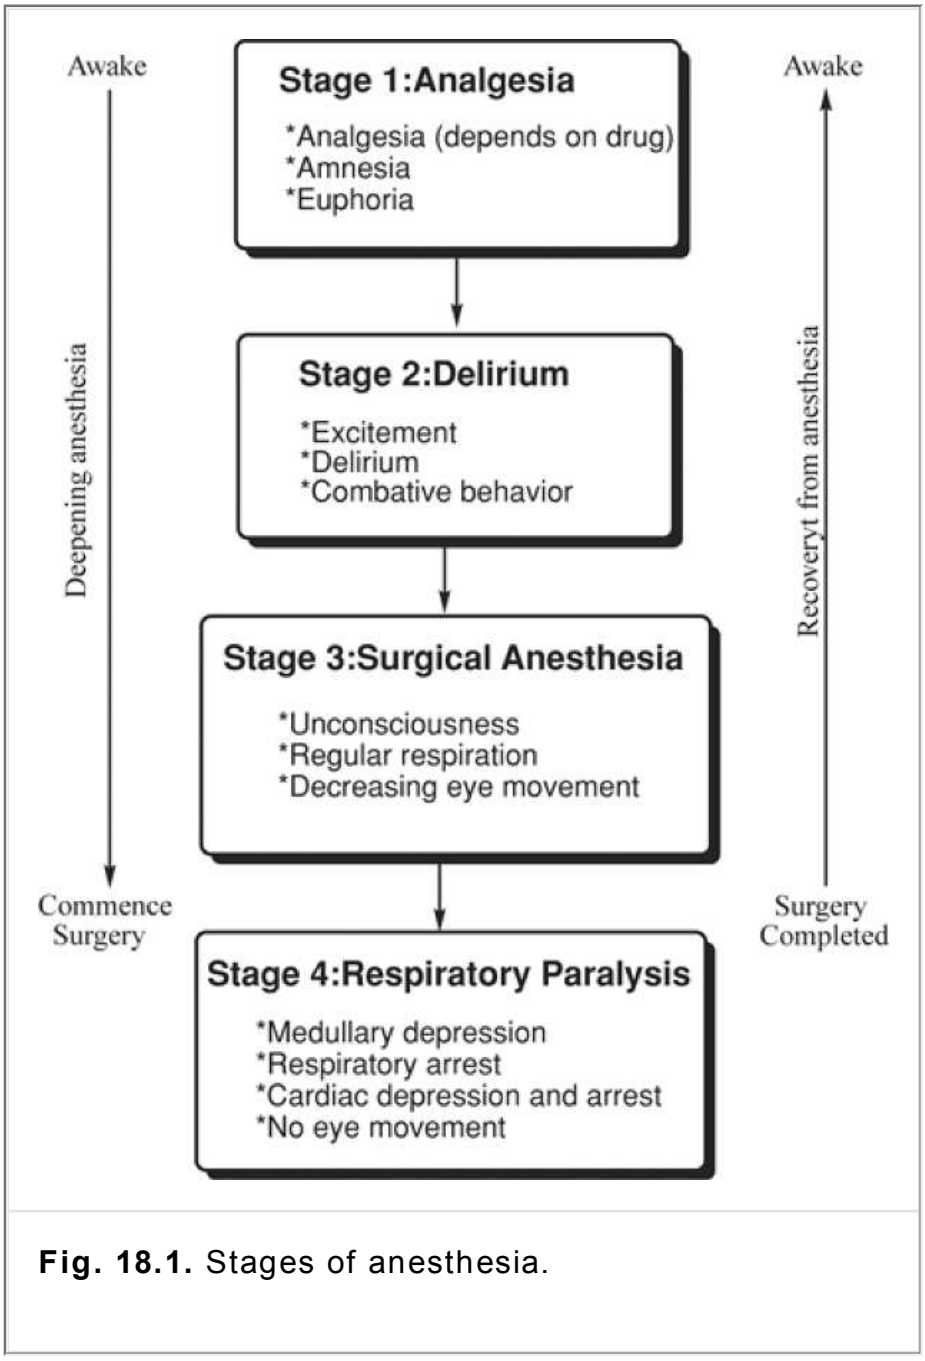

Fig. 18.1. Stages of anesthesia.

Stage 1: Analgesia

Characterized by a mild depression of higher cortical neurons, this stage is suitable for minor surgical procedures that do not require significant neuromuscular relaxation. Depression of thalamic centers probably accounts for the observed analgesia, because many of the neuronal systems that mediate pain sensation traverse through this anatomic area. Some general anesthetic agents do not possess significant analgesic activity, but they all produce a loss of consciousness that, in turn, may produce some degree of insensitivity to painful stimuli.

Stage 2: Delirium

As depression of inhibitory neurons in the central nervous system progresses, especially in the reticular formation, a resultant excitation of cortical motor neurons leads to significant involuntary muscle activity. This paradoxical response is caused by inhibition of inhibitory neurons that

normally function to closely regulate such neuronal activity. Typically, urination, delirium, and uncontrolled muscular movements occur that may be accompanied by increased heart rate, blood pressure, and respiration. Ideally, an anesthetic agent should produce little or no excitatory phase. Together, stages 1 and 2 comprise the induction period, which ideally should be of short duration.

Stage 3: Surgical Anesthesia

This stage is divided into four planes characterized by increasing central nervous system depression: first, loss of spinal reflexes; second, decreased muscle reflexes; third, paralysis of intercostal muscles; and fourth, loss of most muscle tone. Stage 3 also is characterized by regular breathing, a loss of many reflexes, and roving eyeball movements.

Stage 4: Respiratory Paralysis

Characterized by respiratory and vasomotor paralysis, this stage represents an overdose or toxic level that should be avoided. Normally, this stage is never reached, because the anesthesiologist is careful to monitor abdominal respiration to prevent apnea, blood pressure to prevent hypotension, and heart rate to prevent asystole.

Modern Anesthetic Agents

Although these stages have been described for diethylether, an anesthetic agent not used today, some of today's clinically useful anesthetic agents fail to follow this described pattern of anesthetic progression. Some attempts have been made to correlate changes in the electroencephalograph (EEG) with the depth of anesthesia. Most of these studies, however, have failed to yield a reliable predictor for anesthesiologists to utilize. Additionally, concomitant drugs used as preanesthetic agents may alter the EEG while not altering the depth of anesthesia. Rather than describing specific stages or using EEG patterns, a number of useful signs that more accurately reflect the depth of anesthesia for most of the anesthetic agents currently are employed. When during the initial

period of anesthetic administration a patient has irregular respiratory depth and rate, is still swallowing, blinks the eyes when the eyelashes are touched, the desired surgical stage of anesthesia likely has not been reached. When a loss of the eyelash reflex occurs along with rhythmic breathing, however, a level of adequate surgical anesthesia generally has begun. If a patient at this stage exhibits elevations in blood pressure, increased respiration rate, or increased jaw tension when a surgical incision is attempted, the subject is considered to be “light” and typically requires additional anesthesia to facilitate further surgical manipulations. These responses decrease further—until they are abolished—as the depth of anesthesia progresses. By monitoring reflexes, blood pressure, and respiration rate and depth, today's anesthesiologist is capable of effectively maintaining an appropriate depth of surgical anesthesia without producing unwanted medullary depression.

Pharmacokinetic Principles of Volatile Anesthetics

The production and maintenance of the anesthetic state is believed by most to be dependent on the concentration, or partial pressure, of the anesthetic agent in yet unknown areas of the brain. Obviously, the concentration of the anesthetic agent in the gas mixture administered, as well as the rate and depth of respiration of the patient, will influence the rate of anesthesia induction. The rate at which delivery of anesthetic agents to these sites occurs is dependent on their physicochemical properties, particularly their solubility in lipid and blood.

Administration of Volatile Anesthetics

The administration of gaseous or volatile liquid anesthetics involves a number of sophisticated

devices that have been refined over the years to aid the anesthesiologist in carefully controlling the amount of anesthetic delivered to the patient. Early systems used a gauze pad in a mask placed over the nose and mouth of the patient. The anesthesiologist would then put drops of the volatile anesthetic on the gauze pad, and as the patient breathed, the anesthetic was delivered to the lungs. This procedure was somewhat effective, but it allowed little or no control over the amount of anesthetic and oxygen delivered to the patient. Additionally, the anesthetic not inhaled was allowed to penetrate the surrounding area and posed a significant risk to the surgical personnel. Today, flowmeters, vaporizers, and absorber devices are routinely available, allowing precise determination and control of the amount of volatile anesthetic, oxygen, and carbon dioxide administered while preventing significant exposure to workers. Typically, oxygen is bubbled through a volatile anesthetic liquid, and the resultant gas mixture is delivered to the patient for continual inhalation. Many of these devices are described in greater detail elsewhere (1).

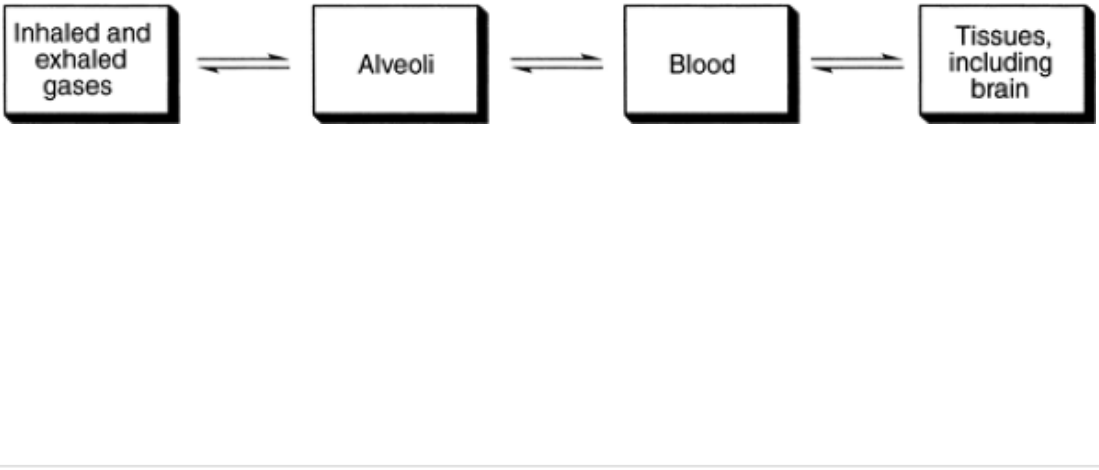

Fig. 18.2. Dynamic equilibria existing during the state of anesthesia.

The inhaled anesthetic concentration is controlled by the anesthesiologist, who can increase or decrease this concentration depending on the observed depth of anesthesia. Eventually, with continued administration, the concentration of anesthetic in the bronchiolar alveoli reaches equilibrium with that in the inspired gas mixture (Fig. 18.2). Transfer from the alveolar space to the blood proceeds quickly, and depending on the concentrations of anesthetic used and its physiochemical characteristics, equilibrium with the arterial blood is achieved. Before appreciable amounts of anesthetic dissolved in the blood will enter tissues, however, the blood must be saturated with the anesthetic. Therefore, anesthetics that are highly soluble in the blood will require a longer time to achieve saturation of the blood compartment. In such cases, the time for induction will be prolonged. On the other hand, an anesthetic that is poorly soluble in blood will quickly saturate the blood compartment and then rapidly enter the tissues to produce a short induction period. Similarly, agents with high blood/gas partition coefficients (i.e., high blood solubility) will require a longer time for recovery from anesthesia. The solubility of an agent in the blood usually is expressed as the blood/gas partition coefficient, which is the ratio of the concentration of anesthetic in blood to that in the gas phase at equilibrium (Table 18.2). These values correspond well with the oil/gas partition coefficient, which is easier to determine experimentally. The blood/gas partition coefficient can be very high (e.g., 12) for soluble agents, such as methoxyflurane, and extremely low (e.g., 0.47) for poorly soluble agents, such as nitrous oxide.

The solubility of the anesthetic in tissue is expressed as the tissue/blood partition coefficient. Because the concentration of the anesthetic in the brain is probably of most interest, however, the

brain/blood partition coefficient is more useful. Additionally, because the solubility of the anesthetic in lean tissues is essentially equal to that in blood, the tissue/blood or brain/blood partition coefficient typically is close to one. In fatty tissues, however, the partition coefficient can be much larger. The rate of blood flow to a particular organ also will influence the rate at which anesthetics reach their sites of action. The brain, liver, and kidneys have relatively high blood flows, whereas skeletal muscle at rest and fat tissues have relatively poor blood flows.

Reversal of the anesthetic state and recovery requires a reduction in the concentration of the anesthetic in the brain. This is achieved by stopping the delivery of the

anesthetic through the lungs. As the patient continues to breathe, the anesthetic is continually removed, which favors diffusion from the brain to the blood, to the alveoli, and finally, to the expired air. The rate at which this occurs generally parallels that of induction, because the solubility of an agent in the brain and in the blood determines how quickly these compartments will return to a preanesthetic state. The main route of elimination is via the expired air, which can be mostly captured by gas-scavenging devices with absorbers, but some metabolism of these agents does take place (discussed below).

Table 18.2. Partition Coefficients, MACs, and Metabolism of Some General Anesthetics

	Partition Coefficients at 37°C		MAC (vol %)a			
Anesthetics	Oil/Gas	Blood/Gas	Without N_2O	With N_2O (%)	MAC-Awake% (Vol %)	Metabolism
Methoxyflurane	970	12	0.16	0.07 (56)	—	50
Halothane	224	2.3	0.77	0.29 (66)	0.4	20
Enflurane	98.5	1.1	91.7	0.60 (70)	0.4	2.4
Isoflurane	90.8	1.4	1.15	0.50 (70)	0.4	0.17
Sevoflurane (2)	53.4	0.60	1.71	0.66 (64)	0.6	4–6
Desflurane (3)	16.7	0.42	6.0	2.83 (60)	2.4	0.02
Nitrous oxide	1.4	0.47	104	—	60	None

[a]MAC = minimum alveolar concentration, expressed as volume %, that is required to produce immobility in 50% of middle-aged humans.

Minimum Alveolar Concentration

The minimum alveolar concentration (MAC) is defined as the concentration at 1 atmosphere of anesthetic in the alveoli that is required to produce immobility in 50% of adult patients subjected to a surgical incision. A further increase to 1.3 MAC frequently will cause immobility in 99% of patients. At equilibrium, the concentration (or partial pressure) of an anesthetic in the alveoli is equal to that in the brain, and it is this concentration in the brain that probably most closely reflects the concentration at the site responsible for the anesthetic actions. Thus, the MAC often is used as a measure of the potency of individual anesthetic agents. The MAC of many of the volatile and gaseous anesthetics in use today is shown in Table 18.2.

When used in combinations, the MACs for inhaled anesthetics are additive. For instance, the anesthetic depth achieved with 0.5 MAC of enflurane plus 0.5 MAC of nitrous oxide is equivalent to that produced by 1.0 MAC of either agent alone. The combination of two anesthetics is a very common practice, because this technique allows a reduction in the patient exposure to any one of the individual agents, thereby decreasing the likelihood of adverse reactions.

Many factors can influence the MAC via a number of different mechanisms (Table 18.3). Factors that have been shown to increase the MAC for many volatile anesthetics include elevated catecholamines in the central nervous system following pharmacological treatments, hypernatremia, and hyperthermia. Factors known to decrease MAC include alcohol ingestion, clonidine, lithium, lidocaine, centrally administered opioids, and drugs that decrease central catecholamine levels. Additionally, hyponatremia, hypotension, hypothermia, hypoxia, increasing age, and pregnancy also have been shown to decrease MAC. Plasma potassium, hypertension, gender, and the duration of anesthesia typically have minimal effect on the MAC (2).

Another term, the “MAC-Awake,” is used to describe the concentration of anesthetic at which appropriate responses to verbal commands are lost in 50% of the patients tested. At this concentration, amnesia and a loss of awareness are evident, and the patient is said to be in a state of hypnosis. The MAC-Awake occurs at concentrations significantly lower (e.g., 50–75% lower) than those required for surgical anesthesia.

Theories About the Mechanisms of Anesthesia

Meyer-Overton Theory

In the early 1900s Hans Meyer and Charles Overton suggested that the potency of a substance as an anesthetic was directly related to its lipid solubility, or oil/gas partition coefficient (4,5). This has commonly been referred

to as the “unitary theory of anesthesia.” They used olive oil, octanol, and other “membrane-like” lipids to determine the lipid solubility of the agents available at the time. Compounds with high lipid solubility required lower concentrations (i.e., lower MAC) to produce anesthesia. Later, it was postulated that the interaction of the anesthetic molecules with a hydrophobic portion of the membrane caused a distortion of the membrane near the channels that conducted sodium ions, those that mediated the fast action potentials and neuronal cell firing. The presence of this critical volume of anesthetic dissolved within the membrane caused the membrane to “bloat” and “squeeze” in on the channel to interfere with sodium conductance and normal neuronal

depolarization. In support of this theory, it was found that at high pressures (40–100 atmospheres), the anesthetic actions of many of these agents could be partially reversed, presumably by compressing membranes back to their original conformation. Arguing against this theory, however, is the finding that not all highly lipid-soluble substances are capable of producing anesthesia. Additionally, more recent work involving protein–drug interactions has seriously challenged this theory. Today, more than 150 years after the first demonstration of the use of a volatile anesthetic agent, most theories about the mechanisms of anesthesia suggest that multiple selective lipid–protein membrane interactions, involving numerous receptor types, are responsible for the anesthesia produced and that no reason exists to believe that all anesthetic agents need to produce their effects via identical actions. Thus, a single molecular target for anesthetic actions is no longer required (6).

Table 18.3. Factors That May Alter MAC

Increase MAC	Increased catecholamine levels in CNS Hypernatremia Hyperthermia	
Decrease MAC	Decreased catecholamine levels in CNS	
	Alcohol ingestion	Hyponatremia
	Clonidine	Hypotension
	Lidocaine	Hypothermia
	Lithium	Hypoxia
	Opioids	Increased age Pregnancy
No effect on MAC	Plasma potassium Gender Hypertension Duration of anesthesia	

Stereochemical Aspects

The volatile anesthetics isoflurane, desflurane, enflurane, and halothane each contain an asymmetric carbon and, thus, can exist as (+)- or (–)-enantiomers. Although all of the commercially available preparations are racemates, some researchers have been able to determine the anesthetic properties of individual enantiomers. The (+)-enantiomer of isoflurane is at least 50% more potent as an anesthetic in the rat than the (–)-enantiomer is (7). In that study, the MAC values were 1.06 and 1.62% for the (+) and (–)-enantiomers, respectively. In another study, however, the potency of the individual isoflurane enantiomers to depress myocardial activity was

not found to be different, suggesting possible involvement of mechanisms dissimilar from that responsible for producing anesthesia (8). These findings argue against the original and simple lipid-solubility theory of anesthesia, and they support a more complex mechanism, probably likely involvement of proteins in the form of receptor–anesthetic interactions (9).

Ion Channel and Protein Receptor Hypotheses

More recently, investigators have determined the effects of anesthetics on a number of protein receptors within the central nervous system. Features that support the likelihood of an interaction with a protein include 1) the steep dose–response curves observed, 2) the stereochemical requirements of various anesthetics, 3) the finding that increasing the molecular weight and corresponding lipid solubility of an anesthetic may actually decrease or abolish anesthetic activity, and 4) the finding that specific ion channels and neurotransmitter receptor systems are required for most of the observed effects of the anesthetics. What appears to be emerging as a central theme for the mechanism of action of general anesthetics involves the interaction of the anesthetics with receptors that allosterically modulate the activity of ion channels (e.g., chloride and potassium) or with the ion channel directly (e.g., sodium). Many other mechanisms also are emerging to help explain the mechanisms of action of the general anesthetics.

Chloride Channel

The ion channel that has received the most investigative attention is that for chloride (Fig. 18.3). Both the γ-aminobutyric acid$_A$ ($GABA_A$) and the glycine$_A$ (strychnine-sensitive) receptors are ligand-gated ion channels and linked to chloride channels that normally mediate inhibitory responses within the central nervous system. Halothane, isoflurane, and other volatile anesthetics are capable of inhibiting the synaptic destruction of GABA, thereby increasing the GABAergic neurotransmission, which typically is inhibitory in nature (10). Additionally, studies have demonstrated the ability of these anesthetics to enhance the binding of GABA or other allosteric modulators within the GABA receptor complex (11). In one such study, (+)-isoflurane was significantly more potent than the (–)-enantiomer at enhancing GABAergic function (12). The volatile anesthetics, and many of the intravenous anesthetic agents, bind to discrete cavities within the $GABA_A$ receptor complex to enhance GABA neurotransmission (13,14), Studies using mutant chimeric $GABA_A$ receptors have identified a specific binding site for general anesthetics located between transmembrane segments 2 and 3 (15). At therapeutic concentrations, just about all of the inhalational general anesthetics are capable of enhancing GABAergic function, whereas at considerably higher concentrations, many also may act directly as GABA mimetics (16). Recent studies have demonstrated an effect of these agents not only on the synaptic $GABA_A$ receptor function that mediates phasic neuronal responses but also on those extrasynaptic $GABA_A$ receptors that mediate tonic neuronal activity (17). Other specific anesthetic agents may alter $GABA_A$ receptor function via different mechanisms. For instance, propofol, an intravenous anesthetic, appears to slow the desensitization of the $GABA_A$ receptor during bouts of rapid, repetitive activation at inhibitory synapses (18). Most of these agents also potentiate the actions of glycine, the other important inhibitory amino acid neurotransmitter (16). The combination of GABAergic and glycinergic potentiation by the general anesthetics probably accounts for the

vast majority of the observed activity of the inhalational agents as well as that of the barbiturates.

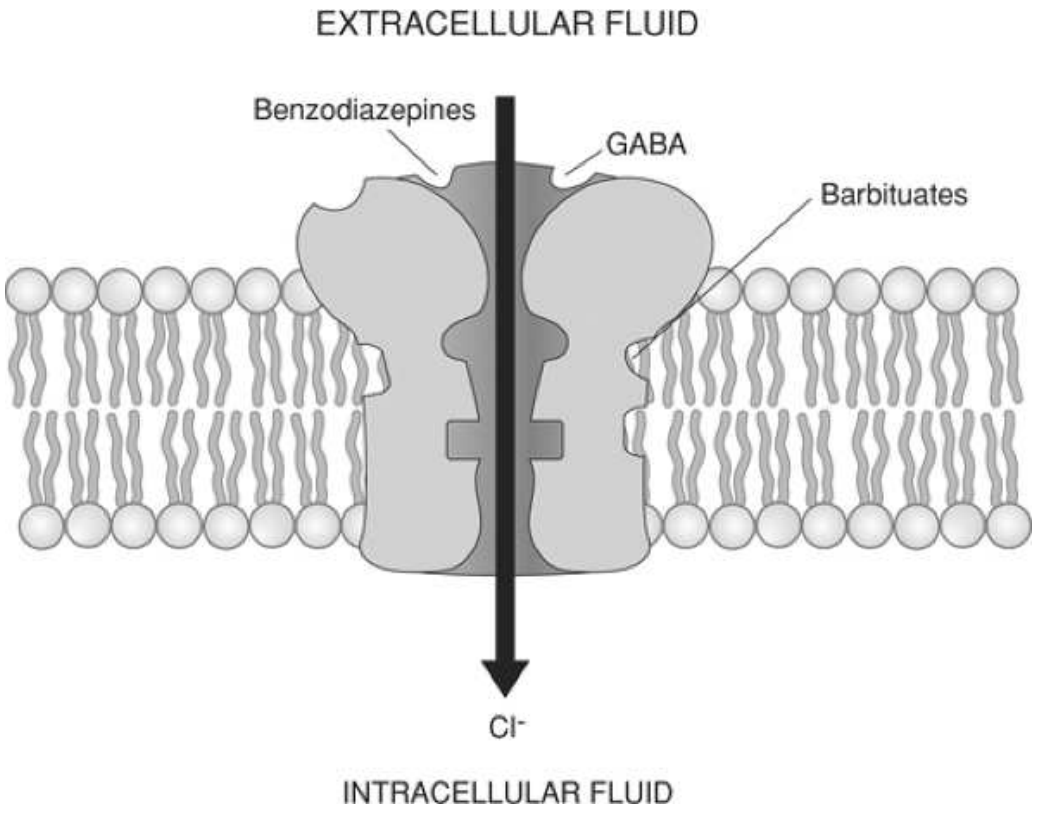

Fig. 18.3. The $GABA_A$ receptor controls the chloride ion channel. GABA binds to its receptor, opening the chloride ion channel and resulting in hyperpolarization of the neuron. Benzodiazepines and barbiturates may produce anesthesia by allosterically enhancing GABA opening of chloride channels, which are located at inhibitory synapses on pyramidal cells. ECF = extracellular fluid; ICF = intracellular fluid.

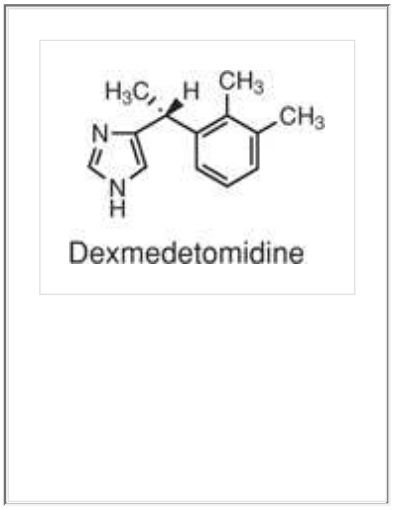
Sodium Channels

One channel that has received much attention regarding the mediation of drug-induced anesthetic actions is the ligand-gated sodium channel within the N-methyl-D-aspartate (NMDA) receptor complex. When activated by the excitatory amino acid neurotransmitter, glutamate, an increase in the conductance to sodium occurs that promotes neuronal depolarization (Fig. 18.4) (19). Compounds known to stimulate NMDA receptors typically are capable of increasing alertness and of acting as convulsants, whereas pharmacological agents that act as antagonists at this site usually are sedatives, anticonvulsants, and dissociative anesthetics (e.g., ketamine). Halothane has been demonstrated to specifically antagonize the glutamate-stimulated depolarization of neurons (20), whereas isoflurane has been shown to decrease glutamate release and enhance its removal from the synaptic cleft (21). Glutamate acting at NMDA and other non-NMDA receptors within the central nervous system probably is one of the most important excitatory inputs that supports consciousness. It is not surprising that the general anesthetics would act via altering neurotransmission in this system (22). Others have reported an interaction of general anesthetics with the neuronal nicotinic acetylcholine receptor–linked sodium ion channel (23). Voltage-gated sodium channels in small, nonmyelinated hippocampal axons also appear to be inhibited by general anesthetics, such as isoflurane (24).

Potassium Channels

Potassium channels also have been suggested as a site for general anesthetic agents. Increasing K^+ conductance normally functions to maintain the polarized state of neurons and to assist in the repolarization of neurons following their stimulation-induced depolarization (Fig. 18.5). Thus, enhancing the activity of certain K^+ channels would be expected to result in a decreased likelihood of neuronal excitation. A novel, anesthetic-sensitive K^+ current ($I_{K(an)}$) has been identified that is stereoselectively activated by isoflurane (25). Mice with a targeted deletion of the TREK-1 two-pore-domain K^+ channel show significantly reduced sensitivity to general anesthetics compared to wild-type controls (26). Additionally, certain α_2-adrenoceptor agonists (e.g., dexmedetomidine) when injected produce an anesthetic state that is mediated by a G protein–coupled receptor that allosterically modulates K^+ channels. These responses can be antagonized by pertussis toxin and 4-aminopyridine, agents that inactivate G proteins and block K^+ channels, respectively, lending further support to the role of this ion channel (27). Similarly, G protein–mediated mechanisms appear to be involved with the action of morphine via the μ-receptor (Fig. 18.5).



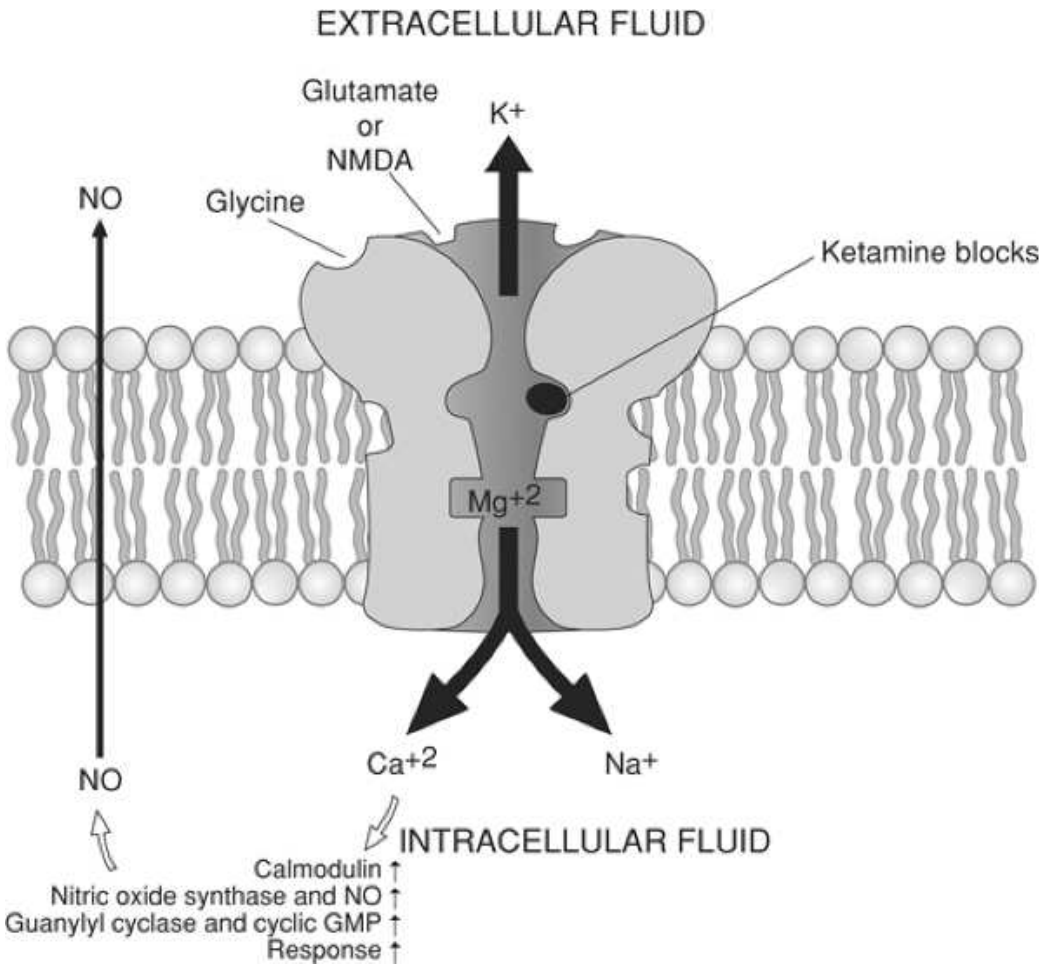


Fig. 18.4. Glutamate or NMDA receptors in the central nervous system. Binding of agonists (glutamate or NMDA) opens the channel, allowing potassium ions to flow outward to extracellular fluid (ECF) and sodium and calcium ions to flow into the nerve cells. Increased intracellular (ICF) calcium ion concentration triggers a cascade that produces a response and liberates the neuronal messenger nitric oxide (NO). Ketamine may produce anesthesia by blocking these NMDA-controlled channels, which are located at excitatory synapses on pyramidal cells (3). Glycine acts as a positive allosteric modulator at the NMDA receptor.

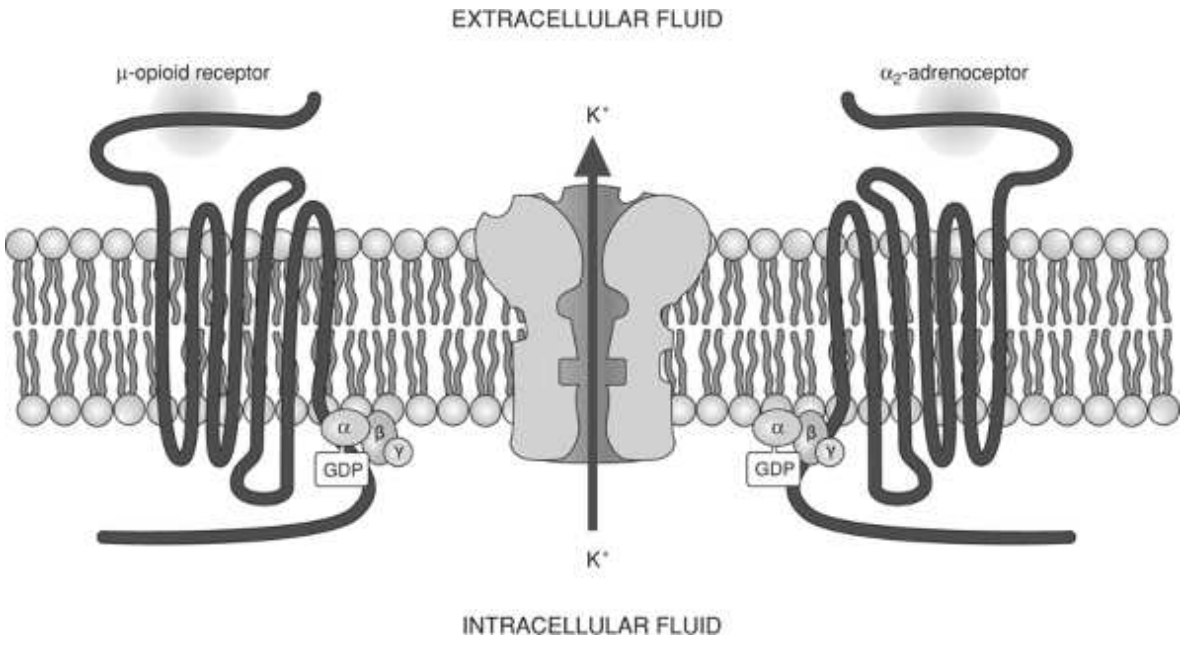

Fig. 18.5. Morphine and α_2-agonists activate their respective G proteins, which hyperpolarize neurons by lowering intracellular fluid (ICF) potassium ion concentration.

Halogenated Hydrocarbons and Ethers

Historical Aspects

Ether

The useful volatile anesthetics, with the exception of nitrous oxide, are halogenated hydrocarbons and ethers. Diethyl ether (Fig. 18.6), one of the first agents to be introduced as an anesthetic, has high potency with significant analgesic and neuromuscular relaxing effects. This agent is flammable, and when mixed with air, oxygen, or nitrous oxide, it is explosive. Induction with diethyl ether is very slow; significant time can be spent progressing through the delirium stage. Irritation of the respiratory tract by diethyl ether may lead to excessive bronchial secretions complicating adequate ventilation. In addition to the unpleasant induction and adverse effects, recovery is similarly prolonged and may be accompanied by vomiting. These pharmacological and physical characteristics of diethyl ether limit the utility of this anesthetic in humans.

Short-Chain Hydrocarbons

Many of the short-chain alkanes, alkenes, and alkynes are capable of producing an anesthetic state when administered to patients. Potency generally increases as chain length increases. Because of their flammability and increased propensity to cause cardiovascular toxicity, however, these nonsubstituted hydrocarbons are not useful as anesthetic agents.

Chloroform

Another of the earlier anesthetic agents to be employed was chloroform. This halogenated

hydrocarbon was first officially used in the United States in 1847; however, its toxicity seriously limited its utility. The addition of halogens to the hydrocarbon backbone increases potency and decreases flammability. Similar effects also are observed with such substitutions on ethers. As an anesthetic agent, chloroform is very potent and possesses significant analgesic and neuromuscular relaxing activity. Chloroform, a known carcinogen, has the disadvantage of being both hepatotoxic and nephrotoxic, in addition to producing adverse cardiovascular effects, such as arrhythmias and severe hypotension. As a result of these toxicities, chloroform has an unacceptable therapeutic index that prohibits its use in anesthesia. Knowledge regarding the influence of the halogen substitutions on the potency and flammability of hydrocarbons and ethers, however, has significantly contributed to our understanding of the structure–activity relationship of volatile anesthetics and the eventual design of substantially improved agents.

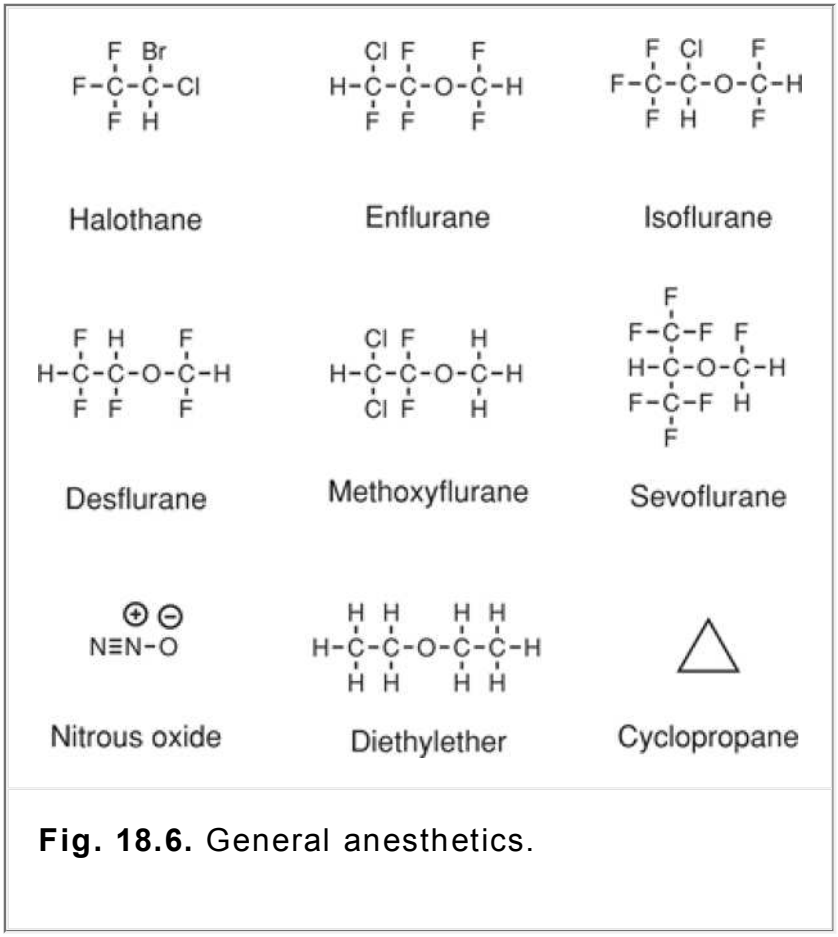

Fig. 18.6. General anesthetics.

Table 18.4. Relative Flammability of "Nonflammable" Anesthetics

	Halothane (%)	Enflurane (%)	Isoflurane (%)
Minimum flammable conc (MFC) of agent in 30% O_2 with remaining atmosphere N_2O	4.75	5.75	7.0
Minimum effective alveolar conc. (MAC) of agent given in above	0.28	0.65	0.46

atmosphere			
MAC in humans in the absence of N_2O	0.75	1.68	1.15
MFC/MAC in N_2O	17	8.9	15.2

Flammability

The occurrence of fires in operating rooms is of great concern to all participants in the surgical procedure. Although the introduction of "nonflammable" agents, such as halothane, enflurane, and isoflurane, has substantially decreased this hazard, such fires still occur. Three essential ingredients are required for any combustion: 1) an ignition source (e.g., a laser), 2) a combustible material (e.g., gauze, drapes, or rubber tubes), and 3) an oxidizing agent (e.g., O_2 or N_2O). Many substances are flammable in pure oxygen, N_2O, or mixtures but not air. Certain substances are flammable in N_2O at concentrations that are too low to permit ignition in pure oxygen (28). The concentrations required for combustion, as indicated in Table 18.4, are higher than those generally encountered, except possibly during induction.

Clinically Useful Inhalation Agents

Fluorinated Hydrocarbons

The structure and physical properties of the volatile anesthetics are given in Table 18.5. Toxic degradation products are formed by reaction of the anesthetic agent with the

bases used as carbon dioxide absorbents during anesthesia. This reaction results in the conversion of halothane to 2-bromo-2-chloro-1,1-difluoroethylene, sevoflurane to 2-(fluoromethoxy)-1,1,3,3,3-pentafluoro-1-propene (Compound A), and desflurane, isoflurane, and enflurane to carbon monoxide. Compound A forms a glutathione S-conjugate, which undergoes hydrolysis to cysteine S-conjugates and bioactivation of the cysteine S-conjugates by renal cysteine conjugate β-lyase to give nephrotoxic metabolites.

Table 18.5. Physicochemical Properties of Clinically Useful Volatile Anesthetics

Generic Name (Trade and Structure Name)	Boiling Point (°C)	Chemically Stablea
Desflurane (Suprane) $F_2HC–O–CHF–CF_3$	23.5	Yes
Enflurane (Ethrane) $F_2HC–O–CF_2–CHFCl$	56.5	Yes

Halothane (Fluothane) $F_3C–CHBrCl$	50.2	No
Isoflurane (Forane) $F_2HC–O–CHCl-CF_3$	48.5	Yes
Methoxyflurane (Penthrane) $H_3C–O–CF_2–CHCl_2$	104.7	No
Nitrous oxide N_20	–*8.0	Yes
Sevoflurane (Ultane) $(CF_3)_2CH–O–CH_2F$	58.5	No

[a]Indicates stability to soda lime, ultraviolet light, and common metals.

Halothane

Halothane (Fig. 18.6) was introduced into medical practice in the United States in 1956 as a nonflammable, nonexplosive, halogenated volatile anesthetic that usually is mixed with air or oxygen. The presence of the carbon–halogen bonds contributes to its nonflammability. This clear liquid with a sweet odor was developed based on predictions that its halogenated structure would provide chemical stability, an intermediate blood solubility, and significant anesthetic potency. Halothane is the only useful volatile anesthetic possessing a bromine atom, which has been suggested to contribute to its potency. Similarly, the addition of fluorine atoms, of which halothane has three, is thought to contribute to the increased potency, volatility, and increased chemical stability of the hydrocarbon skeleton (Table 18.5).

Halothane produces rapid onset and recovery from anesthesia with high potency when used alone or in combination with nitrous oxide. Most metals, with the exception of chromium, nickel, and titanium, are easily tarnished by halothane. Although halothane is relatively stable, it is subject to spontaneous oxidative decomposition to hydrochloric acid, hydrobromic acid, and phosgene. For this reason, it is available in dark, amber glass containers with thymol added as a preservative to minimize decomposition. Halothane may permeate into the rubber components of the anesthetic delivery devices, which might account for some slowing of the induction onset and recovery. Approximately 20% of an administered dose is metabolized, which accounts, in part, for the increased hepatotoxicity observed with this agent (Fig. 18.7).

Enflurane

Enflurane (Fig. 18.6) was introduced into medical practice in the United States in 1973 and is a clear, colorless, nonflammable general liquid with a mild, sweet odor. Although relatively stable chemically, enflurane does not attack aluminum, copper, iron, or brass and is soluble in rubber (partition coefficient = 74), which can prolong induction/recovery times, as seen with halothane

(Table 18.5). Enflurane has an intermediate solubility in blood and significant potency. Most of its pharmacological properties are similar to those of halothane, although there may be slightly less nausea, vomiting, arrhythmias, and postoperative shivering than observed with halothane. High concentrations of enflurane, however, are more likely to produce convulsions and circulatory depression. Enflurane also relaxes the uterus and, thus, should not be used as an anesthetic during labor. Metabolism via CYP2E1 accounts for 2% of an inhaled dose and includes transformation to the fluoride ion and fluoromethoxydifluoroacetic acid (Fig. 18-7) (30). During recovery, enflurane leaves the fatty tissues rapidly and, therefore, is not available for a prolonged period of time for significant metabolism to proceed.

Isoflurane

Isoflurane (Fig. 18.6) was introduced in the United States in 1981 and is a potent anesthetic agent with many similarities to its isomer enflurane (potent, nonflammable, and intermediate blood solubility). It does produce significantly fewer cardiovascular effects than enflurane, however, and it can be used safely with epinephrine without as great a concern for arrhythmia production. Isoflurane has a more pungent odor than halothane and, thus, can cause irritation to the throat and respiratory tract, triggering coughing and laryngospasm. To overcome this problem, it often is supplemented with intravenous agents. Less than 0.2% of an administered dose is metabolized, mostly to fluoride and trifluoroacetic acid (Fig. 18.7). As discussed below, some minimal potential for hepatotoxicity is associated with a trifluoroacetyl halide metabolite.

A comparative assessment of the volatile anesthetic properties of enflurane, halothane and isoflurane are shown in Table 18.6.

Desflurane

Desflurane (Fig. 18.6) was introduced in the United States in 1992 and is a pungent, volatile agent that is nonflammable and noncorrosive to metals. With a poor blood solubility similar to that of nitrous oxide, desflurane rapidly induces anesthesia. Because the boiling point of desflurane is close to room temperature, a specially designed, heated vaporizer is used to deliver the anesthetic with appropriate concentrations of oxygen either alone or in combination with nitrous oxide. Recovery from the anesthetic

state also is rapid, being approximately twice as rapid as that with isoflurane. Because of the rapid induction and recovery associated with desflurane, this anesthetic has gained popularity in outpatient surgical procedures. Desflurane is rather pungent, so patients often are induced with an intravenous anesthetic agent and then maintained with desflurane. Desflurane is not metabolized to any great extent and, therefore, has not been associated with hepatotoxicity or nephrotoxicity (31). Metabolites, mostly trifluoroacetate, account for less than 0.02% of the administered dose (Fig. 18.7). Whereas desflurane can react with soda lime or Baralyme to form carbon monoxide, no reports of adverse outcomes in patients have appeared.

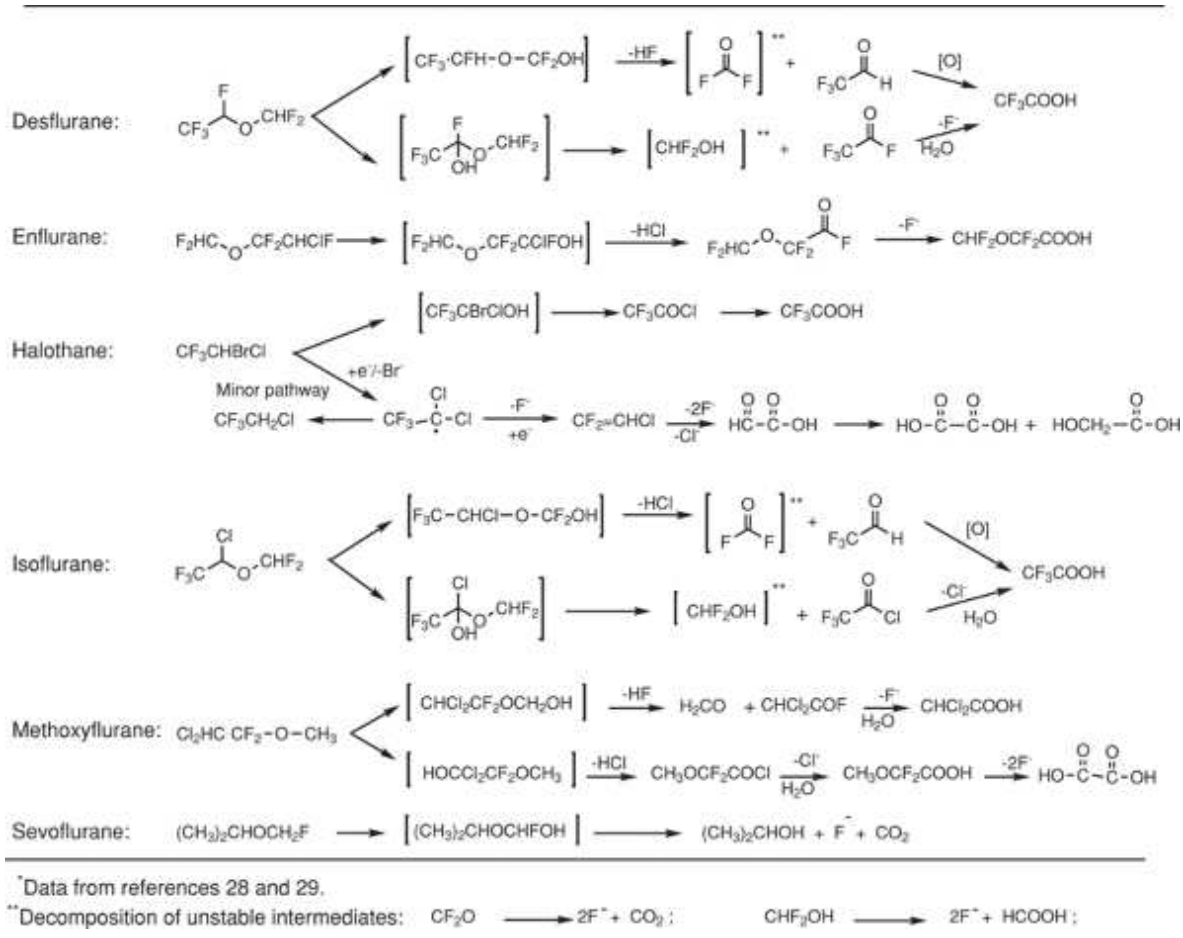

Fig. 18.7. Proposed metabolites of fluorinated anesthetics.

Table 18.6. Comparative Assessment of Enflurane (E), Halothane (H), and Isoflurane (I)

Property	Superior	Intermediate	Inferior
Stability	I = E	—	H
Blood solubility	I	E	H
Pungency	H	I	E
Respiratory depression	H	I	E
Circulatory depression	I	H	E

Induction of arrhythmias	I	E	H
Muscle relaxation	I = E	—	H
Increased intracranial pressure/cerebral blood flow	I	E	H
Seizure activity	H = E	—	E
Metabolism	I	E	H
Toxicity	I	E	H

Adapted from Wade JG, Stevens WC. Isoflurane; an anesthetic for the eighties? Anesth Analg 1981;60:666–682; with permission.

Sevoflurane

Sevoflurane (Fig. 18.6) is a nonflammable, nonirritating, pleasant-odored volatile anesthetic available for use in the United States. Similar to desflurane in many of its pharmacological actions, sevoflurane has low blood solubility, higher potency, and the advantage of not being irritating to the respiratory tract. Induction and recovery are rapid. Sevoflurane undergoes significantly more metabolism (CYP2E1) than desflurane, however, and as much as 3% of an administered dose can be recovered as hexafloroisopropanol (Fig. 18.7). Some fluoride ion also can be produced, but the incidence of nephrotoxicity or hepatotoxicity appears low, especially when used infrequently for short periods of time. There have been concerns regarding the reactivity of sevoflurane with

soda lime or Baralyme, in which a potentially toxic olefin by-product termed “Compound A” (2-(fluoromethoxy)-1,1,3,3,3-pentafluoro-1-propene) can be formed. With appropriate precautions, however, sevoflurane can be used safely in both children and adults.

Methoxyflurane

Methoxyflurane (Fig. 18.6) is seldom used because of its propensity to cause renal toxicity. It is the most potent of the agents discussed here, and it has the highest solubility in blood. Induction and recovery would be expected to be slow. Chemically, it is rather unstable, and as much as 50% of an administered dose can be metabolized. Toxic metabolites significantly limit its utility as a general anesthetic (Fig. 18.7).

Toxicity of Fluorinated General Anesthetics

Although few signs of toxicity usually are observed during the short-term, infrequent administration of general anesthetics, a few well-defined toxic effects have been noted. For instance, halothane and methoxyflurane are known to produce hepatotoxicity and nephrotoxicity, respectively. Both of these toxic reactions are believed to result from highly reactive metabolites of the parent

compound. Overall, however, the therapeutic ratio for most of the general anesthetics approaches 4:1 (32).

Hepatotoxicity

Hepatitis caused by halothane occurs in 1 in 20,000 patients exposed to this anesthetic. It is thought to result from the binding of a reactive free radical metabolite to liver tissue (Fig. 18.7). The resultant abnormal molecular product in the liver is viewed by the immune system as a foreign substance (e.g., an antigen), which then sensitizes cells to produce antibodies. Some have suggested that the trifluoroacetyl halide metabolite is responsible for the initiation of halothane hepatitis. Interestingly, both enflurane and isoflurane can be metabolized to the acylated halides and produce a similar immune-mediated syndrome, although to a much lesser extent. Additionally, there appears to be cross-reactivity among these three agents, because the antigen formed is similar enough in structure to elicit the immune system response. Some investigations have suggested that a genetic susceptibility factor may be responsible, in part, for this serious form of hepatitis.

Halothane also can produce another form of hepatotoxicity. This is a self-limiting hepatic dysfunction characterized by elevated liver transaminase enzymes, which probably results from impaired oxygenation of the hepatocytes during exposure to this anesthetic. Isoflurane and enflurane also have been reported to produce a similar elevation of liver enzymes, although to a lesser extent than halothane.

Malignant Hyperthermia

This rare (1 per 15,000 anesthetic uses) but potentially fatal complication associated with the use of certain anesthetics (e.g., halothane) is characterized by a rapid rise in core body temperature associated with hypermetabolic reactions in the skeletal muscle of genetically susceptible subjects. Such individuals appear to have an autosomal dominant mediated defect in the Ca^{2+}-release channel commonly referred to as the ryanodine receptor. The large amounts of heat generated, massive increase in oxygen consumption, and production of carbon dioxide may quickly lead to death or permanent neurological damage unless appropriate supportive treatment, including rapid cooling, 100% oxygen, and control of acidosis, is promptly initiated. The administration of the skeletal muscle relaxant dantrolene, which blocks release of Ca^{2+} from the sarcoplasmic reticulum, reduces muscle rigidity and heat production, which significantly improves the prognosis of the patient. Besides the fluorinated volatile anesthetics, some depolarizing neuromuscular blocking agents (e.g., succinylcholine) and some neuroleptics (e.g., haloperidol) also are reportedly associated with similar malignant hyperthermic syndromes, although the underlying mechanism mediating these may differ somewhat from those associated with the general anesthetics.

Nephrotoxicity

Fluorinated anesthetics that undergo metabolism to inorganic fluoride have the potential to produce damage to the renal tubular cells. Of the fluorinated anesthetics, methoxyflurane is the only agent commonly associated with nephrotoxicity. Methoxyflurane is subject to metabolism (Fig. 18.7), yielding plasma fluoride ion levels in excess of the threshold value for renal damage of 40 μM. Others, such as sevoflurane, have only very rarely been associated with nephrotoxicity—and then usually in patients with severe renal compromise. Plasma levels of fluoride only reach 15 to 20 μM following 2.5 MAC-hour exposure to enflurane (33). The rates of metabolic defluorination of the useful anesthetic agents are as follows: methoxyflurane > enflurane = sevoflurane > isoflurane > desflurane = halothane.

Low-Level Chronic Exposure

Typically, patients are exposed to greater-than-MAC concentrations of the volatile anesthetics for limited periods of time, such as a number of hours during a surgical procedure and not for extended periods of time (e.g., days or weeks). Because surgical and dental personnel, however, may be exposed to low levels of the general anesthetics for prolonged periods over many years or even decades, the ability of such agents to produce chronic toxicity is of paramount concern. Although the occupational exposure to these agents has been minimized with improved waste gas–scavenging devices, some epidemiological studies have demonstrated increased levels of spontaneous abortions, congenital birth defects in offspring, and increased rates of certain cancers in chronically exposed medical personnel (34).

Nitrous Oxide

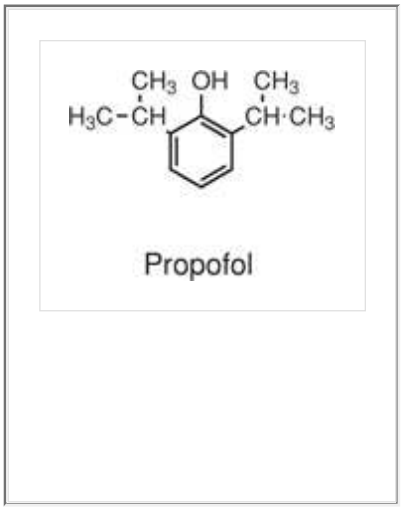
Commonly called “laughing gas,” nitrous oxide (dinitrogen monoxide, or N_2O) is a gas at room temperature

and is the least potent of the inhalation anesthetics used today (Table 18.5). With an MAC value in excess of 105%, this colorless, tasteless, and odorless to slightly sweet-smelling gas is not normally capable of producing surgical anesthesia when administered alone. The MAC for nitrous oxide has been demonstrated to be between 105 and 140% and, thus, cannot achieve surgical anesthesia under conditions at standard barometric pressure. To demonstrate that the MAC was greater than 100%, Bert in 1879 used a mixture of 85% nitrous oxide with oxygen at 1.2 atmospheres in a pressurized chamber. Only at this elevated pressure could an MAC adequate for surgical anesthesia be achieved. Decreasing the oxygen content of a nitrous oxide mixture to values less than 20% to allow an increase in the concentration of nitrous oxide to greater than 80% can be dangerous, because hypoxia would be expected to result. Thus, when administered alone, nitrous oxide finds utility as an anesthetic agent during certain procedures (e.g., dental) in which full surgical anesthesia is not required. Most commonly, however, nitrous oxide is used in combination with other general anesthetics, because it is capable of decreasing the concentration of the added anesthetic required to produce an adequate depth of anesthesia for surgical procedures.

While no firm underlying mechanisms have been demonstrated, some authors have suggested that irreversible oxidation of the cobalt atom in vitamin B_{12} by nitrous oxide can lead to inactivation of enzymes dependent on this vitamin, with resultant metabolic aberrations. Such examples have included methionine synthetase and thymidylate synthetase, which are essential in the synthetic pathways leading to the production of myelin and thymidine, respectively. Should these enzymes be impaired during the sensitive periods of in utero development, the potential for malformations may unfortunately be realized. To date, no studies have been able to demonstrate conclusively that low-level exposure to nitrous oxide is associated with a meaningful disruption of crucial metabolic functions to produce the above-described toxicity; however, measures including improved waste gas–scavenging systems should be taken to minimize exposure of personnel.

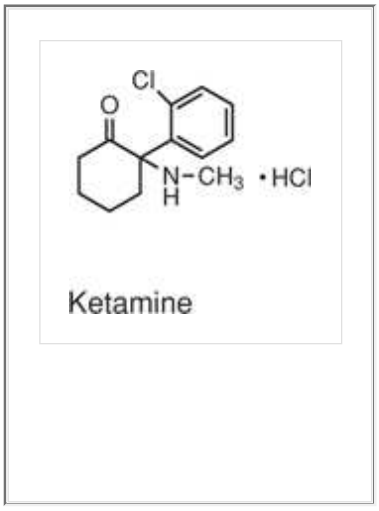
Clinically Useful Intravenous Agents

Propofol



The most commonly used parenteral anesthetic used in the United States is propofol. Used intravenously, propofol is not chemically related to the barbiturates or other intravenous anesthetics. Propofol appears to act via enhancing GABAergic neurotransmission within the central nervous system. This occurs most likely at the GABA receptor complex, but at a site distinct from where the benzodiazepines bind. Because of its poor water solubility, propofol is formulated as a 1 or 2% emulsion with soybean oil, egg lecithin, and glycerol. Sodium metabisulfite or ethylenediaminetetra-acetic acid also is included in the parenteral dosage form. Because of the likelihood of bacterial contamination of open containers, propofol should be either administered or discarded shortly after sterility seals are broken. Following intravenous administration of a dose of 2.0 to 2.5 mg/kg, a state of hypnosis is achieved within 1 minute, which lasts for approximately 5 minutes. A longer anesthetic state can be achieved by additional propofol dosing or, as typically is the case, maintenance with a volatile anesthetic agent. Blood pressure and heart rate usually are decreased following propofol administration. Metabolism of propofol proceeds rapidly via hepatic conversion to its glucuronide and sulfate conjugates, with less than 0.3% excreted unchanged. Because this agent produces a rapid induction and recovery and is infrequently associated with episodes of vomiting, propofol has found utility as an anesthetic agent in outpatient surgical environments.

Ketamine



Ketamine hydrochloride is an injectable, very potent, rapidly acting anesthetic agent. As with propofol above, its duration of anesthetic activity also is relatively short (10–25 minutes). Ketamine does not relax skeletal muscles and, therefore, can only be used alone in procedures of

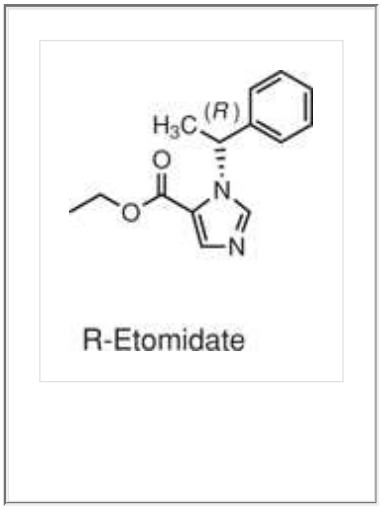
short duration that do not require muscle relaxation. Recovery from anesthesia may be accompanied by “emergence delirium,” which is characterized by visual, auditory, and confusional illusions. Disturbing dreams and hallucinations can occur up to 24 hours after the administration of ketamine. Its elimination half-life is 2 to 3 hours, and its volume of distribution is 2 to 3 L/kg. Ketamine has an oral bioavailability of less than 16%. Termination of the acute action of ketamine is largely a result of its redistribution from the brain into other tissue; however, the formation of the glucuronide conjugate and metabolism in the liver to a number of metabolites does occur. One of these metabolites of interest, norketamine, is formed via the action of CYP2B6. This N-demethylated derivative retains significant activity at the NMDA receptor and may account for some of the longer-lasting effects of this anesthetic agent. Eventual conversion of norketamine

to hydroxylated metabolites and subsequent conjugation leads to metabolites that can be renally eliminated. Less than 4% of a dose is excreted unchanged in the urine.

Ketamine is capable of producing a “dissociative” anesthesia, which is characterized by EEG changes indicating a dissociation between the thalamocortical and limbic systems (35). These neuronal systems, which normally are associated with one another, help to maintain the neuronal connections required for consciousness. When disassociated, the subject will appear to be cataleptic, with the eyes open in a slow, nystagmic gaze (1). A potent analgesic and amnesic effect is produced, as is an increase in muscle tone in some areas. Although patients may appear to be awake, they are incapable of communicating and do not remember the event or the people around them. Blood pressure and heart rate usually are increased following ketamine administration.

Ketamine appears to act similarly to phencyclidine (PCP; also known as Angel Dust), which acts as an antagonist within the cationic channel of the NMDA receptor complex (36). By preventing the flow of cations through this channel, ketamine prevents neuronal activation, which normally is required for the conscious state. The analgesic activity of ketamine, however, is more likely the result of an interaction with an opioid receptor or the less-well-understood σ-receptor. Other studies have suggested a possible involvement of serotonin receptors and muscarinic receptors (37). Ketamine, like PCP, has a significant potential for abuse.

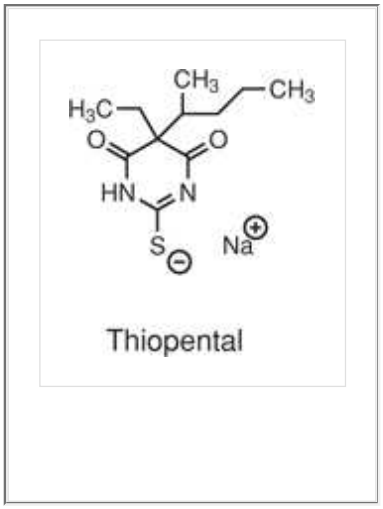
Etomidate



Etomidate is the ester of a carboxylated imidazole, with a log P of 3 and a weak base pK_a of 4.5, that is available as the D-isomer solubilized in 35% propylene glycol for intravenous injection in addition to being available for rectal administration. It is a potent, short-acting hypnotic agent (<3 min) without analgesic activity and with a rapid onset of action. This agent is useful for the induction of anesthesia in hemodynamically unstable patients prone to hypotension because of hypovolemia, coronary artery disease, or cardiomyopathies. Recovery is similarly rapid following

discontinuance of the drug. Etomidate is hydrolyzed by hepatic esterases to the corresponding inactive carboxylic acid, with subsequent renal and biliary excretion terminating its action. Its apparent elimination half-life is approximately 5 to 6 hours, with a volume of distribution of 5 to 7 L/kg. Changes in hepatic blood flow or hepatic metabolism will have only moderate effects on etomidate disposition. Concerns regarding the ability of etomidate to precipitate myoclonic jerks and inhibit adrenal steroid synthesis have been reported.

Ultrashort-Acting Barbiturates



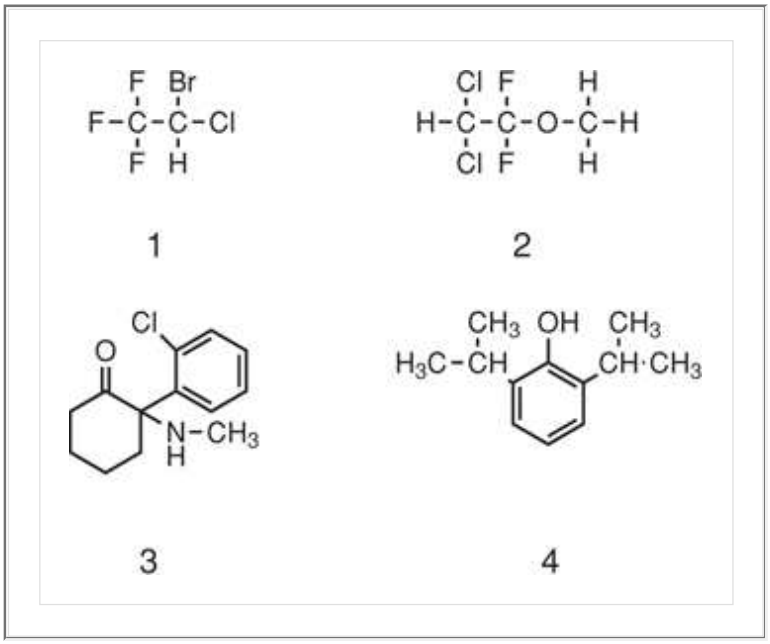
The ultrashort-acting barbiturates (e.g., thiopental) are used intravenously to produce a rapid unconsciousness for surgical and basal anesthesia. These agents may be used initially to induce anesthesia, which then can be maintained during the surgical procedure with a general anesthetic agent. The induction typically is very rapid and pleasant. (These ultrashort-acting barbiturates are discussed in Chapter 19.)

Case Study

Victoria F. Roche

S. William Zito

JA is a brought to the emergency department where you work. He is a 58-year-old street person. His clothes are disheveled, he needs a bath and a shave, and he smells of alcohol. JA is in extreme pain and grumpily complains that he was pushed down hard by a couple of young “punks” who were after his shopping cart, which contained all of his worldly possesions. The pain is radiating from his right hip, and radiographs reveal that he has an intertrochanteric hip fracture just below the femoral neck of his right leg. This type of fracture is treated by repairing the fracture with a metal plate and screws. Tests reveal that JA has slightly low blood pressure (105/70 mm Hg), and his liver enzymes and creatinine clearance are indicative of decreased liver and kidney function, most likely because of alcohol and the hard life on the streets. Evaluate structures 1 to 4 for use as the general anesthetic for JA's surgery.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 19

Sedative-Hypnotics

William Soine

Drugs covered in this chapter:

Benzodiazepine sedative-hypnotics

- Estazolam
- Flurazepam
- Quazepam
- Temazepam
- Triazolam

Nonbenzodiazepine sedative-hypnotics

- Zolpidem
- Zaleplon
- Eszopiclone

Barbiturate

- Amobarbital
- Aprobarbital
- Butabarbital
- Pentobarbital
- Phenobarbital
- Secobarbital

Melatonin receptor agonist

- Ramelteon

Chloral hydrate Antihistamines

- Diphenhydramine
- Doxylamine

Introduction

Hypnotics often are referred to as sleeping pills, sedative medications, soporifics, and sedative-hypnotics and are used to treat insomnia. This class of drugs causes drowsiness and facilitates the initiation and maintenance of sleep. The observed pharmacological effects of most drugs in this class usually are dose related. Small doses cause sedation, larger doses cause hypnosis (sleep), and still larger doses may bring about surgical anesthesia. Drugs used as hypnotics often are sedative and anxiolytic (depending on the dose), but not all anxiolytic drugs cause sedation. See Chapter 22 for more information concerning sedative/anxiolytic use of the benzodiazepines. This chapter will emphasize the concepts important in sleep and wakefulness, then present current drugs used to initiate and maintain sleep.

Clinical situations commonly are encountered that require the use of hypnotics. Insomnia can be classified as primary (pathogenesis unknown) or secondary (from other causes). Secondary insomnia is more common and can be the result of situational stress, lifestyle habits, drugs, and psychiatric or medical disorders (1). There are effective nonpharmacological treatments for insomnia; however, a need remains to use hypnotics on both a

short-term and a long-term basis to facilitate sleep (2). The drugs currently used as hypnotics are effective, but there is ample need for newer and safer hypnotics. The introduction of supposedly a newer yet safer and more effective hypnotic drug has always been greeted with optimism, such as the piperidinedione thalidomide (3). Thalidomide was proposed to be a substitute for the barbiturates in the 1950s. Similar to most other drugs used as hypnotics or sedatives, however, only after its introduction and extensive clinical use did its limitations become better understood. The ideal hypnotic should 1) cause a transient decrease in the level of consciousness for the purpose of sleep without lingering effects (sleep induction and sleep maintenance), 2) have no potential for decreasing or arresting respirations (even at relatively high doses), and 3) produce no abuse, addiction, tolerance or dependence (4). A search for newer and better hypnotics continues.

Physiology of Sleep

Sleep Cycle

At the start of the 20th century, sleep was considered to be a passive process. During the late 1920s and 1930s, it was possible to monitor human electrical brain activity using the electroencephalogram (EEG). Using the EEG, it was established that there occurred a passive nature of sleep that alternated with wakeful activity (5). This was followed by the discovery by Moruzzi and Magoun of the ascending reticular activating system and its relationship to the EEG (6). This discovery provided the basis for the modern theories of sleep and was validated by finding that sleeping animals could be awakened through stimulation of electrodes implanted in the midbrain reticular formation. Sleep is studied using related techniques that permit electronic monitoring of the head and neck muscles (electromyogram) and eye movements (electro-oculogram). From these and related studies, three states have been defined: 1) wakefulness, 2) slow-wave sleep (nonrapid eye movement [NREM] sleep), and 3) paradoxic sleep (PS; rapid eye movement [REM] sleep). Wakefulness is characterized by low-voltage fast activity of the EEG, high muscle activity, and numerous REMs, indicating intensive interaction with the environment.

The two states of sleep, NREM and REM, have been characterized primarily using EEG. The NREM sleep has been subdivided by Dement and Kleitman into four stages, which are precisely defined (although somewhat arbitrarily) using the EEG (5). Stages 1 through 4 follow a sleep continuum, with the ability to arouse an individual

being lowest in stage 1 and highest in stage 4 sleep. When sleep overtakes wakefulness, the transition is gradual; indeed, not one single measure is reliable all of the time.

Clinical Significance

The pharmacotherapy of insomnia has improved dramatically, and the recent development of novel agents has continued to grow thanks to the drug discovery process.

Older medications, such as the barbiturates, are used as sedative-hypnotics, but toxicity limits their widespread use. For example, they can cause significant central nervous system (CNS) depression, physical dependence, and tolerance. Additionally, they are potent inducers of liver enzymes, which can lead to clinically significant drug interactions when these medications are administered with other drugs extensively metabolized by the liver.

The benzodiazepines are much safer for the treatment of insomnia and are commonly used for this purpose. Within the benzodiazepine class, drug discovery has resulted in medications with improved pharmacokinetic profiles for the treatment of insomnia. For example, the newer triazolobenzodiazepines posses a much shorter elimination half-life, and this feature can be used clinically to improve sleep while at the same time inducing less daytime sedation.

The nonbenzodiazepine agents also are effective and, thus far, appear to be even safer than the benzodiazepines. The three medications belonging to this class are known as the “Z” drugs and are zolpidem, zopiclone (i.e., eszopiclone), and zaleplon. With these drugs, the basic sciences have provided clinicians with medications that are both safe and effective.

The most recent addition to the armamentarium is the melatonin receptor agonist ramelteon. Molecular modifications to melatonin resulted in this potent and selective melatonin receptor agonist. This medication is very unique in that it does not appear to posses any abuse liability and is not a controlled substance like

most other sedative-hypnotics. Also, it does not appear to interfere with cognitive function or memory.

The drug discovery process and an understanding of structure–activity relationships has taken us from very toxic medications that were dangerous at high doses and caused physical dependence (i.e., barbiturates) to medications that are safe and apparently free from any abuse liability (i.e., ramelteon). These newer medications, brought to us by basic science techniques, will improve the quality of life for many who suffer from insomnia.

Christian Teter Pharm.D.
Assistant Professor, Northeastern University, Department of Pharmacy Practice, Bouvé College of Health Sciences

The simplest pattern of sleep is that associated with a normal young adult. The normal adult enters sleep through NREM sleep. After approximately 90 minutes of NREM sleep, the first REM sleep occurs, with a mean duration of approximately 20 minutes. Thereafter, NREM and REM sleep alternate cyclically through the night, with the average length of the NREM-REM sleep cycle being approximately 90 to 120 minutes. REM sleep tends to be greatest during the last third of the night. Therefore, a normal young adult displays a sleep pattern of 75 to 80% NREM and 20 to 25% REM sleep. The length of nocturnal sleep is dependent on a number of factors, of which voluntary control is the most significant. Other important factors are genetic determinants and processes associated with circadian rhythms. As sleep is extended, the amount of REM sleep is increased.

A number of factors modify sleep stage distribution: age, previous sleep history, drug ingestion, circadian rhythms, temperature, and pathology. Only the first four factors will be discussed in this chapter.

Age

Age related differences are seen in infants. The cyclic alteration of NREM-REM sleep at birth has a period of 50 to 60 minutes versus 90 minutes in adults. Infants gradually develop normal nocturnal slow-wave sleep after 2 to 6 months of life. Slow-wave sleep becomes maximal in young children and decreases markedly with age. Slow-wave sleep may no longer be present by 60 years of age, but this is more common in men than in women. The interindividual variability in the elderly is greatly increased, and the generalizations made for young adults concerning “normal” sleep are no longer applicable.

Previous Sleep History and Drug Ingestion

Previous sleep history and the effects of drug ingestion on sleep history are important when comparing hypnotics. An individual experiencing sleep loss on one or more nights will show a sleep pattern of increased slow-wave sleep during the first recovery night, with REM sleep showing a rebound on the second or subsequent nights. When an individual becomes deprived of REM sleep by being awakened every time the electro-oculogram and EEG indicated that dreaming has begun, the individual becomes selectively deprived of REM sleep, and a pressure for REM sleep builds. A preferential rebound of REM sleep will occur. The cyclic patterns of sleep states and sleep stages can be affected by many common drugs, including the hypnotics. The ability of drugs to differentially affect one sleep stage over another can, on withdrawal, produce rebound effects leading to exacerbation of the sleep disorder, comparable to deprivation of REM sleep.

Circadian Rhythms

The importance of the circadian phase at which sleep occurs and its effect on the distribution of sleep stages has become of interest because of the current popularity of melatonin. It has been shown that with individuals sleeping in situations free of all time cues, circadian phase can influence the timing of sleep onset and length of sleep. If sleep onset is delayed until the peak REM phase of circadian rhythm (early morning), REM sleep can predominate and even may occur at the onset of sleep. This abnormal sleep-onset pattern or phase shift can occur because of a work-shift change or a change resulting from jet travel across a number of time zones.

As a brief summary, the normal adult human enters sleep through NREM sleep. After approximately 80 minutes or longer, the individual starts REM sleep after which NREM-REM sleep alternates through the remainder of the sleep period. Any situation that causes an alteration of this normal sleep cycle leads to compensation of REM or NREM sleep in subsequent nights.

Sleep Factors

The involvement of many autonomic, physiologic, and biochemical changes are associated with wakefulness, NREM sleep, and REM sleep. The relationship of cause and effect in relation to these systems is still somewhat controversial and a rapidly changing area of research. Several brain regions that regulate sleep have now been identified; however, the specific contribution on any one region to sleep is still controversial (7). The roles of the major systems are important to be familiar with in relation to sleep. This not only helps one to understand the mechanism by which hypnotics work but also provides some understanding of why unrelated drugs, such as neuroleptics, antihistamines, antidepressants, and antimanic drugs, occasionally are used as hypnotics to facilitate sleep.

Neurotransmitter/Neuromodulator

Every neurotransmitter has, at one time or another, been implicated in sleep or wakefulness. The assumption is that if a neurotransmitter is involved in wakefulness, it may be involved in initiation or maintenance of REM sleep. In contrast, an antagonist of the neurotransmitter would be anticipated to initiate or maintain NREM sleep. Studies of this type rarely are unambiguous because of the integration of the neural pathways. Some of the evidence for the involvement of these neurotransmitters in sleep or wakefulness is presented; however, the reader should consult Kales (7) for details.

Catecholamines

It would be anticipated that catecholamines (originating from the locus ceruleus) would be involved in wakefulness and REM sleep (8). Initial experiments with reserpine suggested that a decrease in catecholamines involved in neurotransmission caused a decrease in REM sleep. Contradictory and inconsistent findings with other compounds that modulate catecholamine synthesis, however, gave ambiguous results concerning the relationship between monoamine levels and stages of sleep. The only consistent finding is that an intact catecholamine transmission system is needed for the REM component of sleep.

The catecholaminergic effects on sleep and wakefulness can be broken down in the following manner:

a. Drugs interfering with catecholaminergic transmission via the depletion or inhibition of the synthesis of the catecholamines.

b. α_1-and α_2-agonists and antagonists and β-adrenergic agonists and antagonists.

c. Dopamine 1 and 2 agonists and antagonists.

Studies support the hypothesis that norepinephrine neurons aid in regulating wakefulness and REM sleep. For example, an α_1-agonist (e.g., methoxamine) decreased REM sleep, whereas an α_1-antagonist increased REM sleep. Clonidine, primarily an α_2-agonist is associated with a sleep induction but inhibits deep NREM (stages 3 and 4) sleep. Involvement of the β-adrenergic receptors for regulation of sleep is ambiguous. Propranolol in humans often is associated with the side effect of insomnia that can be reversed by β-agonists and has been interpreted as suggesting these receptors are involved in regulation of REM sleep. It has been proposed that dopamine has a facilitative and active role in the sleep-wakefulness cycle. Waking appears to be a state maintained by D2 activation, whereas decreased D2 activity appears to promote sleep. The D1 receptor may be important in the regulation of REM sleep, but it is not important in initiation or timing of REM sleep.

Serotonin

Initially, serotonin was thought to be a sleep-promoting neurotransmitter or an “antiwaking” agent (9). The recognition of the numerous 5-HT receptor subtypes, often with unique anatomical distribution, has required that a more complex role for serotonin be developed. Current studies indicate that conditions for sleep are now met when the serotoninergic system becomes inactive. The serotonin agonists for the 5-HT_1 (via the 5-HT_{1A} and 5-HT_{1B} types at the hypothalamic level), 5-HT_2, and 5-HT_3 receptors cause wakefulness and inhibit sleep. Blockade of the 5-HT_2 receptors (e.g., the 5-HT_2 antagonist ritanserin) results in increased NREM sleep and inhibition of REM sleep. It has been proposed that the 5-HT_{1A} and 5- HT_2 may be involved in sleep by regulation of sleep-promoting substances in the hypothalamus. With the development of newer and more selective ligands for use in studying the numerous serotonin receptor subtypes (see also Chapter 14), a better understanding of the role of serotonin in sleep will evolve.

Histamine

It is proposed that histamine may have an involvement in wakefulness and REM sleep (10). Histamine-related

functions in the CNS are regulated at postsynaptic sites by both the H_1 and H_2 receptors, whereas

the H_3 receptors appear to be a presynaptic autoreceptor regulating the synthesis and release of histamine. These three receptors differ in molecular structure, distribution in the CNS, and physiologic responses. The H_1 receptor agonists and the H_3 receptor antagonists increase wakefulness, whereas the H_1 receptor antagonists (e.g., diphenhydramine) and H_3 receptor agonists have the opposite effect. The H_2 receptor agonists and antagonists have not been shown to have any effect on wakefulness or sleep parameters. The H_1 receptor agonists do not modify sleep induction or maintenance, although it does increase stage 4 NREM sleep and sleep latency. In controlled sleep laboratory studies, the H_1 receptor antagonists (e.g., diphenhydramine), when given before bedtime to normal subjects, have little effect on wakefulness. In equal doses given during the day, however, they increase drowsiness, with an increased tendency to sleep and impair performance.

Acetylcholine

The cholinergic system was the first neurotransmitter system shown to have a role in wakefulness and initiation of REM sleep (11). Because of the poor penetration of the cholinergic drugs into the CNS, the role of this system in sleep has relied on animal studies using microinjection into the brain, primarily in the area of the dorsal pontine tegmentum. Acetylcholine, cholinergic agonists (e.g., arecoline or bethanechol), and cholinesterase inhibitors are effective in the initiation of REM sleep from NREM sleep after microinjection. Conversely, administration of anticholinergic drugs (e.g., atropine or scopolamine) hinders the transition to REM sleep. Increase in the rate of discharge of these cholinergic cells (that activate the thalamus, cerebral cortex, and hippocampus) during REM sleep parallel the same pattern seen with arousal and alertness.

Adenosine

Adenosine acts as neurotransmitter in the mammalian nervous system (12). Because of the highly polar nature of adenosine, it also has to be injected into the brain (intracerebroventricular and preoptic). The stimulation of the adenosine A1 receptors with adenosine causes a hypnotic effect. It has been proposed that the hypnotic effect occurs via suppressing calcium efflux into presynaptic nerve terminals and decreasing the amount of neurotransmitters released into the synapse in brain regions critical for sleep. This apparent induction and maintenance of sleep is associated with increases in both NREM and REM sleep. Consistent with the above proposal is that blocking of the central adenosine receptors with methylxanthines (e.g., caffeine or theophylline) is associated with wakefulness and a reduction in total sleep time. Studies also suggest that some of the actions of the benzodiazepines may be related to their ability to inhibit adenosine uptake, leading to downregulation of central adenosine receptors.

g-Aminobutyric acid

γ-Aminobutyric acid (GABA) probably represents the most important inhibitory transmitter of the mammalian CNS (also see Chapter 15) (13). Both types of GABAergic inhibition (pre- and postsynaptic) use the same $GABA_A$ receptor subtype, which acts by regulation of the chloride channel of the neuronal membrane. A second GABA receptor type, $GABA_B$, that is a G protein–coupled receptor is not considered to be important in understanding the mechanism of hypnotics. Activation of a $GABA_A$ receptor by an agonist increases the inhibitory synaptic response of central neurons to GABA through hyperpolarization. Because many, if not all, central neurons receive some GABAergic input, this leads to a mechanism by which CNS activity can be depressed. For example, if the GABAergic interneurons are activated by an agonist that inhibits the monoaminergic structures of the brainstem, hypnotic activity will be observed. The specific neuronal structures in different brain regions affected by $GABA_A$ agonist continues to be better defined.

Neurohumoral Modulators

Sleep and circadian rhythmicity, both of which are controlled by the CNS, can exhibit significant effects on hormonal release. Many of the hypophyseal hormones follow a circadian rhythm; however, both growth hormone (GH) and prolactin (PRL) appear to be the most closely linked with sleep. This suggests that these hormones may affect sleep and contribute to the maintenance and quality of sleep.

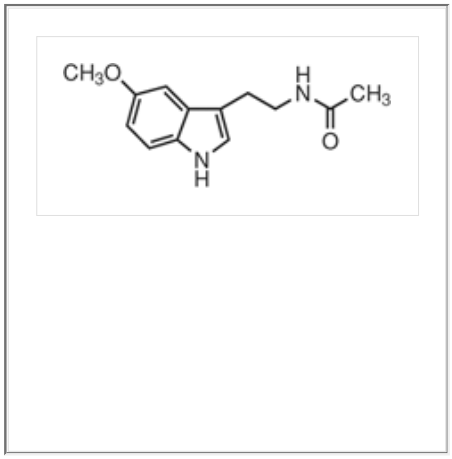
Growth hormone and prolactin

In normal adult subjects, the plasma level of GH remains very stable at a low level; however, a secretory pulse of GH occurs in association with the first phase of NREM sleep (14). Most of the GH pulse secretions occur during NREM sleep, and a good correlation has been observed between the amount of GH secreted and the

duration of NREM sleep. Studies in healthy elderly men (age, 67–84 years) have observed that a decreased secretion of GH in the elderly parallels the decrease in NREM sleep and may be related to the decrease in sleep observed in the elderly.

Regardless of the time of day, sleep onset has a stimulatory effect on PRL release (14). Maximal effect is observed, however, when sleep and circadian effects are superimposed. Because of pulse-like secretions of PRL, there seems to be a relationship between the low PRL levels and initiation of REM sleep or nocturnal awakenings, especially in the elderly.

Melatonin



Melatonin, at times referred to as the “hormone of darkness,” normally is secreted during the night (15,16,17). It is synthesized in the pineal gland, and its secretion is controlled by the suprachiasmatic nucleus, following an endogenous circadian rhythm. Studies indicate that melatonin may

have effects on circadian rhythm and sleep processes. The presence of a pharmacologically specific receptor for melatonin in which the molecular structure is known are referred to as MT_1, MT_2, and MT_3 receptors. The MT_1 and MT_2 receptors are high-affinity G protein–coupled receptors, whereas MT_3 is a form of quinone reductase. The MT_1 receptor appears to be primarily involved in initiating sleep, whereas the MT_2 receptor appears to mediate melatonins effect in the eye, circadian rhythm, and vascular effects (18). The importance of MT_3, although widely distributed in different tissues, is currently unknown. The normal physiological concentration of melatonin observed at night is approximately 100 to 200 pg/mL, and oral doses of 0.1 to 0.3 mg of melatonin are adequate to obtain these concentrations even though melatonin frequently is given at doses of 1 to 10 mg to obtain “supraphysiological” levels. These higher doses may be the reason for some of the side effects not currently associated with the melatonin receptors. Melatonin is most effective in young individuals and appears to be less effective in elderly individuals (possibly because of a decreased number of receptors). Melatonin causes a phase shift of approximately 1 hour per day. This means that the use of melatonin in the morning can delay the onset of evening sleepiness, whereas melatonin taken in the evening has been associated with faster onset of sleep and increased total sleep time. Melatonin is sold as a food supplement in the United States, but it has become popular for use as a hypnotic and for alleviating jet lag (a flight across five or more time zones) and helping to resynchronize individuals who have difficulty adapting to night-shift work.

CNS peptides

Several CNS peptides have been associated with regulation of sleep and wakefulness. Currently, the hypocretins (orexins) are of greatest interest (19,20). They consist of two neuropeptides, Hcrt-1 and Hcrt-2, that are synthesized by neurons in the posterolateral hypothalamus. Initially, these peptides were shown to be involved in the regulation of arousal, motor tone, locomotion, regulation of appetite, and neuroendocrine and autonomic functions. Recent research has indicated that these peptides also are involved in the regulation of sleep and wakefulness, especially in relation to narcolepsy. It has been observed that approximately 80% of patients with narcolepsy had low or undetectable levels of Hcrt-1, suggesting that a deficiency or abnormality in hypocretin neurotransmission may play a pivotal role in this disease. The Hcrt-1 is a 33-amino-acid, carboxy-amidated peptide with an N-terminal pyroglutamyl residue and two intrachain disulfide bonds, whereas the Hcrt-2 is a C-terminally amidated, linear peptide of 28 amino acids. The hypocretins bind at two G protein–coupled receptors with high affinity and have excitatory effects on the neurons. It has been proposed that

hypocretin receptor antagonists may be useful in the treatment of insomnia, although no drug is currently in clinical studies based on this concept.

Testing and Development of New Hypnotics

As presented in the earlier section, a number of potential receptors can be identified that are associated with causing sleep and have the potential to be developed into a hypnotic. Initially, animal tests have been used for identifying new hypnotic drugs. In vitro receptor binding studies can then be used for screening of drugs that bind with improved specificity. The animal assays basically measure varying levels of CNS depression instead of sleep. The assumption is that CNS depression will relate to clinical hypnosis, although exceptions commonly occur. Common assays in mice or rats include an increase in sleeping time, a loss of righting reflex, rotorod impairment, decreased activity in an activity cage, or potentiation of other CNS depressants. The observed pharmacological effects of many drugs in this class usually are dose related such that small doses cause sedation, larger doses cause hypnosis, and still larger doses may bring about surgical anesthesia.

Larger animals, including rats, cats, and monkeys, are studied in a sleep laboratory. In these studies, electrophysiologic and electroencephalographic measurements are obtained and often are helpful in gaining information about the site of action of CNS depressants as well as about induced sleep patterns. Drug discrimination studies also have been useful in differentiating sites of action of CNS depressants.

Guidelines for the clinical evaluation of hypnotic drugs have been developed by the U.S. Food and Drug Administration for specific evaluation of this class of drugs. Human sleep laboratory studies have become increasingly valuable in determining a range of efficacy and defining an optimal dose. Because sleep laboratory studies are under closely controlled conditions, they are capable of continuous electrophysiologic measurement throughout the night. This is then followed by objective measurement of pre- and postsleep results to assess effectiveness and withdrawal effects of new hypnotics. The sleep laboratory studies coupled with clinical studies based on patients' subjective estimates of efficacy provide a thorough and clinically relevant approach for developing a new hypnotic (21).

Classification of Hypnotics

Introduction to Classes of Hypnotics

The hypnotic drugs are not characterized by common structural features. Instead, a wide variety of chemical compounds have been used in clinical therapy. An arbitrary classification is as follows:

- $GABA_A$ receptor agonists
  - Benzodiazepines
  - Imidazopyridines and cyclopyrrolones
  - Pyrazolopyrimidines
  - Barbiturates

- Chloral
- Melatonin receptor agonists
- Antihistamines
- Antidepressants
- Herbal preparations

Benzodiazepines

Benzodiazepines are used as daytime anxiolytics, sleep inducers, anesthetics, anticonvulsants (also known as antiseizure agents), and muscle relaxants; they will be discussed in depth in Chapters 20 and 22. Examination of the basic pharmacodynamic properties of the benzodiazepines (defined as receptor-specific binding activity) show that the clinically useful benzodiazepines exhibit comparable sedative activity at therapeutically comparable doses (Fig. 19.1) (13). The use of a specific benzodiazepine as a hypnotic is based primarily on

pharmacokinetic properties and marketing considerations. Hypnotics are unusual in that they normally are given as a single dose. The following variables will determine how well a benzodiazepine will work as a hypnotic: 1) Is acute tolerance developed to the benzodiazepine that will diminish CNS effects before the drug is eliminated from the CNS, 2) is redistribution of the benzodiazepine from the CNS to other tissues very rapid, and 3) is there a rapid drug elimination by biotransformation and the metabolite active? The benzodiazepines that are specifically promoted as sleep inducers are listed in Table 19.1 (22); however, it is important to keep in mind that depending on the dose, any benzodiazepine may be used for its hypnotic effect.

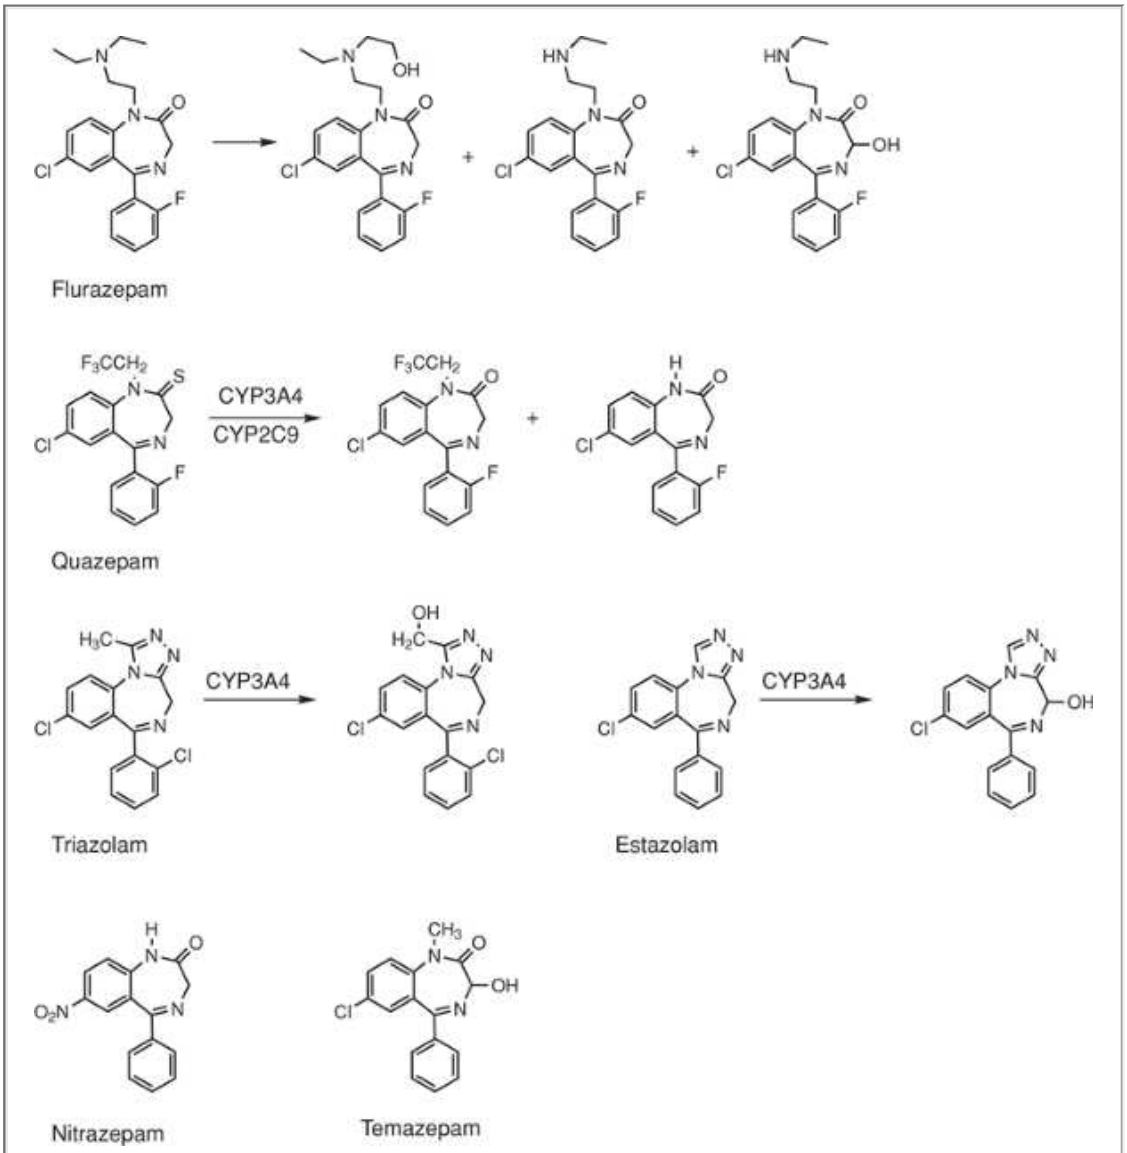


Fig. 19.1. Hypnotic benzodiazepines and their metabolites.

Mechanism of Action

The initial studies suggesting a possible involvement of the benzodiazepines with GABA provided a basis for understanding the pharmacological effects of this class of

drugs. The identification of specific, high-affinity binding sites for the benzodiazepines on the $GABA_A$ receptors was an important advance (23,24). The majority of $GABA_A$ receptors are made up of a mixture to subunit types (α_{1-6}, β_{1-3}, γ_{1-3}, θ, ε, δ, and π) with the majority of receptors composed of α, β, and γ subunits in the ratio of 1:2:1 (13). The major combinations of subunits are $\alpha_1\beta_2\gamma_2$ (~60%) and $\alpha_2\beta_3\gamma_2$ (~15–20%) of the $GABA_A$ receptors. Studies suggest that drugs interacting with the α_1 subunit receptor are involved in the modulation of

sedative, amnesic, and seizure protection, whereas drugs binding with the α_2 subunits receptors provide anxiolytic and myorelaxant properties. The current generation of benzodiazepines bind with comparable affinity at both $GABA_A$ receptor subtypes. It has been proposed that compounds specific for the α_2 subunit would be "nonsedative," whereas compounds specific for α_1 would primarily be sedative-hypnotic (13). All of the benzodiazepines affect the normal sleep stages. They increase total sleep and EEG fast activity, and they decrease nocturnal wakefulness, body movements, number of awakenings, sleep latency (the time required to fall asleep), and stages 3 and 4 sleep (NREM). On withdrawal of the drug, a gradual return to baseline values of NREM sleep returns. They also cause a mild suppression of REM sleep, especially during the first third of the night, with rapid return to baseline on withdrawal.

Table 19.1. Some Properties and Pharmacokinetics of the Benzodiazepine Sedativ

Parameters	Estazolam	Flurazepam	Quazepam	Temazepam
Trade name	Prosom	Dalmane	Doral	Ristoril
Log P (calc)a	3.3 ± 0.9	4.0 ± 0.7	4.1 ± 0.8	2.2 ± 0.6
Log D (pH 7)a	3.3	1.4	4.1	2.2

Pharmacodynamic/Pharmacokinetic Balance

The onset of sedative or hypnotic activity of intravenously administered benzodiazepines is rapid, with a range of 15 to 30 seconds (a single circulation time) to a few minutes, depending on the patient's sensitivity, pharmacological response, and size of the dose. The speed of onset of action by orally administered benzodiazepines can be very dependent on the drug dosage form. For example, when first introduced in the United States, temazepam was formulated as a hard gelatin capsule. This formulation had a very slow rate of absorption following oral administration, with peak plasma levels reaching on average of 1.8 to 4.7 hours after dosing and exhibiting little effect on sleep induction, with most of its effect on sleep maintenance. Total wake time was slightly decreased with short-term drug administration and was similar to baseline with intermediate and long-term use. Temazepam has since been reformulated as a tablet or in a soft gelatin form. These formulations are now more effective in improving sleep by decreasing the time to sleep induction and improved sleep maintenance (25). Among the oral benzodiazepines, formulations specifically indicated for the treatment of insomnia, flurazepam is absorbed most rapidly, triazolam has an intermediate rate of absorption, and temazepam is absorbed slowly and may be given 1 to 2 hours before bedtime.

Hypnotics can be used for short-term (1 week), intermediate-term (2 weeks), and long-term (≥4 weeks) periods. The vast majority of the benzodiazepines are effective for inducing and maintaining sleep when used initially or for a short term Differences are observed when they are used for longer terms. and the proper balance between pharmacodynamics and pharmacokinetic effects become very important.

The pharmacokinetic profile for each of the benzodiazepines is shown in Table 19.1. The benzodiazepines that are slowly eliminated or are metabolized to slowly eliminated active metabolites can be used as hypnotics. For example, flurazepam is primarily metabolized by

N-dealkylation and 1-hydroxylation (26), and quazepam is metabolized by oxidative loss of sulfur to oxygen and N-dealkylation (Fig. 19.1) (27). Both drugs form active metabolites that are slowly eliminated and are associated with the slow development of tolerance to the hypnotic effects. These compounds exhibit good efficacy as hypnotics with long-term use and are associated with little loss of initial effectiveness. Minimal rebound insomnia or rebound anxiety is observed when the drug is withdrawn because of the presence of the active metabolite. As a result of their slow elimination, however, the presence of active drug or active metabolite in blood and brain tissue is responsible for the residual effects of hypnotics in the daytime. These effects may consist of “hangover'' effects and oversedation, which may be so severe, especially in elderly patients, as to cause tremors, ataxia, and confusion. A good example of this is flurazepam, which undergoes N-dealkylation to N-desethylflurazepam (26). This metabolite has its own antianxiety and sedative activities and a long plasma half-life of 47 to 100 hours. Nitrazepam, a hypnotic drug used in Europe, has a moderately long elimination half-life of approximately 30 hours and may cause hangover effects as well as accumulation on repeated use. The presence of active drug or active metabolite in blood and brain tissue is responsible for the residual effects of hypnotics in the daytime.

On development of the newer triazolobenzodiazepines, such as triazolam and estazolam, with high receptor binding affinity and more rapid elimination, it was anticipated that the problem of daytime sedation would be eliminated. The duration of action for triazolam, which has an ultrashort half-life of less than 4 hours because of

biotransformation to inactive metabolites (primarily hydroxylation of the triazole methyl group) and elimination as O-glucuronides (Fig. 19.1) (28). The average oral bioavailability for triazolam was 86%; however, its mean absolute oral bioavailability is 44%. This difference is suggestive of first-pass metabolism in the gut wall by CYP3A4. Moreover, because triazolam is metabolized primarily by hepatic and intestinal CYP3A4, coadministration with grapefruit juice increased its peak plasma concentration by 30%, which was associated with increased drowsiness. Temazepam is rapidly metabolized because of direct conjugation of the 3-hydroxyl with glucuronic acid (29). Triazolam and estazolam have gained popularity as sleep inducers, especially in elderly individuals. Sleep laboratory studies, however, show that these compounds rapidly lose much of their initial effectiveness, often after only 1 week of continuous nightly administration. Estazolam is metabolized primarily by CYP3A4 to its 4-hydroxy metabolite, which is excreted in urine as its O-glucuronide (Fig. 19.1). The effectiveness of other benzodiazepines have been shown to decrease when used long term. In addition, these compounds are associated with hyperexcitability that is exhibited as daytime anxiety, tenseness, or panic and early morning insomnia (25).

Although there exist some disadvantages to using the benzodiazepines as hypnotics, they have other advantages, primarily their relative safety. Fatalities resulting from benzodiazepine overdosage alone are rare. When taken together with other drugs, intoxication probably depends largely on the type and quantity of the benzodiazepine (30). Caution must be taken when coadministering oral benzodiazepines with CYP3A4 inhibitors, particularly in patients with other causes for increases in bioavailability, such as advanced age and liver cirrhosis. In addition, benzodiazepines do not cause significant hepatic enzyme induction in humans; therefore, their tendency to interact with other drugs is less than that seen with other hypnotics. The benzodiazepines are still extensively used and are well tolerated as hypnotics. Because of the modest side effects discussed, however, the use of the benzodiazepines as hypnotics has decreased, and the use of the newer nonbenzodiazepine drugs has been increasing (1).

Nonbenzodiazepine $GABA_A$ Agonists

Historically, benzodiazepines have been the mainstay for treatment of sleeping disorders, yet they have many shortcomings. A new group of sedative-hypnotic agents similar to the benzodiazepines—zaleplon, zolpidem, and zopiclone—have been developed with affinity for the GABA receptor complex (31). This produces a more efficacious clinical profile with fewer side effects than the benzodiazepines. Zolpidem, zopiclone, and zaleplon (the “Z” drugs) are structurally distinct, nonbenzodiazepine structures (see Figs. 19.3, 19.4) (32) and are being used as short-acting sedative-hypnotics in the United States and Europe. They act at the $GABA_A$ high-affinity receptors comparable to the benzodiazepines but with different subunit specificity (Table 19.2) (31). Because of variation in binding to the GABA receptor subunits, these three compounds show subtle differences in their effect on sleep stages and as antiepileptics, anxiolytics, and amnestics.

Some generalities associated with these “Z” compounds is that they are very lipophilic, facilitating their rapid absorption and the absence of active metabolites in the plasma and brain tissue. They can be administered orally without regard to meals, but administration with a high-fat meal before sleep should be avoided because of a potential decreased rate of drug absorption and, therefore, decreased (delayed onset) efficacy in initiating sleep. These drugs are dependent on the liver for metabolism to more water-soluble ionic metabolites for their rapid renal clearance, minimizing any accumulation or residual drug effect. Their duration of action and plasma levels can be related to their individual pharmacokinetic profile, which subsequently determines the time course of drug effect and their dosages in elderly patients, in patients with hepatic insufficiency, or in patients with renal compromise. Each of these compounds has a unique pharmacokinetic profile, with different bioavailabilities, volume of distributions, and elimination half-lives (Table 19.2).

Zaleplon has a rapid elimination, so fewer residual side effects occur after taking a single dose at bedtime. By comparison, zolpidem and zopiclone have a more delayed rate of elimination, which may result with a prolonged drug effect. This can produce residual sedation and side effects but may be useful for sustained treatment of insomnia, with less waking during the night. There also are differences in potency based on plasma concentrations, suggesting that differences exist in binding to the GABA receptor complex. Although zaleplon has a much lower bioavailability (~30%), the treatment dose is similar to those of zolpidem and zopiclone (bioavailability, ~70%) because of the increased potency of zaleplon. The pharmacokinetics and pharmacodynamics of zaleplon, zolpidem, and zopiclone are significantly different from those of benzodiazepines (Table 19.2). Zaleplon may be best indicated for the delayed onset of sleep, zolpidem and zopiclone may be better indicated for maintaining a complete night's sleep. Only the patient's symptoms and response to treatment will dictate the best course of treatment.

Table 19.2. Some Properties and Pharmacokinetics of the Nonbenzodiazepine Sedative-Hypnotics

Parameters	Zolpidem	Zaleplon	Eszopiclone	Ramelteon
Trade name	Ambien	Sonata	Lunesta	Rozerem
cLog Pa	3.1 ± 0.6	0.9 ± 1.2	0.7 ± 0.8	2.6 ± 0.3

[a]Chemical Abstracts, American Chemical Society, calculated using Advanced Chemistry Development (ACD/Labs) Software V8.14 Ser Solaris (1994–2006 ACD/Labs).

Although these compounds show differences from the benzodiazepines in some pharmacological tests, with a reduced ability to cause physical dependence and minimal abuse potential, these drugs are listed as Schedule IV controlled substances.

Specific Drugs

Imidazopyridine

Zolpidem tartrate

Zolpidem exhibits a high selectivity for the α_1 subunit. Its good bioavailability of 72% and rapid onset of action of approximately 1.4 hours following oral absorption can be attributed to its weak base (pK_a = 6.2) and high lipophilicity (mlog P = 3.85). Its pharmacokinetic profile is characterized by rapid absorption from the gastrointestinal tract and a short elimination half-life because of rapid oxidative metabolism to inactive carboxylic acid metabolites (Fig. 19.2). Zolpidem undergoes CYP3A4 (major), CYP2DG, and CYP2D6 hydroxylation of the aryl methyl groups, followed by further oxidation by aldehyde

dehydrogenase to the ionic carboxylic acids, which are readily eliminated in the urine (33). Zolpidem demonstrates linear (dose-proportional) kinetics in the dose range of 5 to 20 mg. Although protein binding was 90%, no drug accumulation was observed following nightly dosing with 20-mg zolpidem tartrate tablets for 2 weeks. Food can prolong the time to peak concentration from 1.4 to 2.2 hours without affecting the half-life. These results suggest that for faster sleep onset, zolpidem should not be administered with or immediately after a meal. In the elderly, the dose should be 5 mg, because the elimination half-life is increased by 50% (from ~2 to ~3 hours). No accumulation was observed in elderly subjects following nightly oral dosing of 10 mg for 1 week. In patients with hepatic insufficiency, the plasma concentration doubled with an increase in the elimination half-life from approximately 2 to approximately 10 hours (range, 4–25 hours). Therefore, dosing should be modified in patients with hepatic insufficiency. No dosage adjustment should be necessary in patients with compromised renal function. Zolpidem is not hemodialyzable, but it does cross the placenta and into breast milk. Because of its longer elimination half-life (when compared to zaleplon), it may be preferred when sleep maintenance is a primary concern.

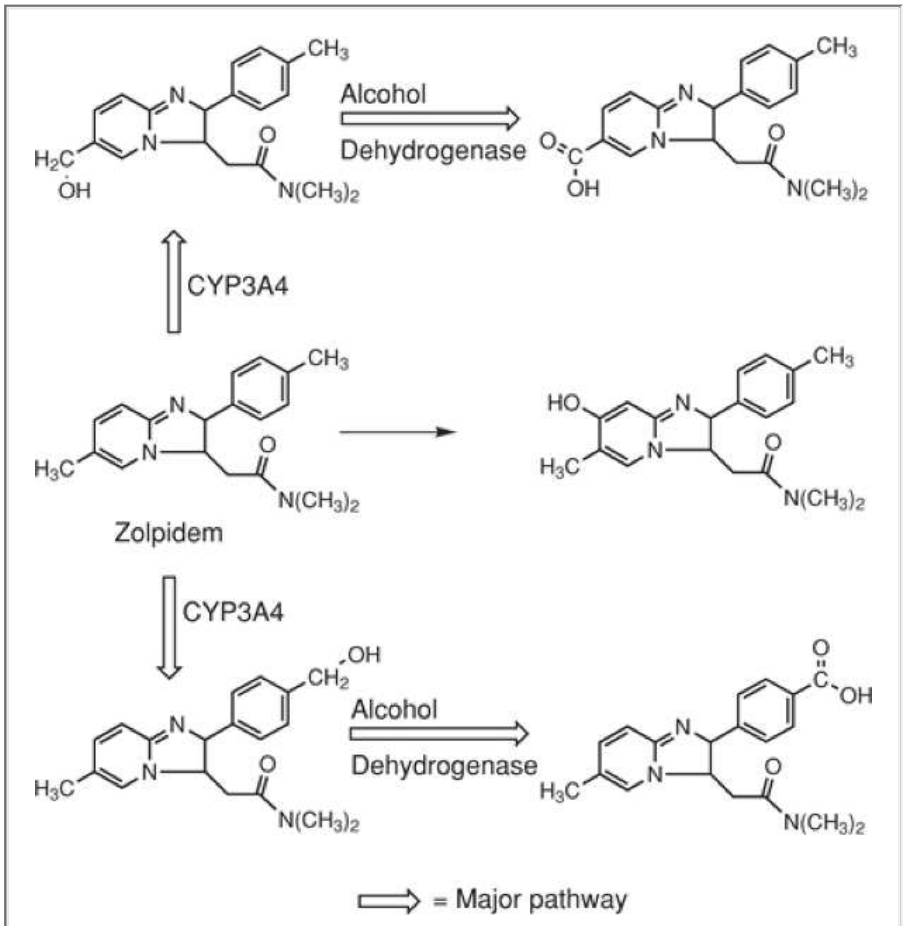

Fig. 19.2. Zolpidem and metabolites.

Pyrazolopyrimidine

Zaleplon

Zaleplon displays a unique binding profile with $GABA_A$ that is distinct from the benzodiazepines but similar to that of zolpidem (31). Because of it greater potency for $GABA_A$, the starting dose for zaleplon is comparable to that of zolpidem. It is rapidly absorbed, with a log P of 1.23, although only 30% of the dose is bioavailable because of rapid first-pass metabolism via liver cytosolic aldehyde oxidase/xanthine oxidase (molybdenum hydroxylases) to its major ring oxidation product, 5-oxo-zaleplon metabolite (Fig. 19.3) (34). The minor metabolism pathways include N-dealkylation from microsomal oxidation via CYP3A4 to N-desethyl-zaleplon and N-desethyl-5-oxo-zaleplon. It is rapidly metabolized by the liver, with an elimination half-life of approximately 1 hour. The oxidative metabolites are inactive, conjugated with glucuronic acid, and eliminated in the urine. Inhibitors of CYP3A4 and aldehyde oxidase can increase the plasma concentration of zaleplon significantly, although this usually does not require dosage modification. Zaleplon does not accumulate with once-daily administration and displays linear pharmacokinetics in the therapeutic range. The elimination half-life of zaleplon is increased in patients with hepatic insufficiency, requiring an adjustment in dosage. High-fat meals increase the time to peak concentration and decrease the plasma concentration without affecting the half-life. These results suggest that for faster sleep onset, zaleplon should not be administered either with or immediately after a meal, which increases the time to reach peak plasma concentrations. In short-term studies (2–5 weeks), zaleplon has been shown to improve sleep quality with minimal adverse effects and no significant rebound insomnia on stopping the drug. Because of its short elimination half-life, zaleplon is quite good at getting people to sleep but is not as good at keeping people asleep. Unlike with zolpidem and eszopiclone, it has been proposed that if the patient awakens in the middle of the night (with ≥4 hours of sleep time remaining), another dose of zaleplon can be taken (35).

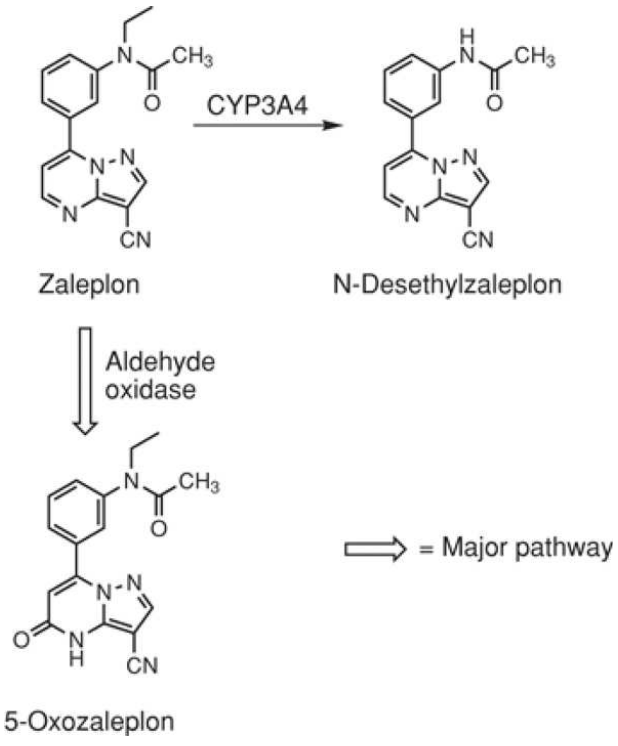

Fig. 19.3. Zaleplon and metabolites.

Cyclopyrrolone

Eszopiclone

Zoplicone was originally marketed as a racemic mixture; however, because the sedative activity is primarily associated with the S-isomer, only the S-isomer is currently marketed in the United States (as esozoplicone) (36). It is soluble in dilute mineral acids. Unlike zolpidem and zaleplon, eszoplicone is not as specific for the α_1 subunit of $GABA_A$, but it binds broadly, like the benzodiazepines (Table 19.2). Its pharmacological and pharmacodynamic activities, however, are more closely related to those of the nonbenzodiazepines (32,37). It is rapidly absorbed, with an oral bioavailability of approximately 80%, reaching peak concentrations in 1 h and having a relatively long elimination half-life of approximately 6 hours (Table 19.2). Eszopliclone is primarily metabolized to (S)-zoplicone N-oxide and (S)-N-desmethylzoplicone by the CYP3A4 (Fig. 19.4). (S)-N-desmethylzopiclone binds to GABA receptors with substantially lower potency than eszopiclone, and (S)-zopiclone-N-oxide shows no significant binding to this receptor. It does not accumulate with once-daily administration, and it exhibits linear (dose-proportional) pharmacokinetics over the range of 1 to 6 mg. Eszopiclone is weakly bound to plasma protein (52–60%), suggesting that eszopiclone distribution should not be affected by drug–drug interactions caused by protein binding. Up to 75% of an oral dose of racemic zopiclone is excreted in the urine, primarily as metabolites. A similar excretion

profile would be expected for eszopiclone. Less than 10% of the orally administered eszopiclone dose is excreted in the urine as unchanged drug. After a high-fat meal, peak plasma concentrations can be delayed by approximately 1 hour without affecting its half-life. The effects of eszoplicone on sleep onset may be reduced if it is taken either with or immediately after a high-fat/heavy meal. In elderly subjects, the elimination half-life was prolonged to approximately 5 to 9 hours. Therefore, in elderly patients, the starting dose should be decreased to 1 mg, and the dose should not exceed 2 mg. No dose adjustment is necessary in patients with renal impairment, because less than 10% of the orally administered eszopiclone dose is excreted in the urine as parent drug. Although no pharmacokinetic or pharmacodynamic or drug interactions have been reported for eszopiclone, potent inhibitors of CYP3A4 could increase plasma levels of eszopiclone. Eszopiclone does not alter the clearance of drugs metabolized by common CYP450 enzymes. Potential pharmacodynamic interactions

(additive pharmacological effects) with CNS depressants such as alcohol, anticonvulsants, antihistamines, antidepressants, or other psychotropic drugs could occur. Dosage adjustment may be necessary when eszopiclone is administered with CNS depressants; concomitant use with alcohol should be avoided.

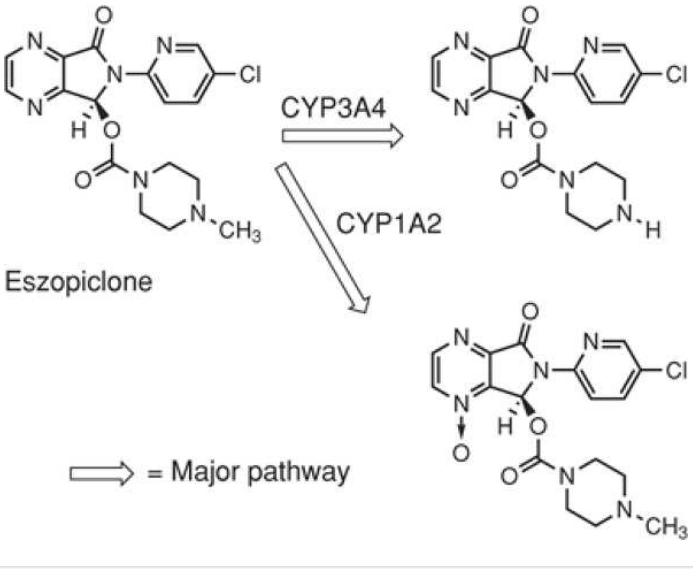

Fig. 19.4. Eszopliclone and metabolites.

The primary advantage of eszoplicone is that it has been shown to be effective in chronic insomnia (long-term treatment) in measures of sleep latency, total sleep time, and wake time after sleep onset without development of tolerance (38). Eszoplicone would appear to be most effectively used for patients who tend to awaken during the night rather than patients for whom the primary problem is initiating sleep (35).

Barbiturates

The barbiturates have a different pharmacological and binding profile from that of the benzodiazepines. They exert a depressant effect on the cerebrospinal axis and depress neuronal activity as well as skeletal muscle, smooth muscle, and cardiac muscle activity. Depending on the compound, dose, and route of administration, the barbiturates can produce different degrees of CNS depression and have found use as sedatives, hypnotics, anticonvulsants, or anesthetics.

Currently, the barbiturates get minimal use as sedatives and hypnotics (especially compared to the benzodiazepines) because of higher toxicity. This is associated with their ability to cause greater CNS depression and their ability to induce many of the liver drug-metabolizing enzymes. In addition, the barbiturates cause tolerance and, often, dependence. Even with all these disadvantages, the barbiturates continue to find occasional clinical applications as sedatives and hypnotics. Their primary use, however, is as general anesthetics (see Chapter 18) and as antiseizure drugs (see Chapter 20). Primarily because of historical convention, the general chemistry, structure–activity relationships, and metabolism of the barbiturates will be covered in this section.

Barbiturates exert their action on the central synaptic transmission process associated with $GABA_A$ (13). A paradoxical effect of barbiturates occurs in which small doses bring about hyperexcitation and agitation instead of sedation. This is because the barbiturate concentration is not sufficient to depress the reticular activating system but is able to impede the inhibitory synapses that normally are present within the cortex. The barbiturates act on the reticular activating system and on the limbic, hypothalamic, and thalamic synaptic systems (39).

Mechanism of Action

The effects of the barbiturates is marked by a decrease in functional activities in the brain. At therapeutic doses, the barbiturates enhance the GABAergic inhibitory response in a mechanism similar to that of the

benzodiazepines (i.e., by influencing conductance at the chloride channel). At higher concentrations, the barbiturates can potentiate the $GABA_A$-mediated chloride ion conductance and enhance both GABA and benzodiazepine binding. Therefore, the barbiturates and benzodiazepines display cross-tolerance, and this can be seen with the barbiturates exhibiting weak anxiolytics and muscle relaxant properties. The barbiturate binding site is different from the benzodiazepines and is believed to occur at the picrotoxin binding site on the chloride channel. These drugs affect the transport of sugars and are noted for their ability to induce liver microsomal enzymes that lead to an increased rate of biotransformation of many commonly used drugs, including the barbiturates. The biochemical effects of these drugs have been summarized elsewhere (40).

Pharmacological Effects

The effects of barbiturates on the sleep pattern are comparable to those of benzodiazepines. In short-term studies, the barbiturates are equally effective as the benzodiazepines. Again, the importance of the pharmacokinetic properties of the barbiturates determines their usefulness

as hypnotics. The barbiturates that are slowly eliminated are capable of producing hangover and persistent psychomotor impairment. For example, amobarbital was once extensively used as a hypnotic but is no longer commercially available for oral dosing as a hypnotic (although it remains available in Tuinal, a combination of amobarbital and secobarbital) because of excessive daytime sedation. Even amobarbital, however, still finds clinical application as a parenteral formulation when used in the “intracarotid amobarbital procedure” to determine lateralization of language and memory before surgery (41).

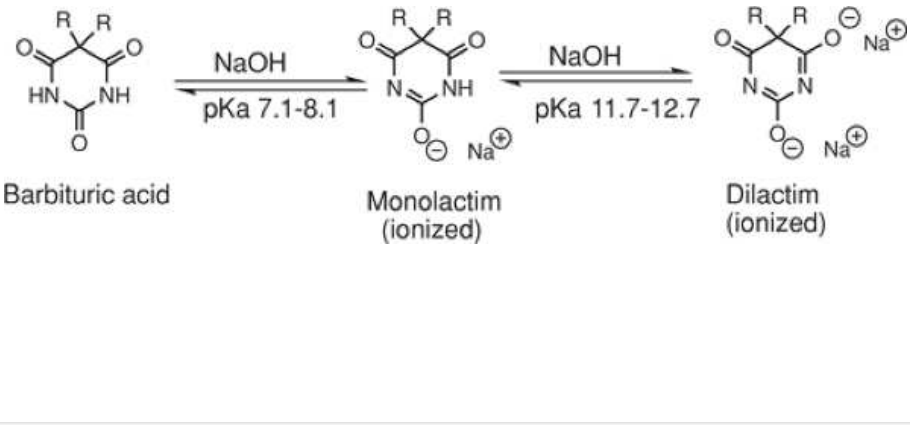

Fig. 19.5. pH-dependent tautomerization of barbiturates.

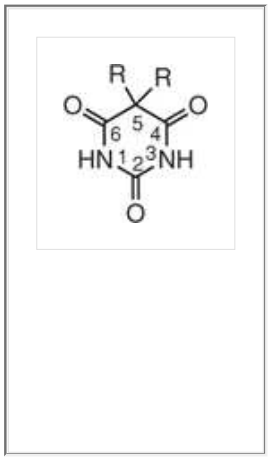
The barbiturates also cause a physical dependence different from the opioid narcotics. In an individual addicted to barbiturates, the barbiturates should not be withdrawn abruptly but, rather, tapered slowly. Sudden withdrawal of the barbiturates can precipitate extreme agitation and grand mal seizures. This can lead to a spasm of the respiratory musculature, producing impaired respiration, cyanosis, and possibly, death (42). As a rule, drug dependence is followed by tolerance, in which increasing doses are required to obtain the same pharmacological effect. Because barbiturates cause tolerance and, often, dependence, their use as a hypnotic rarely is justified.

Structure–Activity Relationships

Hundreds of barbiturates have been synthesized on a trial-and-error basis. Although many structural features required for hypnotic activity have been recorded, no clear correlation between structure and activity has emerged. In 1951, Sandberg (43) made his fundamental postulation that to possess good hypnotic activity, a barbituric acid must be a weak acid and must have a lipid/water partition coefficient between certain limits. Therefore, only the 5,5,-disubstituted barbituric acids, the 5,5,-disubstituted thiobarbituric acids, and the 1,5,5-trisubstituted barbituric acids possess acceptable hypnotic, anticonvulsant, or anesthetic activity. All other substitution patterns, such as 5-monosubstituted barbituric acids, 1,3-disubstituted barbituric acids, or 1,3,5,5-tetrasubstituted barbituric acids, are inactive or produce convulsions.



pK_A and structure of the barbiturates

The 5,5-disubstituted barbituric acid contains three lactam groups that can undergo pH dependent lactim–lactam tautomerization, as shown in Figure 19.5.

Ultraviolet spectroscopic studies with 5,5-disubstituted barbituric acids (44) indicated that in aqueous solutions, the dominant forms are either the dioxo tautomeric form (i.e., monolactam in alkaline medium) or the trioxo tautomeric form (barbituric acid structure in acid medium). The acidity of barbiturates in aqueous solution depends on the number of substituents attached to barbituric acid. The 5,5-disubstituted barbituric acids, 5,5-disubstituted thiobarbituric acids, and 1,5,5-trisubstituted barbituric acids are relatively weak acids, and salts of these barbiturates are easily formed by treatment with bases. The pK_a of 5,5-disubstituted barbituric acids ranges from 7.1 to 8.1 (44). The 5,5-disubstituted barbituric acids can undergo a second ionization, having pK_a values in the range of 11.7 to 12.7. The alkali metal salts of the barbiturates coupled with their highly lipophilic character will cause chemical incompatibility reactions (precipitation) when these compounds are mixed with acid salts of weakly basic amines.

5,5-Disubstitution

As the number of carbon atoms at the fifth carbon position increases, the lipophilic character of the substituted barbituric acids also increases (44). Branching, unsaturation, replacement of alicyclic or aromatic substituents for alkyl substituents, and introduction of halogen into the alkyl substituents all increase the lipid solubility of the barbituric acid derivatives. A limit is reached, however, because as the lipophilic character increases, the hydrophilic character decreases. Although lipophilic character determines the ability of compounds to cross the blood-brain barrier, hydrophilic character also is important, because it determines solubility in biological fluids and ensures that the compound reaches the blood-brain barrier. Introduction of polar groups into the alkyl substituent decreases lipid solubility below desirable levels. Modifications at this position by variation of the alkyl substituents were of primary importance in the development of barbiturates with short (3–4 hours) to intermediate (6–8 hours) duration of action. These barbiturates were once extensively used as sedatives and hypnotics.

Substitution on nitrogen

Substitution of one imide hydrogen by alkyl groups increases lipid solubility (44). The result is a quicker onset and a shorter duration of activity. As the size of the N-alkyl substituent increases (methyl → ethyl → propyl), the lipid solubility increases

and the hydrophilic character decreases beyond limits. Furthermore, attachment of large alkyl groups (starting with the ethyl group) to the nitrogen imparts convulsant properties to barbiturates. Attachment of alkyl substituents to both N^1 and N^3 renders the drugs nonacidic, making them inactive. Modifications at this position are of primary importance in the barbiturates used as anticonvulsants and anesthetics.

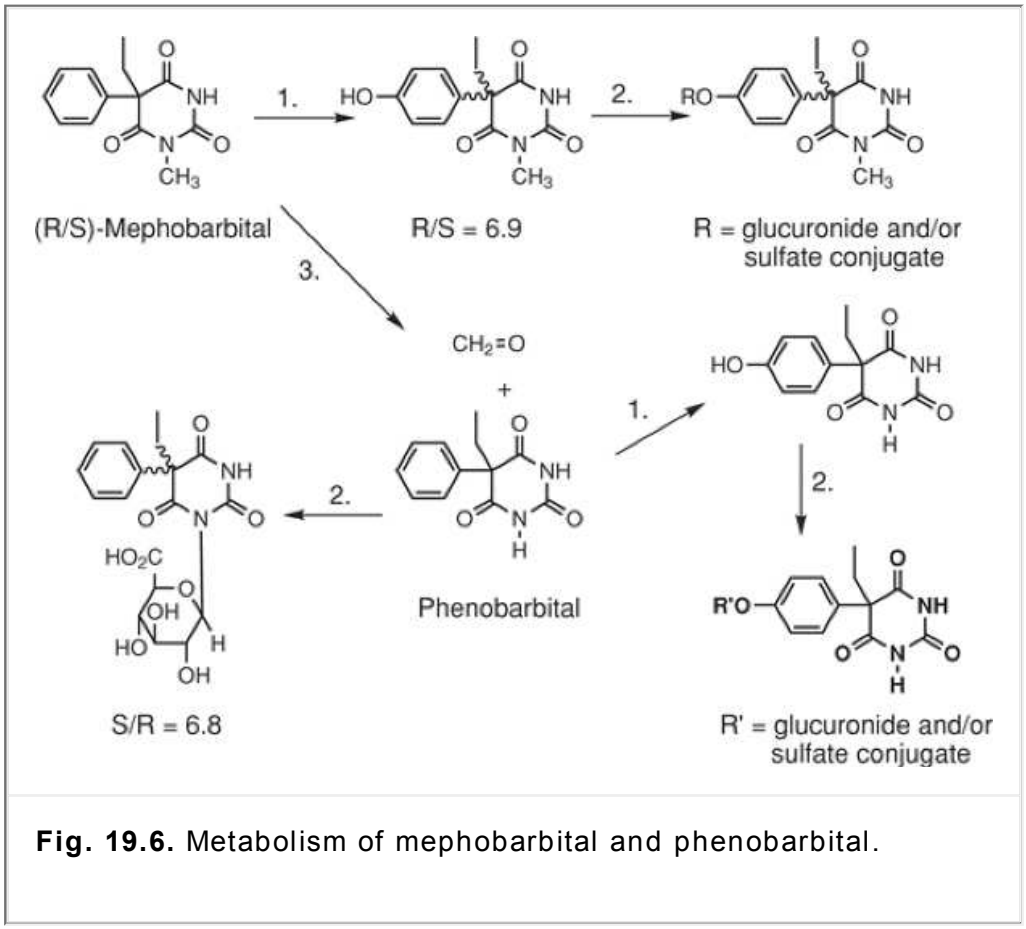


Fig. 19.6. Metabolism of mephobarbital and phenobarbital.

Modification of oxygen

Replacement of C^2 oxygen by sulfur increases lipid solubility (44). Because maximal thiobarbiturate brain levels are quickly reached, onset of activity is rapid. As a result, these drugs (i.e., thiopental) are used as intravenous anesthetics.

Metabolism

Barbiturates lose their activities through metabolic transformations and redistribution. The metabolism of the barbiturates takes place primarily in the liver, in the endoplasmic reticulum (45). After metabolism, the lipophilic character of barbiturates decreases, and this is associated with a loss in depressant activity. Although not used as a hypnotic, the metabolic pathway for mephobarbital (Fig. 19.6) is representative of the metabolic pathway for the barbiturates. The major pathways by which the activity of the barbiturates are terminated include the following:

1. Oxidation of substituents at carbon 5 occurs by CYP2C19. The initial products are alcohols or phenols that form glucuronide and sulfate conjugates. The alcohols can undergo further oxidation to ketones or carboxylic acids, but these pathways generally are of minor importance in the biodisposition of the barbiturates. A pronounced product enantioselectivity often is observed for the chiral barbiturates. The barbiturates containing a propene at the 5-position (e.g., secobarbital) have been shown to inactivate CYP450 by alkylation of the porphyrin ring of CYP450 (46).
2. Conjugation of the heterocyclic nitrogen with glucosides. This unusual conjugation pathway can be as important as oxidative metabolism in the biotransformation of 5,5-disubstituted barbiturates (phenobarbital, amobarbital, pentobarbital). In humans, a pronounced product enantioselectivity is observed for excretion of these metabolites (47).
3. Oxidative N-dealkylation at the nitrogen. The CYP450 oxidation does not proceed rapidly. Introduction of an alkyl group on a barbiturate nitrogen introduces a site of asymmetry at the 5-position. The S-isomers of the these barbiturates primarily undergo N-dealkylation, and the R-isomer primarily undergoes

oxidation at the 5 position. The dealkylated products, however, may be excreted more slowly and, therefore, accumulate in the course of therapy with N-alkylated barbiturates. For example, a definite blood level of phenobarbital has been established in the course of mephobarbital therapy (48).

4. Oxidative desulfurization of 2-thiobarbiturates takes place readily to yield the more hydrophilic barbiturates. This occurs primarily following redistribution of the thiobarbiturate anesthetics.

Clinical Applications

The currently available barbiturates are listed in Table 19.3. It must be concluded that a prescription for long-term use of the barbiturates as hypnotics rarely is indicated.

Table 19.3 Barbiturates Used Clinically as Hypnotics

Barbiturate	R_5	R_5	Hypnotic Dose (mg)	Onset (min)	Duration (hours)
Amobarbital	C_2H_5	$(CH_3)_2CHCH_2CH_2$	100–200	45–60	6–8
Aprobarbital	$CH_2=CHCH_2$	$(CH_3)_2CH$	40–160	45–60	6–8
Butabarbital	C_2H_5	$CH_3CH_2CH(CH_3)$	50–100	45–60	6–8
Pentobarbital	C_2H_5	$CH_3(CH_2)_2CH(CH_3)$	100	10–15	3–4
Phenobarbital	C_2H_5	C_6H_5	100–320	30–60	10–16
Secobarbital	$CH_2=CHCH_2$	$CH_3(CH_2)_2CH(CH_3)$	100	10–15	3–4

Chloral Derivative

During the 1950s and 1960s, chloral hydrate was widely promoted as a hypnotic (doses of 500 mg), because it did not significantly suppress REM sleep (44). Today, it still finds use as a sedative in nonoperating room procedures for pediatric patients (49). Chloral hydrate does demonstrate initial and short-term effectiveness for sleep induction and maintenance. Sleep occurs within 1 hour and lasts from 4 to 8 hours. After 2 weeks of drug administration, however, a marked decrease in effectiveness is observed. Chloral hydrate has no analgesic or tranquilizing effect, and it is devoid of adverse respiratory effects at therapeutic doses.

Chloral is a unique aldehyde because of the electron-withdrawing effect of the CCl_3 group. When chloral (an oily liquid) is treated with water or alcohol, a crystalline solid, chloral hydrate or chloral alcoholate, is formed. Chloral hydrate is stable, but as indicated in Figure 19.7, when it is dissolved in water, it is in equilibrium with the chloral form (equilibrium strongly favoring the chloral hydrate structure). The CCl_3 group is sufficiently electron-withdrawing that chloral hydrate is a weak acid (pK_a = 10.04) (44). A 10% solution of chloral hydrate in water has pH 3.5–4.4. This acidity makes it quite irritating to mucous membranes, such as in the stomach. Therefore, it is not surprising that gastrointestinal upset commonly occurs with chloral if it is undiluted or taken on an empty stomach. This led to the development of adducts or complexes, or pro-drugs, that were widely used but are now no longer available. Only chloral hydrate as a capsule, syrup, or suppository is currently available.

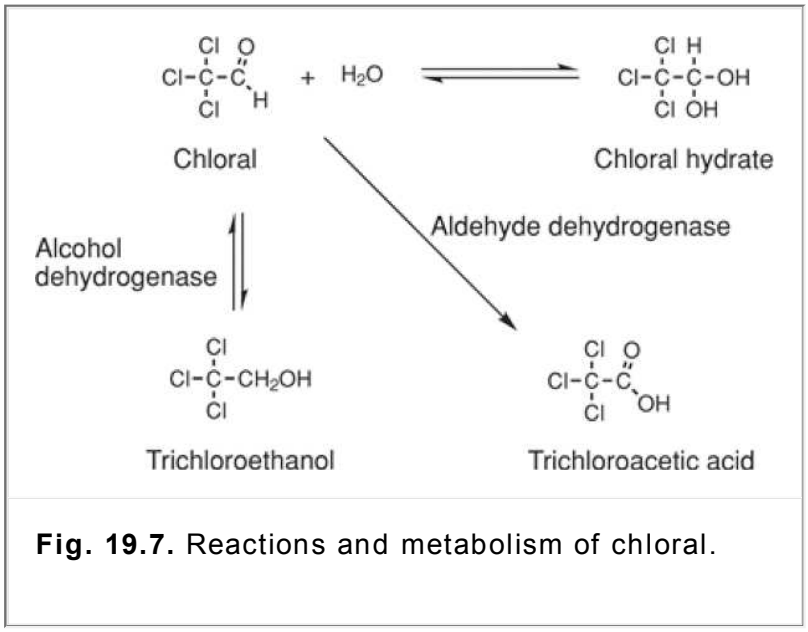

Fig. 19.7. Reactions and metabolism of chloral.

Chloral hydrate is readily absorbed from the gastrointestinal tract following oral or rectal doses of 500 mg to 2 g and is quickly reduced to trichloroethanol, its active metabolite, by alcohol dehydrogenase in the liver and erythrocytes. The plasma half-life of trichloroethanol is approximately 8 to 11 hours. Oral administration of 500 mg to 1 g of chloral hydrate usually produces sleep within 30 minutes to 1 hour; this sleep lasts for 4 to 8 hours. The metabolic transformation to trichloroethanol is so fast that it is difficult to detect appreciable chloral hydrate blood levels. It is believed that the initial hypnotic effect of chloral hydrate is exerted by the drug, but the more prolonged effect is caused by trichloroethanol. In vitro, it has been shown that trichloroethanol can exert barbiturate-like effects on the $GABA_A$ receptor channels. Trichloroethanol is metabolized by alcohol dehydrogenase oxidation to chloral and then to the inactive metabolite, trichloroacetic acid, via aldehyde dehydrogenase (Fig. 19.7), which also is extensively metabolized to acyl glucuronides via conjugation with glucuronic acid and then excreted into the urine (50). Chloral hydrate is not excreted in the urine unchanged; the quantities of metabolites excreted in the urine appear to be variable not only between different individuals but even in the same individual on different days. Trichloroethanol can cross the placenta as well as into the cerebrospinal fluid, but only clinically insignificant amounts are found in breast milk.

Other, older hypnotic drugs are believed to act at the $GABA_A$ receptor and are clinically similar to the barbiturates (e.g., glutethimide, ethychlorvynol, and methaprylon). These drugs are still available and have been reviewed in previous editions of this text. Rarely, however, is the use of these drugs indicated because of their limited effectiveness, tendency of patients to develop tolerance to their effect, depression of cognitive effects, physical dependence, ability to induce microsomal metabolism, and lethal toxicity.

Melatonin Receptor Agonist

As a neurohormone, melatonin is a poor drug because of its poor absorption, low oral bioavailability (<10%), rapid first-pass metabolism by CYP1A2 to 6-hydroxymelatonin (its primary metabolite), and ubiquitous effects. In their

search for melatonin agonists as sedatives, the melatonin molecule was reengineered by substituting the nitrogen of the indole ring with a carbon to give an indane ring bio-isostere of melatonin and by constraining the conformational flexibility of the 5-methoxyl group into a furan ring to form either an angular indeno[5,4-b]furan or a linear indeno[5,6-b]furan heterocyclic ring systems (Fig. 19.8) (51,52). Subsequent M_1 receptor testing revealed that the binding constant (K_i) for the indeno[5,4-b]furan derivative was 0.017 nM, whereas that for the indeno[5,6-b]furan derivative was 255 nM—an approximately 15,000-fold weaker affinity for the M_1 receptor. Furthermore, the S-enantiomer showed approximately 500-fold greater affinity than the R-isomer for this receptor. Molecular modeling of the indeno[5,4-b]furan derivative with the M_1 receptor showed that by fixing the orientation of the 5-methoxyl group of melatonin into an angular furan ring plays a major factor for reinforcing the binding of the nonbonding pair oxygen electrons to a histidine residue in the ligand binding pocket of the receptor. Thus, the methyl orientation of the 5-methoxyl group of melatonin (conformer B) is critical for the optimal orientation of the oxygen lone pairs for optimal ligand binding to the receptor. This

approach culminated in the discovery and approval of ramelteon (Fig. 19.8) as a very potent and very selective ligand for the MT_1 receptor, with superior in vivo activity and safety profile for use in the treatment of insomnia.

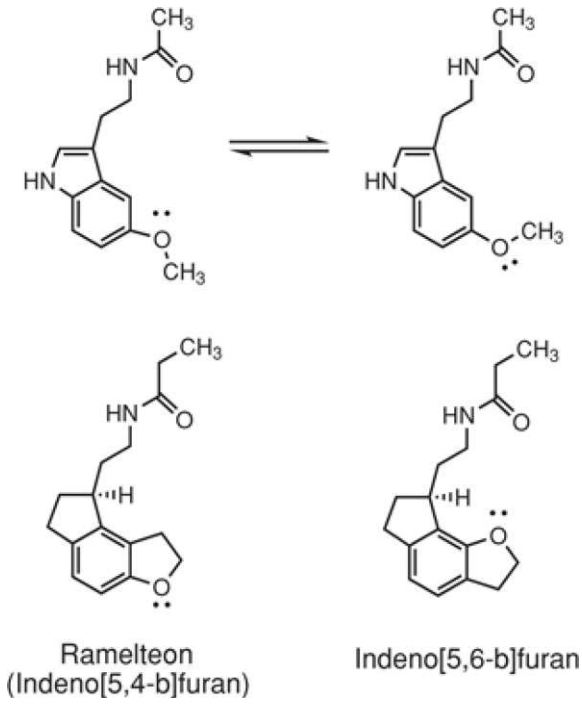

Fig. 19.8. Constrained analogues of melatonin.

Because it does not contain a basic nitrogen (nor is the amide hydrolyzed once absorbed), ramelteon binds primarily with the melatonin M_1 receptor and does not bind with other receptors associated with sleep (e.g., $GABA_A$, dopamine, or opiate receptors). Its greater selectivity for the human MT_1 receptor (K_i = 0.014 nM) versus the MT_2 receptor (K_i = 0.112 nM) is consistent with its ability to primarily shorten sleep onset rather than to readjust the circadian rhythm (51,52,53). Ramelton is rapidly absorbed and undergoes extensive first-pass metabolism with an oral bioavailability of less than 2% and an elimination half-life of approximately 2 hours (Table 19.3). Metabolism is primarily hydroxylation of the propionamide side chain to an active metabolite (Fig. 19.9). Metabolism primarily occurs with CYP1A2, with minor contributions from CYP2C and CYP3A4. The overall mean systemic exposure of the hydroxylated metabolite is 20- to 100-fold greater than ramelton but 17- to 25-fold less potent than ramelton in binding assays (54). Additional oxidative metabolism by the CYP enzymes occurs on the indane ring and the dihydrofuran ring to form a lactone ring and esterase hydrolysis of the lactone to a carboxylic acid. These metabolites are inactive.

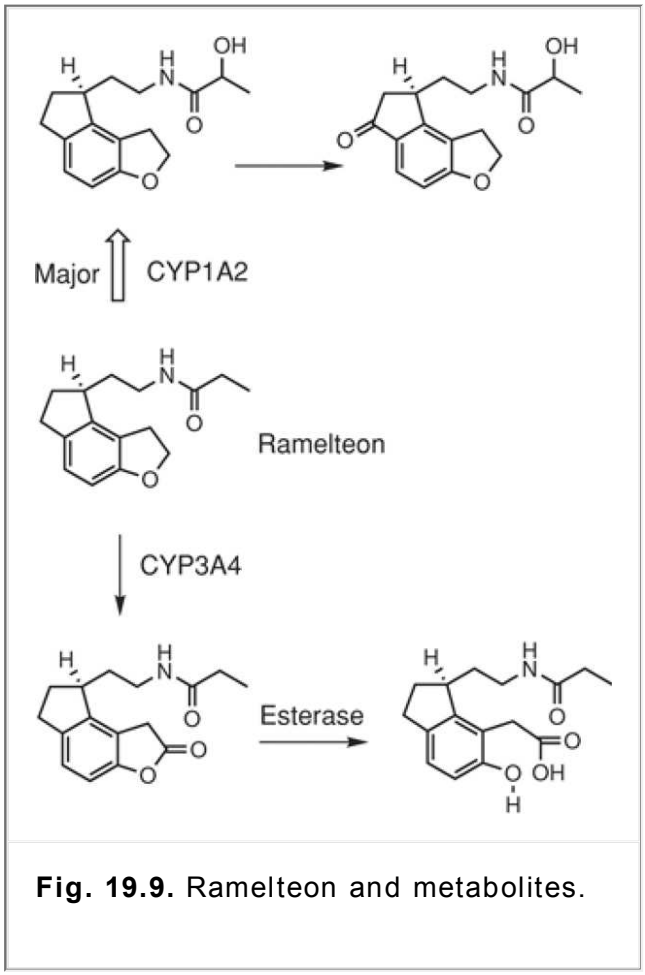

Fig. 19.9. Ramelteon and metabolites.

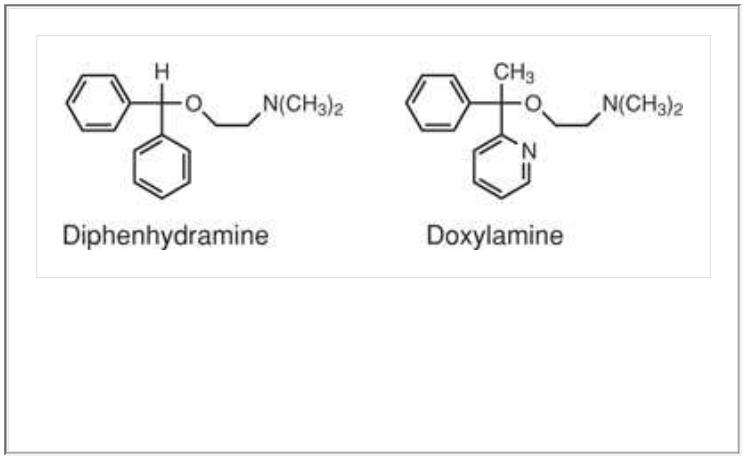
Ramelton has been shown to be effective in initiating sleep (shortening sleep latency) but not in maintaining sleep (promoting night time sleep maintenance; short half-life) (51,52). The recommended dose is 8 mg taken 30 minutes before bedtime. In contrast to the $GABA_A$ agonist drugs, ramelton does not depress cognitive function, memory, or ability to concentrate at normal doses. Ramelton does not appear to have any abuse liability, and it is not listed as a Schedule II to V controlled substance.

Antihistamines and Anticholinergics



Some of the antihistamine (H_1)-receptor antagonists that can cross the blood-brain barrier are used for their hypnotic activity. The primary antihistamines used for their sedative effect are diphenhydramine and doxylamine, which belong to the ethanolamine class of antihistamines (see Chapter 37). Both drugs are sold without prescription. Sleep laboratory-controlled studies indicate that the antihistamines (H_1-receptor

antagonists) have little effect on normal subjects when given before bedtime. The same doses given during the day, however, lead to drowsiness, increased tendency to sleep, and impaired performance (10).

Antidepressants

Antidepressants with sedation as a side effect often are used to treat insomnia. The antidepressants most frequently associated with sedation as a side effect are the tricyclics (amitryptyline, imipramine, nortriptyline, trimipramine, doxepin, amoxapine, and protriptyline), nontricyclics (maprotiline and mirtazepine), trazodone, and nefazodone (55), which are discussed in greater detail in Chapter 21. Of these drugs, trazodone, doxepin, and mirtazepine have been shown to be effective in the treatment of insomnia in patients with depression (1). The effectiveness of these drugs to treat insomnia in nondepressed patients, however, has not been proven. The mechanism by which this occurs is unknown, but most of these drugs have some activity as H_2 antagonists that may contribute to the effect (56).

Herbal Preparations

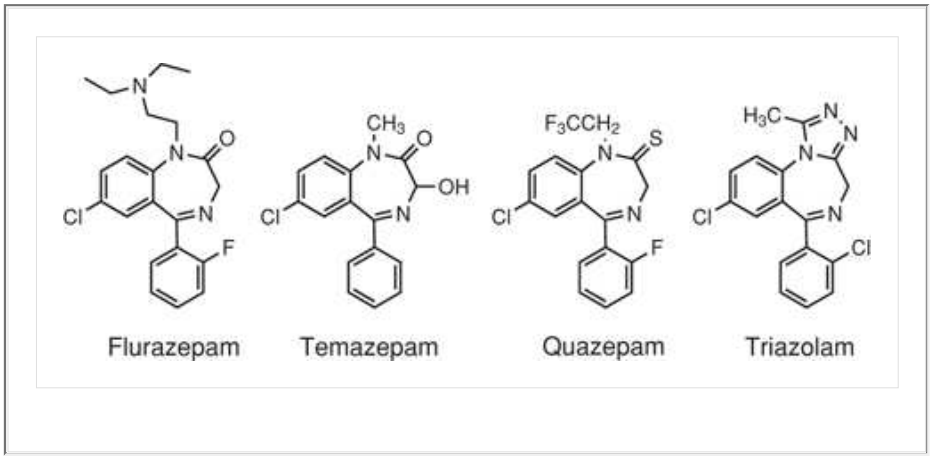
A number of herbal preparations are used as sedatives for the treatment of sleep disorders, including valerian, German camomile, kava, lavender, hops, lemon balm, and passiflora (57). Kava is no longer recommended because of potential hepatotoxicity (58). Of the other preparations, valerian has been most extensively studied for its effectiveness in treating insomnia, but the evidence verifying its sedative effect is still inconclusive (59). The fraction associated with the sedating effects of valerian is the aqueous extract, which contains no valepotriates or volatile oils. Clinical studies suggest that 450 mg of extract is an adequate dose to induce sleep (dose range, 60–900 mg), and effects may not be seen until valerian has been used for a few weeks. When taken at night, valerian does not appear to affect cognitive or motor performance the following day (i.e., comparable to placebo), and no addiction to valerian has been reported. At high doses, disturbance of cardiac function and CNS depression may occur. No data are available regarding the long-term use of valerian. One of the problems in studying valerian is similar to that observed for most herbal preparations. It is unknown exactly what active component(s) is responsible for its proposed sedative effect, and the variability between species and types of extract makes the study of valerian very difficult.

Case Study

Victoria F. Roche

S. William Zito

PQ is a 45-year-old mother of four healthy young children. Her husband died suddenly 6 months ago from a heart attack. PQ's husband was a patent lawyer and left her and the children in an adequate financial state. During the last 4 weeks, however, PQ has had trouble falling asleep, finding herself worrying about the future and staring at the ceiling as she imagines her children being injured in all sorts of weird accidents. PQ needs to drive her children to school each day, and she has taken a part-time job so that she is free each afternoon to pick her children up from school. She misses her husband terribly, and the bedroom has become a lonely place—one that she is becoming fearful to enter. Once asleep, PQ sleeps through the night and wakes rested. PQ is otherwise healthy and has no history of any physical ailments or medication use. She is diagnosed with situational insomnia stemming from the loss of her husband and the change in her responsibilities. Evaluate the following benzodiazepines, and recommend an appropriate one for the treatment of PQ's insomnia.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 20

Antiseizure Drugs

Barbara LeDuc

Drugs covered in this chapter:

Primary drugs for treatment of seizures

- Carbamzepine
- Clonazepam
- Diazepam
- Ethosuximide
- Phenytoin

Alternative drugs for treatment of seizures

- Phenobarbital
- Primidone

Adjunct drugs for treatment of seizures

- Felbamate
- Gabapentin
- Lamotrigine
- Levetiracetam
- Oxcarbazepine
- Tiagabine
- Topiramate
- Valproic acid
- Zonisamide

Introduction

As early as 2000 BC, it was recognized that some people suffered from convulsive seizures. The term “epilepsy,” based on the Greek word *epilambanein* (meaning “to seize''), was first used by Hippocrates. In the world's first scientific monograph on epilepsy, entitled *On the Sacred Disease* (~400 BC), Hippocrates disputed the myth that the cause of epilepsy is supernatural and the cure magic. He described epilepsy as a disease of the brain, which should be treated by diet. At the same time, Hippocrates provided the first classification of epilepsy, which is still used. He distinguished true (idiopathic) epilepsy (i.e., a disorder for which the cause is unknown) from symptomatic (organic) epilepsy (i.e., a disorder resulting from a physiologic abnormality, e.g., brain injury, tumor, infection, intoxication or metabolic disturbances).

Two opinions were put forward as to the causes of epilepsy. One was that epilepsy is a single disease entity, and all forms of it have a common cause. On the other hand, it was proposed that different types of epilepsy result from different chemical, anatomic, or functional disorders. At the Symposium on Evaluation of Drug Therapy in Neurologic and Sensory Disease, the general opinion was that “epilepsy is a symptom complex characterized by recurrent paroxysmal aberrations of brain functions, usually brief and self-limited'' (1).

All forms of epilepsy originate in the brain and appear to be the result of changes in neuronal activity. In turn, these changes, such as an excessive neuronal discharge, may be brought about by a disturbance of physicochemical function and electrical activity of the brain. The cause of this abnormality, however, is not clearly understood.

The most important property of the nerve cell is its excitability. It responds to excitation by generating an action potential, which may lead to repeated discharges. All normal neurons may become epileptic if subjected to excessive excitation. DeRobertis et al. (2) list two possible mechanisms for convulsive disorders: a loss of the normal inhibitory control mechanism, and a chemical supersensitivity that increases excitability of neuronal elements.

The origin of the seizures was established as early as the 19th century by Jackson (3). According to him, an intense discharge of gray matter in various regions of the brain initiates the seizures. As a result, it is only a normal reaction of the brain to initiate convulsive seizures. The discharge of excessive electrical (nervous) energy has, indeed, been substantiated by brain-wave studies made possible by electroencephalography (EEG).

Attempts to classify epileptic seizures have been only partially successful, primarily because of limited knowledge regarding the pathological processes of the brain. At the turn of the century, a classification of seizures had been published (4), and even more attempts appeared during the 1950s and 1960s. (5,6,7,8,9). In 1981, the Commission on Classification and Terminology of the International League Against Epilepsy put forward a new proposal (10). The classification outlined in Table 20.1 is a short version of this proposal, which is based on clinical seizure type, ictal (seizure-induced) EEG expression, and interictal (occurring between attacks or paroxysms) EEG expression.

Seizure Classification

Seizures result from the sudden, excessive firing of neurons. They are classified broadly as either partial seizures, in which the abnormal firing initially occurs in a small number of neurons but may spread to adjacent areas, or generalized seizures, in which virtually the entire brain is affected simultaneously (11). Seizures can be characterized by clinical symptoms and by EEG patterns. In addition, computed tomography and magnetic resonance imaging of the head are used in virtually all patients with suspected epilepsy to aid in identifying the seizure type.

Clinical Significance

Seizure disorders can be devastating to a patient's quality of life. Restrictions placed on patients with epilepsy include revocation of driver's licenses, potential physical limitations, work absenteeism, and various emotional and mental issues related to the disease and to the side effects from many of the medications these patients require. Because of the nature of the pathophysiology of seizures (i.e., abnormal neuron firing involving ion channels and an imbalance between excitatory and inhibitory synaptic function), medicinal chemistry plays a vital role in the understanding of this disease and, particularly, in its treatment. Molecular agents used to treat seizures exert varying effects on neuronal function through their structure–activity relationships and chemical interactions with ion channels (carbamazepine, phenytoin, ethosuximide, and zonisamide) and their similarities to naturally occurring neurotransmitters, such as γ-aminobutyric acid (GABA; benzodiazepines, barbiturates, topiramate, gabapentin, and tiagabine).

Approximately 60% of patients with epilepsy can be controlled with monotherapy, but a significant number of patients will require drug combinations. An understanding of basic chemical principles of antiseizure drugs is critical in making appropriate clinical recommendations regarding drug dosing and other issues, such as combination and concomitant therapies. The pharmacokinetics of antiseizure medications are very complex and require a strong foundational knowledge base routed in medicinal chemistry. Monitoring of side effects (and, specifically, the multitude of drug interactions associated with these agents) is extremely important to ensure patient safety and efficacy in the clinical setting, with the ultimate goals to keep patients seizure-free and to maintain their quality of life.

Michael Gonyeau Pharm.D.
Associate Clinical Specialist, Northeastern University, Department of Pharmacy Practice, Bouvé College of Health Sciences

Partial (Local, Focal) Seizures

Partial seizures are divided into three categories: simple partial, complex partial, and partial progressing to generalized seizures. The key distinction between simple and complex partial seizures is the level of consciousness of the person undergoing the seizure. In partial seizures, the initial neuronal discharge originates from a specific, limited cortical area, which is termed a “focus.” Development of the focus is thought to be caused by scarring after head trauma, infection, or oxygen deprivation. The abnormal EEG seizure patterns are restricted to one region of the brain, at least at the onset. These types of seizures are possible at all ages but are most frequent in the elderly. Partial seizures respond fairly well to antiseizure drugs (most commonly referred to as AEDs) (Fig. 20.1) (12).

Table 20.1. Classification of Epileptic Seizures

I. Partial (local, focal) seizures
   A. Simple (consciousness not impaired)
   B. Complex partial seizures (psychomotor seizures)
      1. Beginning as simple partial seizures, progressing to complex seizures
      2. With impairment of consciousness at onset
   C. Partial seizures evolving to secondarily generalized tonic-clonic convulsions
II. Generalized seizures (convulsive or nonconvulsive)
   A. Absence seizures
      Typical (petit mal)

Atypical
B. Myoclonic
C. Clonic
D. Tonic
E. Tonic-clonic (grand mal)
F. Atonic

III. Unclassified epileptic seizures (includes some neonatal seizures)

Medications to combat partial seizures are effective against secondary or generalized tonic-clonic seizures as well. These seizures respond well to carbamazepine, hydantoins, and barbiturates, although this latter group unfortunately displays substantial sedative effects. The newer AEDs (gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide) are useful for either monotherapy or as adjunctive drugs. On the other hand, oxazolidinediones and succinimides are ineffective in the treatment of partial seizures. Valproate is appropriate when tonic-clonic seizures are combined with either myoclonic or absence seizures.

Simple Partial Seizures

The specific symptoms displayed during a simple partial seizure will depend on the area of the brain that is affected, and they will occur on the opposite side of the body from the lesion. Combinations of symptoms are frequent, making accurate diagnosis a challenge. The temporal lobes are the most common origination site for partial seizures. Seizure foci located within the temporal lobe result in psychic symptoms, such as fear, panic, or hallucinations; autonomic signs, such as flushing and sweating; or unpleasant smells or tastes. Frontal lobe foci usually present with motor symptoms. Focal motor attacks most commonly start in one hand, one foot, or one side of the face. Often, however, the onset of focal seizures is not specific. Should the focal motor seizures spread to contiguous cortical areas, there may be an

orderly sequence of repeated events (movement of hands, face, and legs) known as an epileptic march. This type of seizure is termed a “jacksonian seizure.” If the unilateral movements characteristic of focal motor or jacksonian seizures steadily spread to the other half of the body, a generalized seizure may follow. In contrast, seizures beginning in the parietal lobes are termed “sensory seizures” and present with altered sensations, tingling, numbness, or pain. Foci in the occipital lobes produce nystagmus, blinking, or visual disturbances, such as flashing lights or the appearance of strange colors.

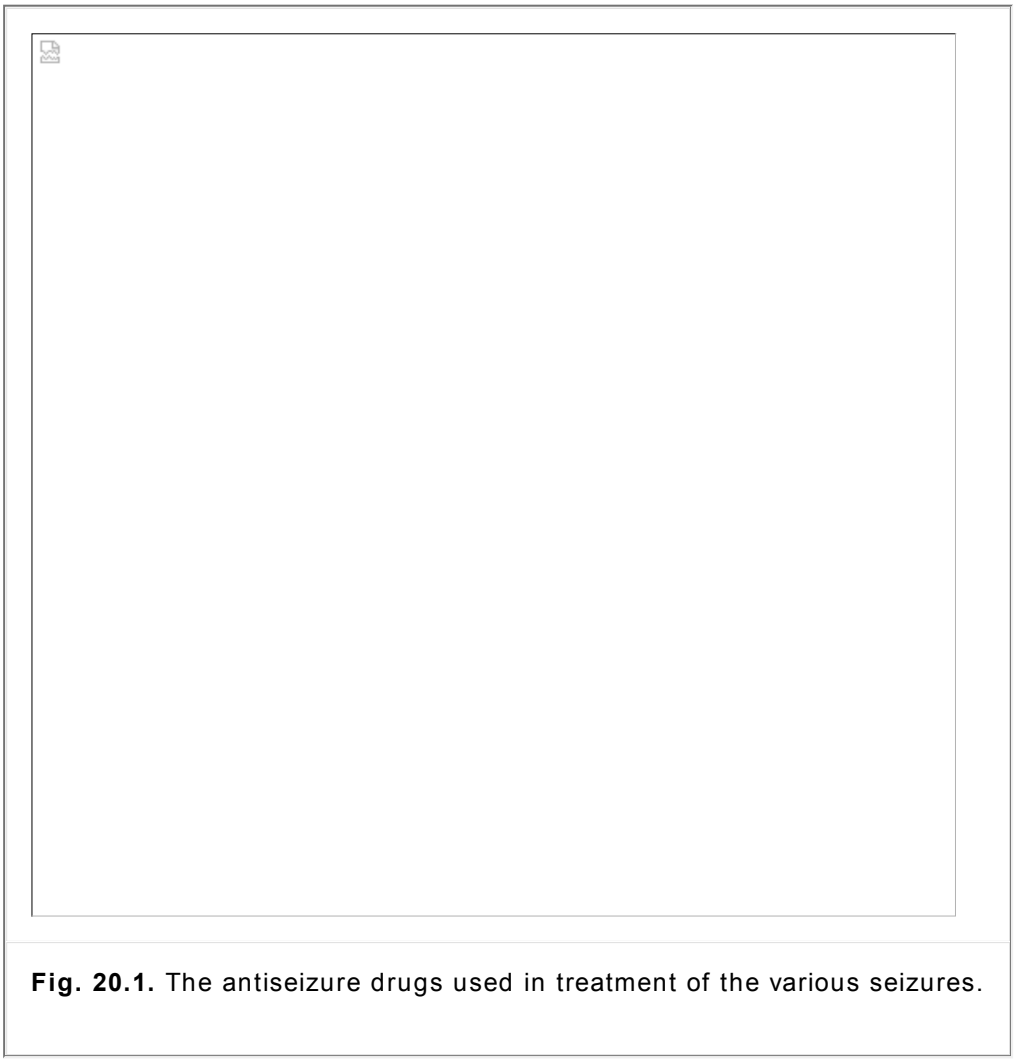

Fig. 20.1. The antiseizure drugs used in treatment of the various seizures.

In simple partial seizures, the patient's consciousness is not impaired. Thus, the person remains able to respond to simple commands, perform simple deliberate movements, and recall events that occurred during the seizure.

Complex Partial Seizures

When consciousness is impaired, the seizure is classified as a complex partial seizure. Impaired consciousness will be manifested by the person's staring, inability to respond to simple commands, by inaccurate recall or amnesia of events occurring during the seizure. Clouding of consciousness may be apparent initially or may appear subsequent to the start of a simple partial seizure. With the exception of the mental status, the other symptoms of complex partial seizures are similar to those outlined above. Many complex seizures have bilateral hemispheric involvement and frequently are accompanied by automatisms (i.e., repetitive involuntary movements, including chewing, swallowing, or wringing the hands).

Partial Seizures Evolving to Secondarily Generalized Seizures

The abnormal electrical activity responsible for any type of partial seizure can generalize throughout the brain, thus evolving into a secondary generalized tonic-clonic seizure. The diagnosis of partial seizures is therefore difficult to establish. The generalization may occur rapidly, or it may occur slowly enough that the symptoms of the partial seizure are experienced by the patient as an “aura” before the generalized tonic-clonic phase. Auras are comprised of symptoms such as seeing blinking lights or hearing unusual sounds, and they serve as an important warning for the patient. The symptoms of tonic-clonic seizures are described below.

Generalized Seizures (Convulsive or Nonconvulsive)

These disorders are generalized from the outset, and they show simultaneous involvement of both cerebral hemispheres and loss of consciousness. It is not possible to single out one anatomic or functional system in one hemisphere of the brain that is responsible for the clinical symptoms. The initial neuronal discharge spreads quickly into the entire (or at least the greater part of) the gray matter. The EEG pattern consists of bilateral, essentially synchronous and symmetric discharges from the

start and indicates the widespread nature of neuronal discharge. The cause rarely is known, but it usually is attributed to

diffuse lesions, to toxic and metabolic disturbances, or to constitutional genetic factors. People of all ages are affected by generalized convulsions. There are several classes of generalized seizures, and useful drugs are selected according to the seizure type that transpires (Fig. 20.1).

Absence (Petit Mal) Seizures

Both typical and atypical absence seizures bring about brief loss of consciousness. Typical absence seizures have a rapid onset and cessation, which may cause them to be misinterpreted as daydreaming; however, the person cannot be alerted or awakened during the seizures. Absence seizures often begin with a change in facial expression, which is followed by a period of motionless, blank staring. After the brief interruption in consciousness (typically ~10 seconds), the activity that was in progress before the seizure is resumed. The individuals have neither memory of events during the seizure nor postictal confusion. Typical absence seizures (petit mal) are more common in children than in adults. They are particularly disabling, because they tend to occur very many times daily. Most children will respond to drug treatment, but a small percentage will go on to develop generalized tonic-clonic seizures as adults. Complex typical absence seizures may include additional phenomena, such as clonic or myoclonic motions, automatisms, or more elaborate behaviors. Between 25 and 40% of affected children have a family history of absence seizures.

Atypical absence seizures have a slower onset and cessation, and they last longer (up to several minutes) than typical absence seizures. They may include clonic motions, automatisms, or autonomic symptoms. Differential diagnosis between these types is made on the basis of the EEG. Typical absence seizures display a 3-Hz spike-and-wave EEG pattern, but the pattern of atypical absence seizures is slower, usually in the range of 1.5 to 2.5 Hz.

Both forms of absence seizure often occur as part of one of the recognized epilepsy syndromes. Typical absence seizures respond fairly well to AEDs; ethosuximide and valproate are first-choice drugs. Clonazepam is effective but sedating, and tolerance to the antiabsence effects may develop. Lamotrigine may be useful. Treatment of atypical absence seizures with AEDs is less successful.

Lennox-Gastaut syndrome is a mixed seizure disorder combining the atypical absence seizures with tonic, tonic-clonic, or myoclonic motor patterns. The syndrome begins in childhood and usually includes mental retardation. Although adequate control of the seizures rarely is achieved, valproate, phenytoin, felbamate, lamotrigine, topiramate, and clonazepam have been useful.

Myoclonic Seizures

Myoclonic seizures consist of sudden, very brief, jerking contractions that may involve the entire body or be confined to limited areas, such as the face and neck. The contractions may affect individual muscles or groups, with simultaneous contraction of both extensor and flexor muscles. These seizures occur in all age groups, with symptoms ranging from rapid tremors to falling down. No loss of consciousness is detectable because of the brief duration of the seizure. Myoclonic seizures often occur in combination with other seizure types. Valproate and clonazepam are used most often to treat myoclonic seizures; lamotrigine and topiramate also have shown some efficacy.

Tonic Seizures

Tonic seizures occur mostly in children and are characterized by increased tone in extensor muscles, resulting in falling to the ground. Although brief, the duration of contractions is somewhat longer than in myoclonic seizures. Vocalization may occur as a result of contraction of thoracic muscles, forcing air past the larynx. Brief periods of apnea and postictal tiredness may be associated.

Atonic Seizures

In atonic seizures, a very sudden decrease in muscle tone occurs, leading to a head drop, drooping of a limb, or loss of all muscle tone, resulting in falling. The risk of injury is high in these sudden “drop attacks.” Atonic seizures are more common in children.

Attaining good control of tonic or atonic seizures is difficult. Valproate, felbamate, lamotrigine, benzodiazepines, and topiramate have proven to be effective in some individuals.

Clonic Seizures

Clonic seizures nearly always occur in babies or young children. A loss or impairment of consciousness occurs simultaneously with a decrease in muscle tone or with a generalized tonic contraction, and it is followed by period of asymmetric jerking motions.

Tonic-Clonic (Grand Mal) Seizures

Generalized tonic-clonic seizures represent a maximal epileptic response of the brain. These seizures are characterized by the absence of an aura and by tonic stiffening of all muscle groups, causing the patient to fall. The initial contraction may be flexor and is rapidly followed by prolonged extension. Subsequently, there is a period of bilateral symmetric jerking of the extremities. The seizure may be associated with loss of bladder control and biting of the tongue or inside of the mouth. There is a pronounced postictal state following the seizure, and the person may pass directly into sleep before waking several hours later.

Status Epilepticus

Status epilepticus is a condition in which there is a single prolonged seizure lasting more than 5 minutes or in which there is insufficient time between multiple seizures to permit recovery. Several types exist, depending on the

type of seizure involved (i.e., tonic-clonic, simple partial, complex partial, or absence). Tonic-clonic status epilepticus is both the most common and the most life-threatening. Pharmacological treatment of most forms of status epilepticus may include intravenous (IV) administration of diazepam or lorazepam, fosphenytoin, and lastly, phenobarbital. Although lorazepam is not approved by the U.S. Food and Drug Administration (FDA) for this purpose, it sometimes is preferred because of its longer half-life.

Absence status epilepticus is a condition of impaired consciousness, perhaps including mild motor symptoms, that lasts from 30 minutes to 12 hours. It can be distinguished from ongoing seizures because of organic or toxic causes by the spike-and-wave EEG pattern that is characteristic of absence seizures. The usual pharmacological treatment of absence status employs diazepam or lorazepam, followed by ethosuximide.

Mechanisms of Action for the Antiseizure Drugs

Seizures result from bursts of abnormal synchronous discharging by a network of neurons. Although the mechanisms of seizure generation are still poorly understood, the causes of abnormal firing appear to involve neuronal ion channels and an imbalance between excitatory and inhibitory synaptic function. Various AEDs exhibit different mechanisms of action on neuronal function, causing them to show selective efficacy against different seizure types (Fig. 20.2).

Ion Channels

Sodium and chloride ions are present at greater concentration outside the cell, whereas potassium, organic cations, and charged proteins are more numerous within the cell. Because the membrane is permeable only to small ions and not large ions or proteins, the neuronal membranes maintain a charge separation, resulting in a "resting potential" in the range -50 to -80 mV versus the outside of the cell.

An increase in interior negativity, termed "hyperpolarization," decreases the resting potential (e.g., to -90 mV), thus making it more difficult for a neuron to reach threshold and subsequently fire. A reduction in interior negativity, termed "depolarization," can result in generation of an action potential if the depolarization is sufficient to reach threshold (approximately -40 mV). Neuronal firing is initiated by an influx of sodium ions.

After each depolarization, voltage-dependent sodium channels adopt an inactive state and remain refractory to reopening for a period of time. While those channels are unable to open, rapid repetitive firing is diminished, and spread of electrical seizure activity to adjacent brain regions is suppressed (14). Stabilization and prolongation of this inactive state appears to be the primary mechanism of action of phenytoin, carbamazepine, and lamotrigine and may be instrumental in the antiseizure actions of phenobarbital, oxcarbazepine, valproate, topiramate, and zonisamide (Fig. 20.2).

Alterations in the structure or function of an ion channel caused by mutations in a gene encoding one of the channel's subunits are termed "channelopathies." Initially, these abnormalities were associated with cardiac and muscular disorders, but today, it is recognized that channelopathies are responsible for several forms of epilepsy (15,16). Presently, most of the discovered channel mutations appear to be associated with the development of idiopathic generalized epilepsy; most partial seizures are believed to be acquired. Minor alterations in gene structure or expression, however, may predispose a given individual to partial seizures. It is estimated that 40% of adult and childhood epilepsy may result from genetic factors.

Mutations in sodium and potassium channels are most common, because they give rise to hyperexcitability and burst firing. Mutations in the sodium channel subunit gene *SCN2A1* have been associated with benign familial neonatal epilepsy; in *SCN1A* with severe myoclonic epilepsy of infancy, and in *SCN1A* and *SCN1B* with generalized epilepsy with febrile seizures. Mutation of the *SCN1B* gene has been shown to reduce the channel's response to phenytoin (17). The potassium channel genes *KCNQ2* and *KCNQ3* are implicated in some cases of benign familial neonatal epilepsy. Chloride channels have been implicated as well. Mutations of the *CLCN2* gene have been found to be altered in several cases of classical idiopathic generalized epilepsy subtypes: Childhood and juvenile absence epilepsy, juvenile myoclonic epilepsy, and epilepsy with grand mal on awakening. Mutations of $GABA_A$ receptor subunits also have been detected. The gene encoding the α_1 subunit, *GABRG1*, has been linked to juvenile myoclonic epilepsy; mutated *GABRG2*, encoding an abnormal γ subunit, has been associated with generalized epilepsy with febrile seizures and childhood absence epilepsy. Lastly, mutations of calcium channel subunits have been identified in juvenile absence epilepsy (mutation in *CACNB4*; the B4 subunit of the L-type calcium channel) and idiopathic generalized epilepsy (*CACN1A1*) (15,16).

Synaptic Inhibition and Excitation

For a neuron, whether an action potential is generated depends on the balance between excitatory and inhibitory stimulation. The predominant inhibitory neurotransmitter in the brain is GABA. It is synthesized from an amino acid, glutamic acid, by glutamic acid decarboxylase and is inactivated by GABA-transaminase. GABA binds to two receptor types, $GABA_A$ and $GABA_B$. $GABA_A$ receptors occur on chloride ion channels, and the binding of GABA causes chloride influx and neuronal hyperpolarization. $GABA_B$ receptors are linked via G proteins and second messengers to potassium and calcium channel activity, also mediating inhibition in the central nervous

system (CNS) (18). $GABA_B$ receptors also may play a role in oscillatory rhythms in some forms of epilepsy (19) (Fig. 20.3).

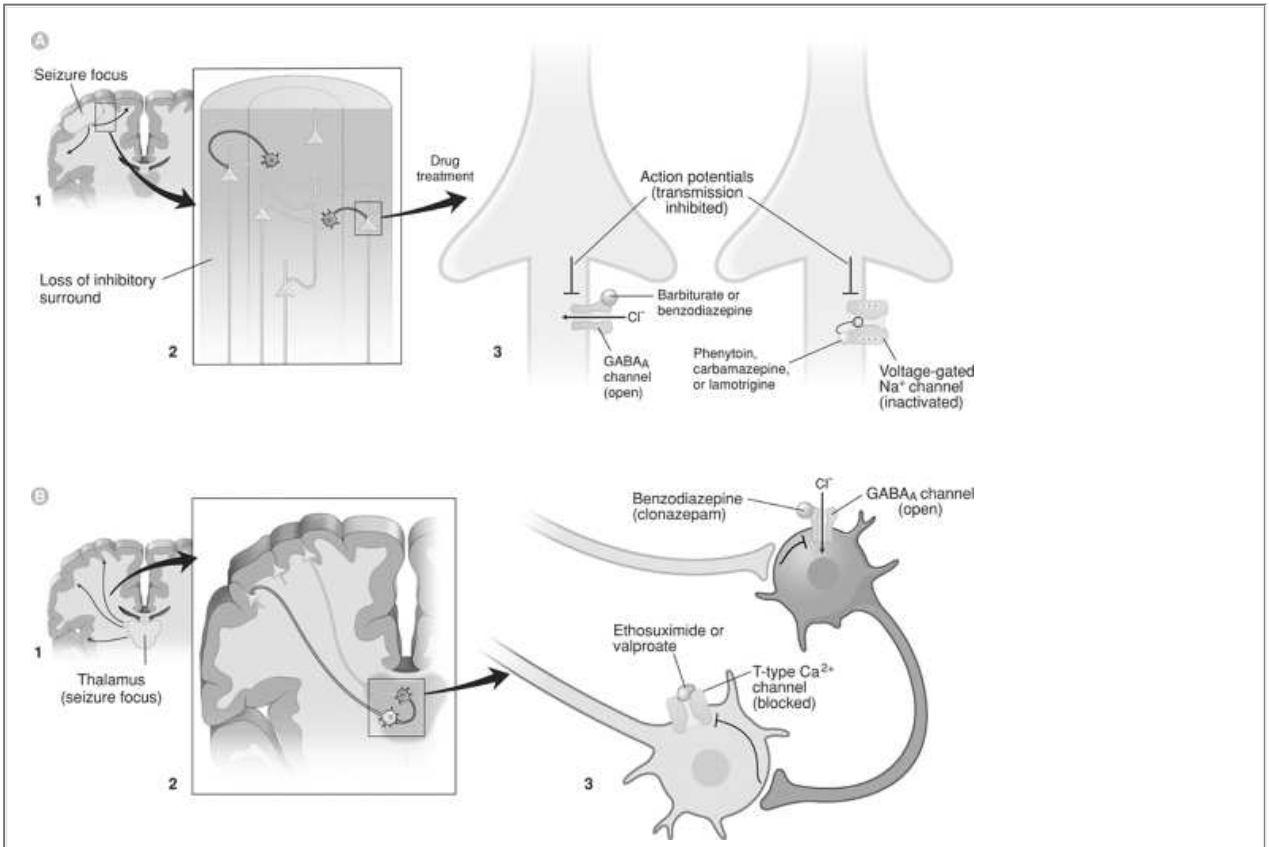

Fig. 20.2. Mechanisms of antiseizure drugs. (A) Drugs for partial seizures: 1) Seizure activity spreads because of loss of surround inhibition; 2) drugs act in the surrounding region to 3) enhance γ-aminobutyric acid (GABA) inhibition or prolong Na^+ channel inactivation. (B) Drugs for absence seizures: 1) The seizure activity results from cyclic activity between the thalamus and the cortex; 2) drugs prevent synchronization by either 3) deactivating the inhibitory reticular neurons and decreasing hyperpolarization of the thalamic relay neurons or blocking T-type Ca^{2+} channels to prevent burst firing by the thalamic relay neurons. (From Griffin EA Jr, Lowenstein DH. Pharmacology of abnormal electrical neurotransmission in the central nervous system. In: Golan DE, Tashjian A, Armstrong E, et al., eds. Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004, pp. 193–203; with permission.)

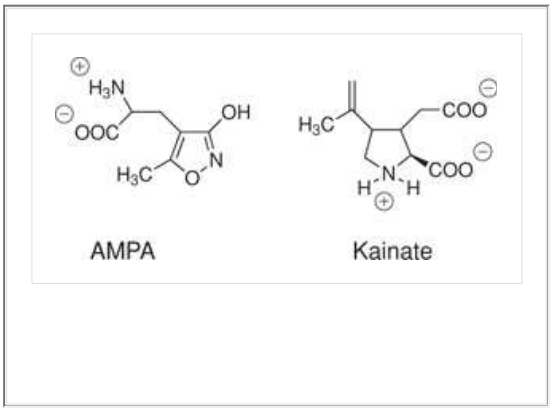
A number of AEDs augment GABA-mediated inhibition or affect GABA concentration. Benzodiazepines, barbiturates, and perhaps, topiramate enhance the action of GABA on the $GABA_A$ chloride channel. Tiagabine decreases the reuptake of GABA and, perhaps, gabapentin decrease its metabolism.

The ionotropic neurotransmitter glutamate provides excitatory neurotransmission via two types of receptors, the N-methyl-D-aspartate (NMDA) and L-α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) and kainate (KA) receptors (see Chapter 15). NMDA, AMPA, and KA are specific agonists for these receptor that are used in experiments to distinguish the glutamate ionotropic receptors.



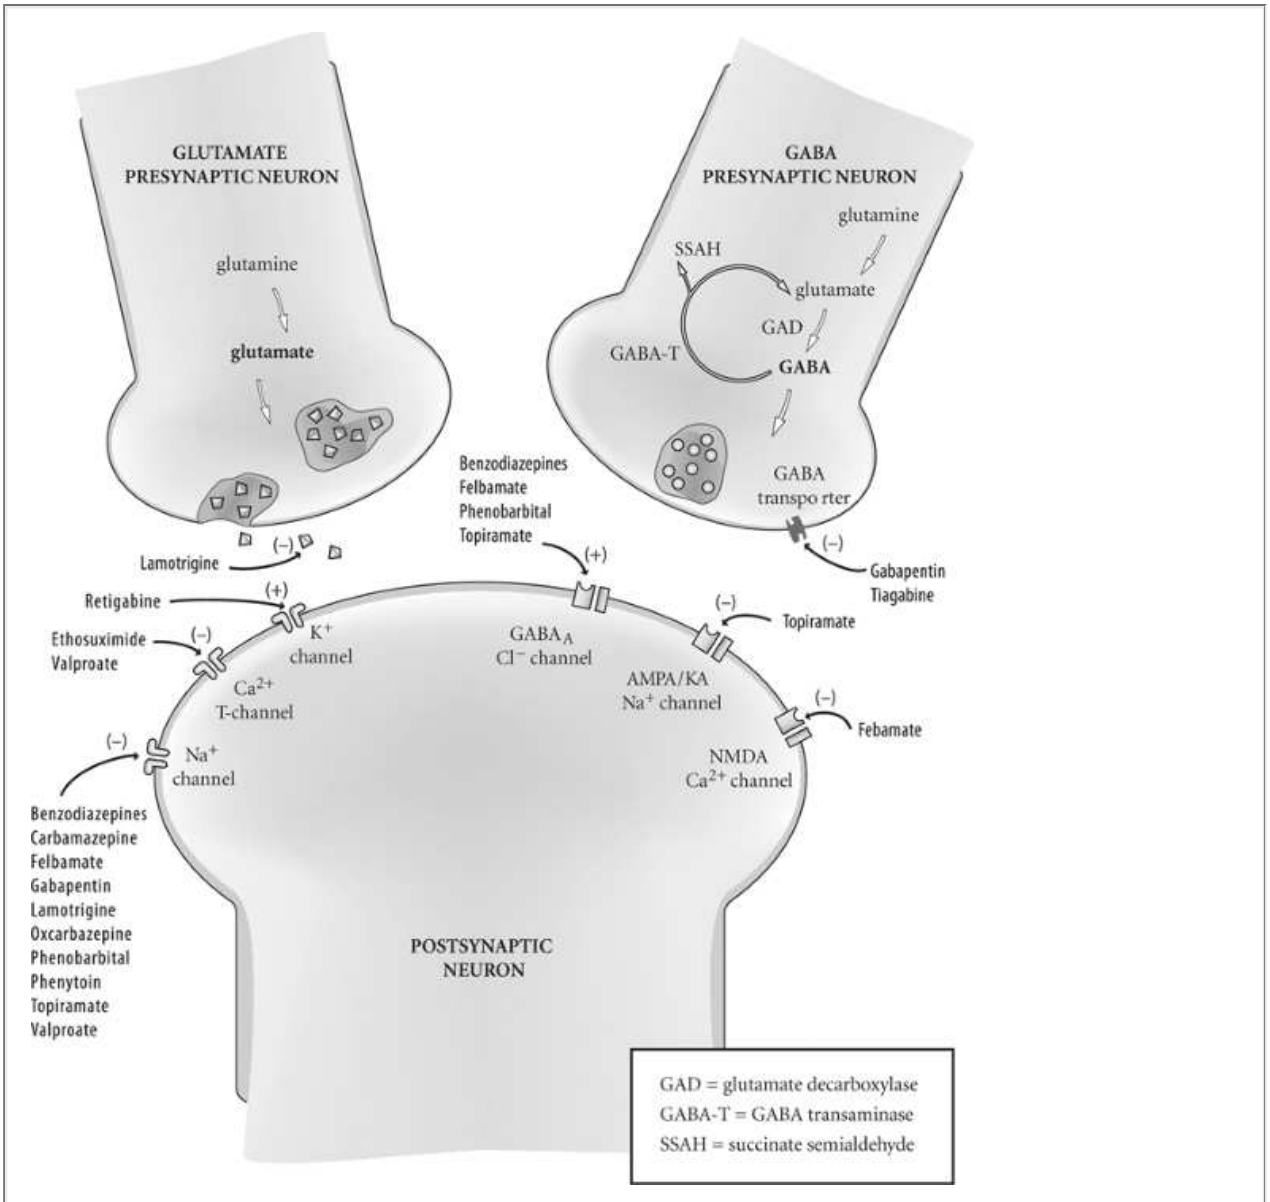


Fig. 20.3. A summary of the sites of action for the antiepileptic drugs (Adapted from Taylor CP. Mechanisms of new antiepileptic drugs. In: Delgado-Escueta AV, Wilson WA, Olsen RW, et al., eds. Jasper's Basic Mechanisms of the epilepsies, 3rd Ed. (Advances in Neurology, vol 79.) Philadelphia: Lippincott Williams & Wilkins, 1999:1012–1027; with permission.)

Activation of these ligand-gated channels enables sodium and calcium influx and potassium efflux, facilitating depolarization. Blockade of the NMDA receptor by felbamate or of the AMPA/KA receptor by phenobarbital and topiramate inhibits depolarization (Fig. 20.3).

Aberrant Calcium Signaling

Low-threshold T-type calcium currents act as pacemakers for normal brain activity, particularly the thalamic oscillatory currents thought to be involved in the generation of absence seizures (19,20). Drugs such as ethosuximide, the oxazolidinediones, and zonisamide, which inhibit T-type currents, are effective against absence seizures but ineffective against partial or other seizure types.

Antiseizure Drugs

Introduction

The primary use of AEDs is in the prevention and control of epileptic seizures. Theoretically, the ideal AED should, among other things, completely suppress seizures in

doses that do not cause sedation or other undesired CNS toxicity. It should be well tolerated and highly effective against various types of seizures and be devoid of undesirable side effects on vital organs and functions. Its onset of action should be rapid after parenteral injection for control of status epilepticus, and it should have a long duration of effect after oral administration for prevention of recurrent seizures.

The first effective remedy, potassium bromide, was introduced by Locock in 1857 (21). This drug was largely replaced by phenobarbital in 1912, when Hauptmann tried this sedative in epilepsy (22). Its great value was recognized at once, and it is still commonly prescribed.

The usefulness of both bromide and phenobarbital in convulsive disorders was discovered by chance, but phenytoin was developed in 1937 as the result of a study of potential AEDs in animals by Putnam and Merritt (23,24). Bromide is highly effective in humans and is relatively nonsedating. Treatment of convulsive disorders using bromide, phenobarbital, and phenytoin constitutes an important advance in clinical therapy.

Many of the standard AEDs that contain the ureide structure, as shown in Figure 20.4, have been used clinically for more than 30 years without much change in their ureide structures. Small changes in the X substituent of the ureide structure can cause significant changes in the type of seizures controlled, which will be discussed for each of the respective drugs. As a result of rapid developments in molecular biological techniques for the study of the neurophysiology of epilepsy and in the interactions of AEDs with neurotransmitters at ion channels or brain receptors (AMPA/KA glutamate receptors), a new generation of clinically available AEDs have emerged. These AEDs include felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, and zonisamide. Their mechanisms of action are targeted toward ion channels and brain receptors either by enhancing brain GABA activity (e.g., tiagabine) or by inhibiting excitatory amino acids (GABA; e.g., lamotrigine and felbamate) (Fig. 20.2). These new-generation AEDs also exhibit limited drug interactions with fewer adverse effects. A rational approach to the drug discovery process is necessary to develop new leads to novel effective therapy and to use structure–activity relationships to fine-tune the pharmacology of existing AEDs with the same or better efficacy and fewer adverse effects (25).

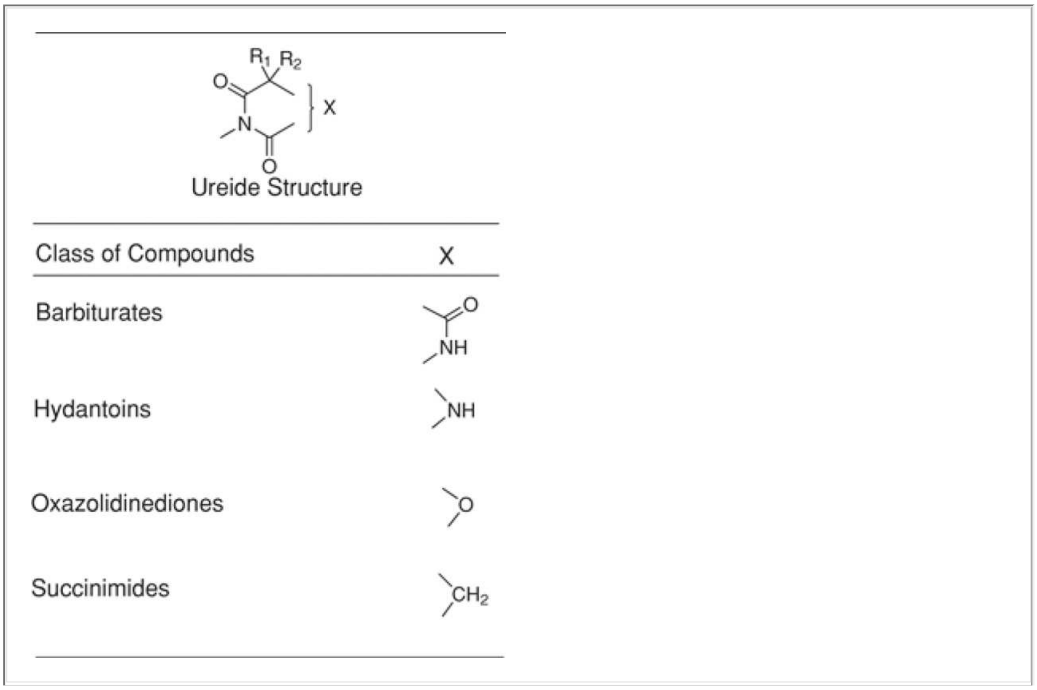

Fig. 20.4. Structure of anticonvulsant drugs containing the ureide structure.

Approximately 60% of patients with epilepsy become seizure-free with monotherapy using frontline drugs, such as carbamazepine, benzodiazepine (clonazepam and diazepam), ethosuximide, or phenytoin. Alternative monotherapy drugs include phenobarbital and primidone. Another 20% have their epilepsy controlled with more than one AED called adjunct drugs (e.g., felbamate, gabapentin, lamotrigine, levetiracetam, oxcambazepine, tiagabine, topiramate, valproic acid, and zonisamide). Despite recent advances in neurobiology and significant insight regarding the molecular dysfunction of epilepsy, the remaining 20% do not completely respond to the current frontline therapeutic drugs and most often are prescribed more than two AEDs without any obvious benefit (11). Recently, much effort has been made to discover new AEDs effective in refractory seizures and partial complex seizures.

Seizure control requires continuous antiseizure action and is not achievable unless plasma concentrations remain relatively consistent at therapeutic levels throughout all 24 hours of the day. Therefore, a knowledge of the therapeutic ranges of plasma concentrations, time to peak serum concentrations, and elimination half-lives help to guide AED administration to achieve consistent therapeutic serum concentrations that control seizures without causing intolerable toxicity (26). Enzymatic biotransformation is the principal determinant of the pharmacokinetic properties for most AEDs, although some drugs are excreted by the kidneys predominantly as unchanged drug. Most AEDs exhibit linear enzyme kinetics, in which changes in daily dose lead to proportional changes in serum concentration if clearance remains constant. The traditional concept of administering a drug at intervals equal to one elimination half-life, however, does not apply to some drugs, in which the half-life of biological activity may exceed its elimination half-life. The standard AEDs have the greatest potential to be involved in pharmacokinetic drug interactions when they are coadministered with other AEDs or other drugs (27). These interactions usually involve changes in the rate of biotransformation or in the protein binding of one or both coadministered drugs (26). Drug-induced changes in the pharmacokinetics for many of the AEDs are particularly pronounced in children, requiring a higher oral dose per kilogram body weight than in adults to obtain an effective plasma concentration (28).

Table 20.2. Mechanism(s) of Action and Pharmacokinetics for Antiseizure Drugs

Drug	Mechanism of Actiona	Elimination Half-life in Children (hours)	Elimination Half-life in Adults (hours)	Time to Steady-state Plasma Concentration (hours)	Protein Binding (%)	Log P (pH 7.4)

This chapter surveys the structure–activity relationship, mechanism of action, metabolism, and pharmacokinetic parameters for the new generation of AEDs (felbamate, gabapentin, lamotrigine, oxcarbazepine, levetiracetam, tiagabine, topiramate, zonisamide, and vigabatrin) and the standard AEDs (phenytoin, carbamazepine, phenobarbital, primidone, valproate, ethosuximide, and the benzodiazepines) as well as for several of the older AEDs that are less commonly used today. The application of AEDs in the treatment of various kinds of epilepsies is shown in Figure 20.1; this illustration is based on AEDs used in clinical therapy. Table 20.2 lists the AED, its mechanism of action, and some of the pharmacokinetic properties.

Drugs Effective Against Partial and Generalized Tonic-Clonic Seizures

Hydantoins

The hydantoins have a 5-membered ring structure containing two nitrogens in an ureide configuration (Fig. 20.4) and were tested as antiepileptics by Merritt and Putnam (23,24). These drugs suppressed electrically induced convulsions in animals but were ineffective against convulsions induced by pentylenetetrazole, picrotoxin, or bicuculline. The structures for the clinically available hydantoins are listed in Figure 20.5.

Phenytoin (Diphenylhydantoin)

Phenytoin is the prototype and most commonly prescribed member of the hydantoin family of drugs. Bioequivalency is a problem with the hydantoins because of their very poor water solubility (~32 mg/L) and a low therapeutic ratio. Phenytoin exhibits nonlinear pharmacokinetics that exaggerate the effects of changes in the fraction of dose absorbed. Its apparent pK_a is in the range of 8.06 to 8.33 and, thus, can form a water-soluble sodium salt (~15 mg/mL at solution pH >11).

Aqueous solutions of phenytoin sodium (pH 11–12) gradually absorb carbon dioxide, neutralizing the alkalinity of the solution and causing partial hydrolysis and crystallization of free phenytoin resulting in turbid solutions. When phenytoin sodium is administered intramuscularly (IM), its absorption may be erratic as a result of crystallization of insoluble phenytoin at the injection site because of the decrease in pH from 11.5. Phenytoin sodium injection is physically and chemically incompatible in D5W, normal saline, or with parenteral solutions of many drugs, especially salts of basic drugs. The nature of the incompatibility depends on several factors, including the type of salt, concentrations of the drugs, diluents used, resulting pH of the final admixture (must be pH >11), and temperature. Phenytoin sodium capsules also will absorb carbon dioxide overtime, resulting in the formation of free phenytoin with a different dissolution profile.

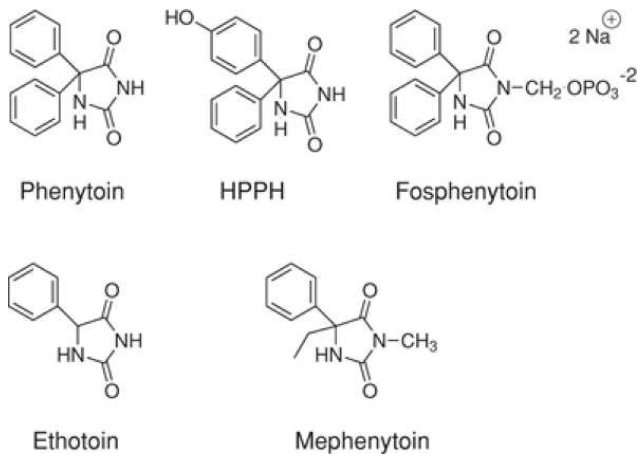

Fig. 20.5. Hydantoins.

Mechanism of action

Phenytoin is indicated for initial monotherapy or adjunct treatment of complex partial or tonic-clonic seizures, convulsive status epilepticus, and prophylaxis. It often is selected for initial monotherapy because of its high efficacy and relatively low incidence of side effects (29). Phenytoin is not used in the treatment of absence seizures, because it may increase their frequency of occurrence (30,31). Phenytoin binds to and stabilizes the inactivated state of sodium channels, thus producing a use-dependent blockade of repetitive firing and inhibition of the spread of seizure activity to adjacent cortical areas.

Pharmacokinetics

Phenytoin sodium from immediate-release capsules is rapidly absorbed and generally attains peak serum concentration in 1.5 to 3.0 hours; extended-release phenytoin sodium is absorbed more slowly, attaining peak serum concentration in 4 to 12 hours. The oral bioavailability for sodium phenytoin (70–100%) may vary enough among formulations from different manufacturers to result in a subtherapeutic serum concentration and, therefore, are ineffective in controlling seizures or a toxic blood concentration. Capsules of sodium phenytoin will absorb carbon dioxide, causing dissociation or neutralization to free phenytoin, thus altering its oral bioavailability (gastrointestinal dissolution), pharmacokinetics, and plasma concentrations that could cause breakthrough seizures. Therapeutic plasma concentrations for phenytoin usually are 7.5 to 20.0 μg/mL, although in some patients, seizure control is not achieved at these plasma concentrations. Phenytoin is highly protein bound (Table 20.2).

Phenytoin is metabolized predominately by CYP2C9 to its primary metabolite, 5-(4′-hydroxyphenyl)-5-phenylhydantoin (HPPH) (Fig. 20-5) (32). Approximately 60 to 75% of an oral dose is excreted as HPPH glucuronide or sulfate metabolites. Approximately 1% is excreted unchanged in urine, and some undergoes enterohepatic circulation. Other minor metabolites also appear in urine. Up to 10% of the oral phenytoin may be excreted unchanged by the kidneys at toxic doses. Phenytoin is notorious for displaying nonlinear pharmacokinetics, because the route of metabolism is a saturable process. Therefore, small increases in dosage may produce substantial increases in plasma phenytoin concentrations; the steady-state plasma concentration (C_p) may double or triple as a result of a 10% or more increase in dosage, possibly resulting in toxicity. Phenytoin also induces CYP3A4 and uridine diphosphate–glucuronyltransferases (UTPs; increased glucuronidation). Therefore, plasma concentrations for drugs metabolized by these isoforms will be affected (see Chapter 10). Thus, the addition of phenytoin to an AED regimen can reduce their plasma levels by inducing their CYP3A4 metabolism for carbamazepine, felbamate, lamotrigine, oxcarbazepine, tiagabine, valproate, and zonisamide. Other drugs for which metabolism is induced by phenytoin include methadone, theophylline, warfarin, and oral contraceptives. On the other hand, plasma phenytoin levels are increased by carbamazepine, felbamate, cimetidine, warfarin, chloramphenicol, isoniazid, and disulfiram. Plasma phenytoin levels are decreased by rifampin, antacids, and valproate (free phenytoin levels remain the same).

The pharmacokinetics of phenytoin is significantly affected by age. Its rate of elimination is strongly dose-dependent (nonlinear) at all ages. The elimination half-life for phenytoin in children increases with age because of an age-dependent

decrease in its rate of metabolism (28). The combination of these factors makes it difficult to predict the phenytoin plasma concentrations following the dose (dose/kg) adjustments in neonates and children, particularly when phenytoin is coadministered with other liver enzyme-inducing AED, such as phenobarbital and carbamazepine.

Adverse effects

Drug interactions, especially with other AEDs and CYP3A4 substrates, are extensive. Although toxic effects may begin in the upper normal plasma range (>20 µg/mL), serious toxicity is rare. Central nervous system effects are most frequent and include nystagmus, ataxia, dysarthria, and sedation. Gingival hyperplasia, usually reversible, is common. Aromatic anticonvulsants, such as phenytoin, have been associated with a number of toxic effects, including a drug-induced hypersensitivity syndrome that manifests with a triad of reactions, such as rash, agranulocytosis, thrombocytopenia, lymphadenopathy, Stevens-Johnson syndrome, and hepatitis that have occurred in affected individuals. Although anticonvulsant-induced hypersensitivity reactions are relatively rare events, occurring with an incidence of between 1:1,000 and 1:10,000 exposures, these idiosyncratic reactions can be potentially life-threatening. The hypersensitivity syndrome is consistent with an immune etiology, with symptoms typically appearing within 2 to 8 weeks after the initiation of therapy and generally abate on discontinuation of phenytoin. Dermal metabolism of phenytoin by CYP2C18 to reactive metabolites may be related to the occurrence of hypersensitivity

rashes (33). Although the mechanism by which the aromatic anticonvulsants induce hypersensitivity reactions has not been well characterized, recent studies have suggested that the immune response elicited by phenytoin may be caused, at least in part, by its metabolism into chemically reactive metabolites and may be the critical step in the formation of protein adducts and subsequent immune responses. Identification of the reactive metabolite(s) for phenytoin has been difficult, because the rate at which human liver microsomes convert phenytoin to metabolites capable of binding to proteins is quite low. It also is important to note that phenytoin typically is administered in doses ranging from hundreds of milligrams to grams per day, suggesting that a substantial amounts of reactive metabolites could be formed on a daily basis. Therefore, it is conceivable that individuals with a low capacity to detoxify reactive metabolites via glucuronidation or other secondary pathways may represent individuals at risk for idiosyncratic toxicity.

The incidence of phenytoin toxicity may be increased in the elderly, or in those patients with hepatic or renal impairment, because of alterations in its pharmacokinetics. Plasma level determinations may be indicated in these cases. Although a role for P-glycoprotein transporter alleles in the development of phenytoin toxicity remains controversial, phenytoin is a robust substrate for the non-ABC efflux transporter RLIP76. Because RLIP76 has been found to be overexpressed in excised human epileptic foci, its action may account for treatment failures; conversely, inhibition of transport may cause toxicity (34). There is a 2 to 3% increase in the risk of fetal epilepsy syndrome if the mother is taking phenytoin. Phenytoin is contraindicated in cardiac patients with bradyarrhythmias. Induction of CYP2C19 by ginkgo biloba may increase phenytoin clearance and precipitate serious seizures (35).

Fosphenytoin (Cerebyx)

Fosphenytoin sodium (Fig. 20.5) is a soluble pro-drug disodium phosphate ester of phenytoin (142 mg/mL) that was developed as a replacement for parenteral phenytoin sodium to circumvent the pH and solubility problems associated with parenteral phenytoin sodium formulations (36,37). Unlike phenytoin, fosphenytoin is freely soluble in aqueous solutions and is rapidly absorbed by the IM route. It is rapidly metabolized (conversion half-life, 8–15 minutes) to phenytoin by in vivo phosphatases. Therapeutic free (unbound) and total plasma phenytoin concentrations are consistently attained following IM or IV administration of fosphenytoin (26). It is administered IV following benzodiazepines for control of status epilepticus or whenever there is a need to rapidly achieve therapeutic plasma concentrations. Severe bradycardiac adverse events to fosphenytoin, including some fatalities, have been reported (38). A dose reduction in patients who are elderly or have renal or hepatic impairment has been suggested.

Ethotoin (Peganone)

Ethotoin differs from phenytoin in that one phenyl substituent at position 5 has been replaced by hydrogen, and the N-H at position 3 is replaced by an ethyl group (Fig. 20.5). It may be indicated for treatment of tonic-clonic and complex partial (psychomotor) seizures. Because it is considered to be less toxic but also less effective and more sedating than phenytoin, ethotoin usually is reserved for use as an add-on drug (39). Ethotoin does not share phenytoin's profile of antiarrhythmic action. The metabolism of ethotoin, like phenytoin, is saturable and nonlinear. Its administration is contraindicated in patients with hepatic abnormalities and hematologic disorders.

Mephenytoin

Mephenytoin is N-methylated at position 3 with an ethyl group replacing one of the phenyl substituents at position 5 (Fig. 20.5). It is indicated for focal and jacksonian seizures in patients refractory to less toxic AEDs. Mephenytoin produces more sedation than phenytoin and should be used only when safer drugs have failed, because it is associated with an increased incidence of serious toxicities, such as severe rash, agranulocytosis, and hepatitis (40). Its N-desmethyl metabolite, 5-phenyl-5-ethylhydantoin, contributes to both efficacy and toxicity for mephenytoin. The drug is no longer commercially available inside but is still available outside the United States

Iminostilbenes

Carbamazepine

Carbamazepine (CBZ; Tegretol) (Fig. 20.6) was approved by the U.S. FDA in 1968, and it is presently indicated as initial or adjunct therapy for complex partial, tonic-clonic, and mixed-type seizures. It is one of the two safest and most effective older AEDs for these seizure types (phenytoin is the other) and is chosen for monotherapy because of its high effectiveness and relatively low incidence of side effects (40). Its tricyclic structure resembles that of the psychoactive drugs imipramine, chlorpromazine, and maprotiline and also

shares some structural features with the AEDs phenytoin, clonazepam, and phenobarbital. In addition, CBZ has been found to be effective for treatment of bipolar disorder and trigeminal neuralgia.

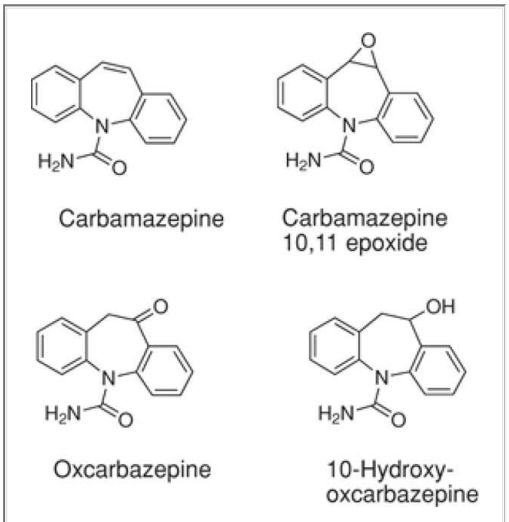

Fig. 20.6. Iminostilbenes.

Mechanism of action

In animals, the profile of antiseizure properties for CBZ is similar to that of phenytoin. CBZ is effective in the maximal electroshock (MES) test (electrically induced seizure test) but is ineffective against pentylenetetrazole-induced seizures. It is not effective for absence or myoclonic seizures and, indeed, may exacerbate their onset (30,41). Like phenytoin, CBZ acts on voltage-dependent sodium channels to prevent the spread of seizures. CBZ depresses synaptic transmission in the reticular activating system, thalamus, and limbic structures. In a double-blind, crossover study in patients whose seizures were not controlled completely by combinations of AED, CBZ was equal in efficacy to phenobarbital and phenytoin in controlling seizure frequency, and side effects were minimal.

Pharmacokinetics

Following the administration of an oral dose, CBZ is slowly absorbed, with the attainment of peak concentration from immediate-release tablets in 4 to 5 hours and from extended-release tablets in 3 to 12 hours. The normal half-life averages between 12 and 17 hours; however, because of autoinduction, the half-life may range from 8 to 29 hours. The half-life for CBZ-10,11-epoxide is 5 to 8 hours. Therapeutic plasma concentrations range from 4 to 12 μg/mL (in adults) and may require a month to achieve a stable therapeutic concentration for the desired antiseizure effect because of induction of hepatic metabolizing enzymes.

CBZ is principally metabolized by CYP3A4 its 10,11-epoxide, with CYP2C8 and CYP1A2 having minor roles. CBZ epoxide is hydrolyzed to inactive 10,11-dihydroxy CBZ by epoxide hydrolase. CBZ epoxide is active and appears to be more toxic than CBZ (42,43). However, CBZ not only induces CYP3A4 activity but also its own metabolism (an autoinducer) as well as UGT and the increased formation of glucuronide metabolites. Like phenytoin, CBZ has been associated with a number of toxic effects, including a drug-induced hypersensitivity syndrome. Although phenytoin-induced hypersensitivity reactions are relatively rare events, they can be potentially life-threatening. Although the mechanism by which CBZ induces hypersensitivity reactions has not been well characterized, recent studies have suggested that the immune reaction may be caused, at least in part, by its metabolism into chemically reactive metabolites, which may be the critical step in the formation of protein adducts and subsequent immune responses. Identification of the reactive metabolite(s) has been difficult, because the rate at which human liver microsomes convert CBZ to metabolites capable of binding to proteins is quite low. Furthermore, it also is important to note that CBZ typically is administered in doses ranging from hundreds of milligrams to grams per day, suggesting that a substantial amounts of reactive metabolites may be formed on a daily basis. Therefore, it is conceivable that individuals with a low capacity to detoxify reactive metabolites via glucuronidation or other pathways may present individuals at risk for

idiosyncratic toxicity. Although an arene oxide was originally proposed as the reactive species and an iminoquinone metabolite derived from the CBZ metabolite (CBZ-IQ) or 2-hydroxyiminostilbene (2-OHIS) are potential candidates for the reactive metabolite, because quinone- and iminoquinone-type metabolites have been implicated in drug-induced hepatotoxicity (see Chapter 10). CYP3A4-catalyzed secondary metabolism of 2-hydroxycarbamazepine to 2-OHIS or to CBZ-IQ, followed by nonenzymatic reduction to 2-hydroxyiminostilbene, may well underlie subsequent development of drug-induced hypersensitivity to CBZ (Fig. 20.7) (44). Based on the formation of glutathione and N-acetylcysteine conjugates, it has been suggested that 2-OHIS is the target for the formation of protein adducts, which could lead to localized idiosyncratic toxicities. Like phenytoin, CBZ is highly protein bound (Table 20.2) and is extensively transformed. Approximately 72% of an oral dose is excreted in the urine as metabolites and 3% as unchanged drug. The 28% found in the feces may be the result of incomplete absorption and enterohepatic cycling. As previously mentioned, interindividual variability in apparent plasma half-life and total body clearance is related to the phenomenon of autoinduction.

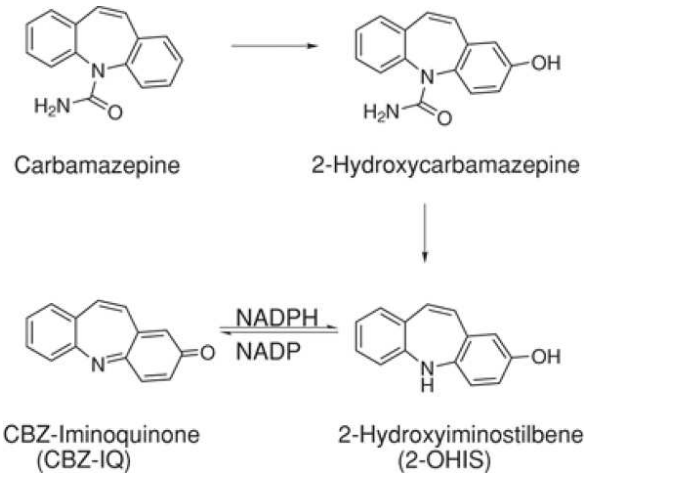

Fig. 20.7. Bioactivation pathway for carbamazepine.

Adverse effects

Gastric upset from CBZ may be diminished by taking the drug after meals. Common toxicities include blurred vision, dizziness, drowsiness, and ataxia. Tremor, depression, hyponatremia, and cardiac disturbances are seen at high serum concentrations. Idiosyncratic rashes are common; rarer severe idiosyncratic effects include aplastic anemia, agranulocytosis, thrombocytopenia, and jaundice. Therefore, patients receiving CBZ should have periodic blood count determinations and liver function tests. Both CBZ and oxcarbazepine can reduce plasma 25-hydroxy vitamin D levels (45). CBZ increases levels of phenytoin and decreases levels of

felbamate, lamotrigine, oral contraceptives, theophylline, valproate, and zonisamide. CBZ levels are increased by propoxyphene, erythromycin, chloramphenicol, isoniazid, verapamil, and cimetidine. CBZ levels are decreased by phenobarbital, phenytoin, felbamate, and primidone. Lamotrigine and valproic acid may elevate CBZ epoxide levels. Administration of the extended-release form has been associated with fewer side effects and with improved seizure control (46).

Macrolide antibiotics inhibit CBZ metabolism, thus increasing CBZ plasma levels and decreasing clearance with the potential for toxicity effects. Drug-induced changes in CBZ pharmacokinetics are particularly pronounced in children (28).

CBZ should be used with caution in patients with a history of congestive heart failure or cardiac arrhythmias (because it may aggravate them) and with a history of hematologic reactions to other drugs or hypersensitivity to tricyclic antidepressants. Blood levels should be monitored in patients with renal or hepatic impairment.

Oxcarbazepine

Oxcarbazepine (Trileptal®) is the 10-keto analogue of carbamazepine (Fig. 20.6). It is indicated as monotherapy or adjunctive therapy for partial seizures in adults with epilepsy, as monotherapy for the treatment of partial seizures in children 4 years of age or older, and as adjunct therapy in children 2 to 4 years of age.

Mechanism of action

Although oxcarbazepine is less potent that CBZ, its mechanism of action is similar (47). The majority of the pharmacological activity for oxcarbazepine is attributed to its primary metabolite, 10-monohydroxycarbazepine (MHD) (Fig. 20.6), the plasma levels of which may be ninefold higher than those for CBZ. Both oxcarbazepine and MHD produce a blockade of voltage-dependent sodium channels, thus decreasing repetitive firing and spread of electrical activity. An additional action on calcium

and potassium channels may contribute to the therapeutic effect. Like carbamazepine, oxcarbazepine may worsen juvenile myoclonic or absence seizures (41).

Pharmacokinetics

Oxcarbazepine is completely absorbed, and food has no effect on its absorption. Unlike CBZ, it does not cause autoinduction of its own metabolism. The metabolism of oxcarbazepine is different from that of CBZ. Oxcarbazepine is reduced by cytosolic enzymes to MHD before its O-glucuronidation. More than 95% of its oral dose is excreted as conjugated metabolites, with approximately 4% of the drug converted to inactive 10,11-dihydroxy CBZ. Unlike CBZ, no epoxide nor aromatic hydroxylation metabolites are formed. The half-life is 2 hours for oxcarbazepine and 9 hours for the active 10-monohydroxy metabolite. In patients with impaired renal function, the half-life for MHD is prolonged to 19 hours, with a doubling in its area under the plasma concentration curve. Peak plasma concentration following an oral dose occurs at approximately 4.5 hours.

Oxcarbazepine induces CYP3A4/5 and UTP, and it also inhibits CYP2C19, producing significant effects on the plasma concentration of other drugs. Therefore, oxcarbazepine decreases felodipine bioavailability and lowers plasma levels for lamotrigine, CBZ, CBZ epoxide, calcium channel blockers, and oral contraceptives (48). Oxcarbazepine increases plasma levels of phenobarbital and phenytoin. Unlike carbamazepine, oxcarbazepine has no effect on plasma levels of risperidone or olanzepine (49,50). The plasma levels for oxcarbazepine or MHD are decreased by CBZ, phenobarbital, phenytoin, valproate, and verapamil. Serum MHD may decrease during pregnancy but increase following delivery (51). Oxcarbazepine clearance is decreased in renal impairment and the elderly. In children, a higher dose/kg for oxcarbazepine than in adults is required to obtain an effective plasma concentration.

Adverse effects

Patients with hypersensitivity reactions to carbamazepine can be expected to show cross-sensitivity (e.g., rash) or related problems to oxcarbazepine. The improved toxicity profile for oxcarbazepine when compared to CBZ may result from absence of the epoxide or CBZ-iminoquinone metabolites (47). The most common side effects are headache, dizziness, nystagmus, blurred vision, somnolence, nausea, ataxia, and fatigue. The incidence of adverse effects has been related to elevated serum MHD concentrations (52). Adverse effects on cognitive status, hyponatremia, and serious dermatological reactions have been reported, as has hyponatremia (53).

Barbiturates

The barbiturates are substituted pyrimidine derivatives with an ureide configuration (Fig. 20.4). They are lipophilic weak acids (pK_a 7–8) that are well distributed into brain (see Appendix A for the respective pKa values). Although many barbiturates display sedative-hypnotic activity (see Chapter 19), only a few have antiseizure properties. Paradoxically, many barbiturates cause convulsions at larger doses. The barbiturates clinically useful as AEDs are phenobarbital, mephobarbital, and primidone (Fig. 20.8). In laboratory animals, phenobarbital is effective by several tests in nontoxic doses. It is active against electrically induced seizures (MES), and it elevates the threshold for pentylenetetrazole stimulation. The mechanism of antiseizure action for the barbiturates

is unknown but is thought to involve blockade of sodium channels and enhancement of GABA-mediated inhibitory transmission.

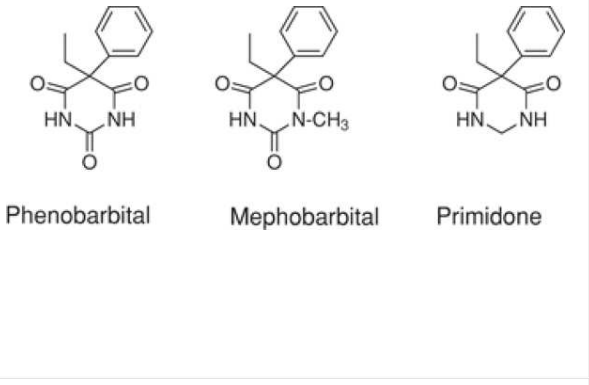

Fig. 20.8. Barbiturates.

Phenobarbital

Phenobarbital is commonly used for convulsive disorders and is the drug of choice for seizures in infants up to 2 months of age. Phenobarbital is indicated for the treatment of partial and generalized tonic-clonic seizures in all age groups, although it is less effective than phenytoin or CBZ in adults (40). Although occasionally used as monotherapy, it usually is combined with another AED. Phenobarbital may be administered parenterally, as its sodium salt, for emergency control of acute convulsive

disorders associated with eclampsia (although magnesium sulfate is the standard treatment), meningitis, tetanus, and toxic reactions to strychnine or local anesthetics. Because of its slow onset of action, it is administered after benzodiazepines for the treatment of status epilepticus.

Pharmacokinetics

Phenobarbital is a weak acid (pK_a 7.4, log P = 1.53 at pH 7.4) that is approximately 50% ionized at physiologic pH and is well distributed into the CNS. Its oral absorption is slow but nearly complete, with an oral bioavailability of 80–100%, and it shows linear kinetics. Phenobarbital is 40 to 60% protein bound and exhibits a long plasma half-life of 2 to 6 days, which yields an extremely stable plasma concentration. Approximately 25 to 50% of a phenobarbital dose is excreted unchanged in the urine. The remainder is metabolized primarily by hydroxylation to its inactive metabolite, 5-p-hydroxyphenyl-5-ethyl-barbituric acid, which is then conjugated as its glucuronide or sulfate and is excreted in the urine. Some of the conjugated metabolites may appear in the feces from enterohepatic cycling. Alkalinizing the urine or increasing the urine flow substantially increases the rate of excretion of unchanged phenobarbital and its metabolites. Phenobarbital is a potent liver enzyme–inducing drug of CYP3A4 and increases the ability of the liver to metabolize many drugs, when taken concurrently, that normally are metabolized by CYP3A4. It also induces UGTs and increased formation of glucuronidation. No conclusive evidence, however, shows that phenobarbital induces its own metabolism (autoinducer), as does CBZ.

Because of its inducing effect on hepatic enzymes, phenobarbital has many drug interactions, decreasing plasma levels of CBZ, valproate, lamotrigine, tiagabine, zonisamide, warfarin, theophylline, cimetidine, and those of other CYP3A4 substrates. Serum concentrations of phenobarbital are increased by valproate.

Adverse effects

Serious toxicity is rare; however, drowsiness is the most common side effect reported for phenobarbital. Of the barbiturates, only phenobarbital, mephobarbital, and primidone are antiseizure at subhypnotic doses. The sedative effect of phenobarbital limits its use in older children and adults, although tolerance to the sedative effects often develops. When compared to phenytoin or CBZ, phenobarbital shows more sedation, irritability, paradoxical hyperactivity, and impaired intellectual function. This may prove to be particularly troublesome in children, especially those of school age, and in the elderly. Quite rare are idiosyncratic hypersensitivity reactions to phenobarbital that include rash, agranulocytosis, aplastic anemia, and hepatitis. Although the mechanism by which the phenobarbital and other aromatic anticonvulsants induce hypersensitivity reactions has not been well characterized, recent studies have suggested that the immune response elicited may be caused, at least in part, by the metabolism of phenobarbital into chemically reactive metabolites, which may be the critical step in the formation of protein adducts and subsequent immune responses (see discussion for CBZ). Long-term use of phenobarbital may precipitate folate, vitamin K, or vitamin D deficiencies.

Phenobarbital should be used with caution in patients with hepatic impairment; therefore, a dose reduction may be needed. It should be avoided in patients with renal impairment. Barbiturates are known to cause fetal abnormalities and a neonatal coagulation defect responsive to vitamin K.

Mephobarbital (Mebaral)

Mephobarbital is a barbiturate-derivative AED with a pK_a of 7.7 (log P = 1.84 at pH 7.4). Approximately 50% of an oral dose of mephobarbital is absorbed from the gastrointestinal tract. The plasma concentrations required for its therapeutic effects are unknown. The principal route of mephobarbital metabolism is N-demethylation by the liver to form phenobarbital, which may be excreted in the urine unchanged and as its p-hydroxy metabolite and glucuronide or sulfate conjugates (see Fig. 19.6). Conversion to the 4-hydroxy metabolite is stereoselective, being catalyzed by either CYP2C19 (R-enantiomer) or CYP2B6 (S-enantiomer); individuals who are CYP2C19 poor metabolizers show decreased clearance (54). Approximately 75% of a single oral dose of mephobarbital is converted to phenobarbital. It has not been determined whether mephobarbital contributes to the antiseizure effect or whether it results from its active metabolite, phenobarbital. Similarly, it is unclear whether mephobarbital, like phenobarbital, is a potent inducer of the enzymes involved in the metabolism of other drugs, but because the drug is chemically and pharmacologically similar to phenobarbital and is metabolized to phenobarbital, this possibility is likely.

Mephobarbital is less commonly used in the treatment of generalized and partial seizures. Like phenobarbital, it is classified as a long-acting barbiturate. No evidence exists that it is more effective than phenobarbital in equivalent doses; however, it may be less sedating in children.

Primidone (Mysoline)

Primidone is the 2-deoxy derivative of phenobarbital (Fig. 20.8) and is approved by the U.S. FDA for initial or adjunctive treatment of simple partial, complex partial, and tonic-clonic seizures. It is less effective against these types of seizures than is phenytoin

or CBZ, and it shares the antiseizure and sedative actions of phenobarbital. Although not approved for the purpose, it often is used to treat benign familial tremor (essential tremor).

Pharmacokinetics

Approximately 60 to 80% of an oral dose of primidone is absorbed and slowly metabolized by the liver to phenobarbital and

phenylethylmalonamide (PEMA) (55,56). All three molecules have antiseizure effects, but PEMA appears to be weaker and to be the more toxic metabolite. During chronic therapy, approximately 15 to 25% of an oral dose of primidone is excreted in the urine unchanged, 15 to 25% metabolized to phenobarbital, and 50 to 70% excreted as PEMA (half-life, 24–48 hours). The phenobarbital metabolite may be excreted in the urine unchanged, as its p-hydroxy metabolite, and as glucuronide or sulfate conjugates. Following an oral dose, the peak plasma levels for primidone are reached in approximately 4 hours, with a reported half-life of 10 to 12 hours. Plasma concentrations in the range of 8 to 12 μg/mL control seizures and minimize adverse effects. Primidone shows antiseizure activity before the phenobarbital levels reach therapeutic range. Only after chronic dosing of primidone are the levels of phenobarbital significant, suggesting autoinduction. Serum levels of chronically administered primidone exceed those of its metabolite, phenobarbital, thus demonstrating that it has antiseizure activity independent of phenobarbital. When primidone is coadministered with enzyme-inducing AEDs, the levels of its phenobarbital metabolite may be two- to threefold higher than those in the noninduced state. Protein binding of primidone and PEMA is negligible, and the phenobarbital metabolite is approximately 50% protein bound.

Primidone use is associated with decreases in CBZ, lamotrigine, valproate, tiagabine, and zonisamide serum levels. Primidone levels are increased by nicotinamide and isoniazid. Hydantoins increase the plasma concentrations of primidone, phenobarbital, and PEMA. CBZ increases levels of phenobarbital derived from primidone. Primidone levels are decreased by succinimides, CBZ, and acetazolamide.

Adverse effects

As with phenobarbital, serious toxicity for primidone is rare, although it may cause disabling sedation, irritability, and decreased mental functioning in a number of persons. Ataxia, dysphoria, idiosyncratic rash, leukopenia, agranulocytosis, lymphadenopathy, hepatitis, and a systemic lupus erythematosus–like syndrome have been reported adverse effects for primidone. Deficiencies of folic acid and of vitamins D and K are possible with long-term therapy of primidone, as is a folate-responsive megaloblastic anemia. Measurement of the complete blood cell count should be performed at 6-month intervals (40).

Benzodiazepines

This class of drugs has been widely used as sedative-hypnotics and antianxiety drugs (see Chapters 19 and 22). In laboratory animals, benzodiazepines display outstanding antiseizure properties against seizures induced by maximal electroshock and pentylenetetrazole. The benzodiazepines diazepam, lorazepam, clonazepam, clorazepate dipotassium, and midazolam are effective for seizure control (Table 20.2 and Fig. 20.9). All benzodiazepines enter cerebral tissue rapidly. Although the duration of action is short for diazepam (2 hours) and midazolam (3–4 hours), longer for clonazepam (24 hours), and much longer for lorazepam (up to 72 hours), no correlation exists with the plasma concentration–time profiles for these drugs (57,58). Diazepam and lorazepam can be administered either IV or IM for control of status epilepticus; however, absorption is slower from the IM site. Midazolam is particularly useful for treating status epilepticus, because its imidazole ring is open at low pH, allowing it to be dissolved in aqueous solution for IM injection, but is closed at physiologic pH, increasing lipophilicity with rapid IM absorption, brain penetration, and fast onset of action. When administered IM, midazolam has a faster onset of action than diazepam and lorazepam because of its rapid absorption from the injection site, with an efficacy at least equal to that of IV diazepam (57,58). Seizure arrest usually is attained within 5 to 10 minutes. In addition, the use of midazolam by the buccal route for initial treatment of acute seizure activity has been shown to be more effective and without increased respiratory depression as compared to the use of rectal diazepam (59). Midazolam has been used intranasally as well (60,61). Lorazepam, although not approved by the U.S. FDA for this purpose, is preferred by some clinicians for the treatment of status epilepticus because of its longer duration of action.

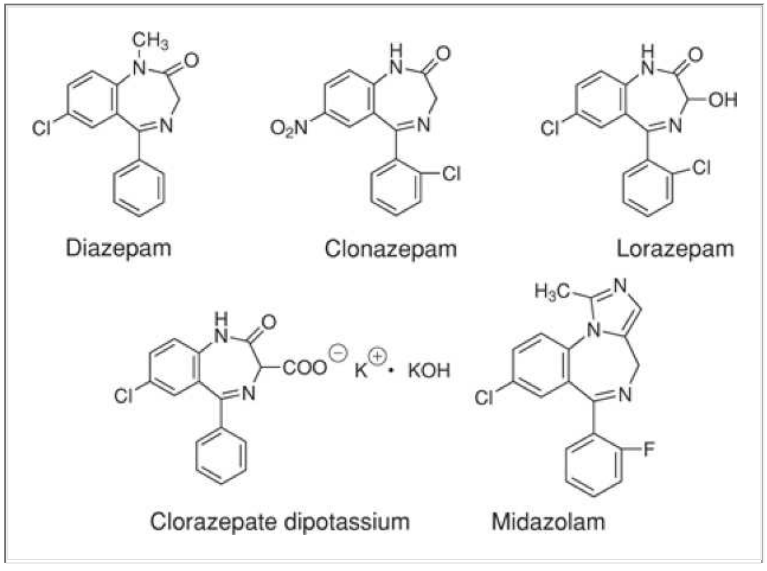

Fig. 20.9. Benzodiazepines.

Mechanism of action

The benzodiazepines are thought to produce their antiseizure effects primarily by enhancing the effect of the inhibitory neurotransmitter GABA on the $GABA_A$ chloride channel (Figs. 20.1 and 20.2).

Additional evidence suggests that the benzodiazepines may diminish voltage-dependent sodium, potassium, and calcium currents in a manner independent of the $GABA_A$/benzodiazepine receptor complex.

Diazepam (Valium)

Diazepam is given orally for adjunctive control of convulsive disorders, as a rectal gel (Diastat) for refractory patients with epilepsy on a stable regimen of AEDs who require intermittent use of diazepam to control bouts of increased seizure activity, and parenterally as part of the regimen for the treatment of status epilepticus or other severe, recurrent seizures. Rectal diazepam gel is an effective and well-tolerated therapy for acute repetitive seizures (59).

Pharmacokinetics

Orally administered diazepam is less effective as an AED, because tolerance to the antiseizure effects of diazepam develops within a short period. Diazepam gel is rapidly absorbed rectally, having greater than 90% bioavailability. In addition to cluster seizures, it has been proven to be useful to control prolonged febrile seizures in children.

Intravenously administered diazepam is the route of choice for rapid control of status epilepticus (62). Because of its high lipid solubility, IV diazepam enters the CNS rapidly. However, the initial high brain concentration is reduced quickly because of its redistribution; thus, status epilepticus may return. To prevent the return of status epilepticus, the initial dose of diazepam is followed sequentially by parenteral phenytoin (fosphenytoin) and phenobarbital as needed for control of tonic-clonic status epilepticus. For absence status epilepticus, diazepam usually is followed by ethosuximide.

The half-life for diazepam is 46 hours and is metabolized by CYP2C19 and CYP3A4 to desmethyldiazepam, an active metabolite with a half-life of 71 hours. Diazepam is 95% protein bound. Cimetidine, by inhibiting CYP3A4, decreases the metabolism and clearance of diazepam. Drugs that affect the activity of CYP2C19 or CYP3A4 may alter diazepam kinetics, and vice versa.

Adverse effects

The most frequent side effect for diazepam is somnolence; dizziness, ataxia, headache, nervousness, euphoria, and rash occur less frequently. Excessive use of rectal diazepam may produce rebound seizures (63). Intravenous administration may produce infrequent respiratory depression and hypotension. Other sedative drugs, such as barbiturates, valproate, narcotics, phenothiazines, monoamine oxidase inhibitors, and antidepressants, can potentiate the effects of diazepam.

Because diazepam clearance is decreased in the elderly and in patients with hepatic insufficiency, a dosage reduction may be warranted. Intravenous diazepam should be used cautiously in patients who are elderly, very ill, or have limited pulmonary reserve, because respiratory depression has occurred. Rarely, IV diazepam is given to patients for absence status (typical and atypical), because it will precipitate tonic status epileptic.

Clonazepam

Clonazepam (Klonopin) was approved in 1975 for monotherapy or adjunctive treatment of akinetic (atonic), myoclonic, and absence variant seizures (64). Clonazepam also was found to be effective in controlling absence seizures, but because of the high incidence of side effects, it is rated second to ethosuximide. It may be useful, however, in absence seizures when succinimide therapy has failed. It is considered to be a third-line drug after 1) ethosuximide or valproate and 2) lamotrigine or valproate for the treatment of absence seizures. It is ineffective for treatment of generalized clonic-tonic seizures.

Clonazepam is well absorbed, 95 to 98% protein bound, and extensively metabolized by CYP3A4. Clonazepam displays a wide spectrum of antiseizure activities and is one of the most potent AEDs. Side effects are common, however, and the development of tolerance is more frequent than with ethosuximide or valproate. Sedation is prominent, especially early in treatment. Drowsiness, ataxia, and behavioral changes may be disabling, but slowly increasing its dose over a 2-week period is recommended to minimize adverse effects. Diplopia, headaches, nystagmus, and other neurologic effects have been reported with the use of clonazepam.

Serum levels of clonazepam are decreased by the enzyme-inducing properties of phenobarbital, phenytoin, and CBZ. Concurrent administration of amphetamines, methylphenidate, ethanol, antianxiety drugs, or antipsychotics may cause CNS depression or altered respiration. The combined administration of clonazepam and valproate may cause absence status, and in patients displaying a mixed seizure pattern, clonazepam may precipitate grand mal seizures.

Clorazepate dipotassium

Clorazepate dipotassium (Tranxene) was approved for use as an AED by the U.S. FDA in 1981. It is less commonly used as

adjunct therapy for the management of partial seizures in adults and children older than 9 years. Clorazepate is decarboxylated by the acidity of the stomach to desmethyldiazepam, which also is the major active metabolite of diazepam. Therefore, clorazepate exhibits the profile and properties of diazepam.

Lorazepam (Ativan)

Lorazepam is a benzodiazepine (Fig. 20.6), with pK_a values of 1.3 and 11.5. Its parenteral solutions are formulated with polyethylene glycol and dilution with diluents may cause its crystallization from solution. Lorazepam also is used IV or IM for the management of status epilepticus. Although IV diazepam has been used more extensively, some clinicians prefer IV lorazepam because of its more prolonged duration of effect. It has been recommended for initial treatment of generalized convulsive status epilepticus in the elderly (65). A long-acting AED, such as IV phenytoin or fosphenytoin, can be added to IV benzodiazepine therapy for the management of recurring seizures associated with status epilepticus.

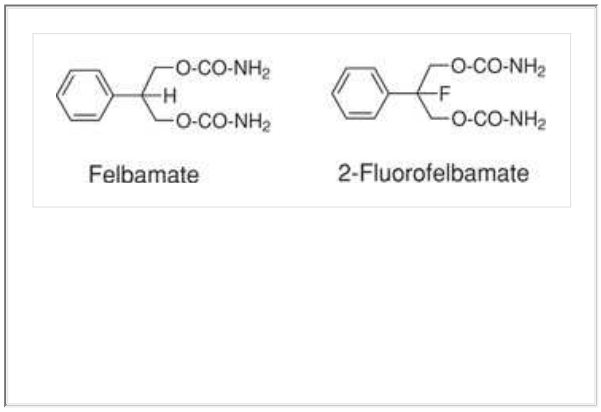
Intramuscular lorazepam is slowly absorbed, with peak plasma concentrations reached in approximately 60 to 90 minutes. The half-life for unconjugated lorazepam is approximately 16 hours when given IV or IM, and it is eliminated in the urine as its major metabolite, lorazepam 3-O-glucuronide. Lorazepam glucuronide has no demonstrable CNS activity in animals but has a half-life of approximately 18 hours. Lorazepam is 85% bound to plasma proteins. Drugs that inhibit or induce the oxidative metabolism of benzodiazepines (CYP3A4) are less likely to affect lorazepam, because it undergoes only glucuronide conjugation.

Other benzodiazepines

In addition to their anxiolytic and sedative-hypnotic properties, several other benzodiazepines also display antiseizure activity. They include clobazam and nitrazepam, which are used outside the United States.; they have not demonstrated any clinical advantage over clonazepam.

Bis-Carbamates

Felbamate (Felbatol)



Felbamate is a dicarbamate that is structurally similar to the antianxiety drug meprobamate. It was approved by the U.S. FDA for antiseizure use in 1993. Following the occurrence of rare cases of aplastic anemia and of severe hepatotoxicity associated with the use of felbamate during early 1994, however, a black box warning was added to the drug's package insert (53). Despite this, felbamate continues to be used in many patients, although not as a first-line treatment. These toxicity effects may be attributed to the formation of toxic metabolites (66). Although felbamate use is now uncommon, it is used for severe refractory seizures, either partial, myoclonic, or atonic, or in Lennox-Gastaut syndrome.

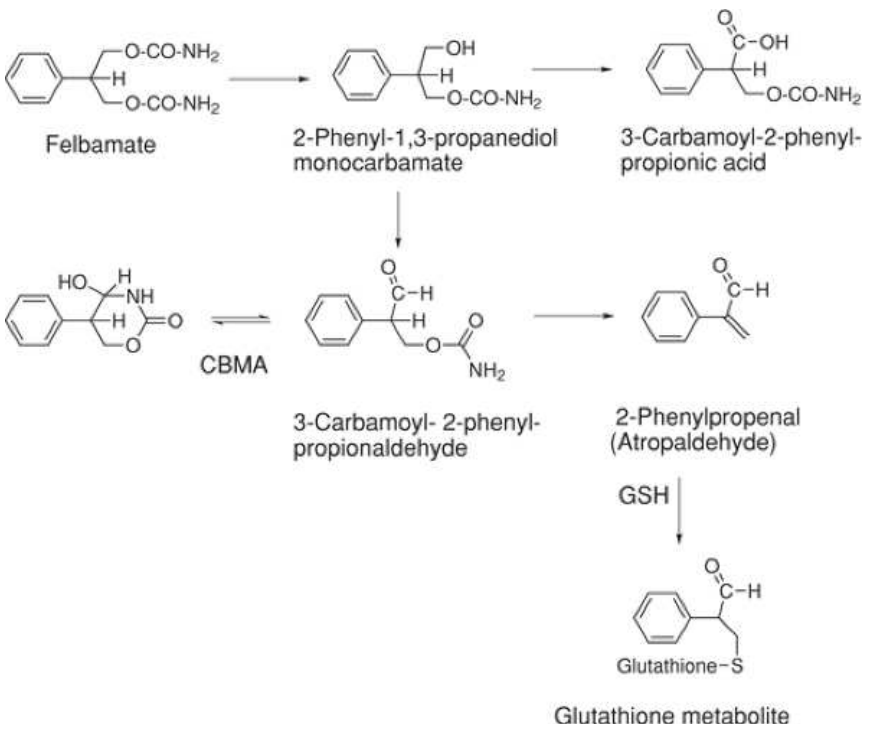


Fig. 20.10. Metabolism of felbamate.

Mechanism of action

Although its mechanism of action is unknown, felbamate antagonizes the NMDA receptor by binding to the glycine recognition site, preventing the usual glycine-induced increase in calcium channel opening frequency and lowering calcium currents (Fig. 20.2) (67).

Metabolism and pharmacokinetics

Although the metabolism of felbamate has not been fully characterized, felbamate is esterase hydrolyzed to its monocarbamate metabolite, 2-phenyl-1,3-propanediol monocarbamate, which subsequently is oxidized via aldehyde dehydrogenase to its major human metabolite 3-carbamoyl-2-phenylpropionic acid (Fig. 20.10). Other metabolites include the p-hydroxy and mercapturic acid metabolites of felbamate, which have been identified in human urine. Felbamate is a substrate for CYP2C19, with minor activity for CYP3A4 and CYP2E1. Thompson et al. (68) has provided evidence for the formation of the reactive metabolite, 3-carbamoyl-2-phenylpropionaldehyde (CBMA), from the alcohol oxidation of 2-phenyl-1,3-propanediol monocarbamate. CBMA then undergoes spontaneous elimination to another reactive intermediate, 2-phenylpropenal (more commonly known as atropaldehyde), which is proposed to play a role

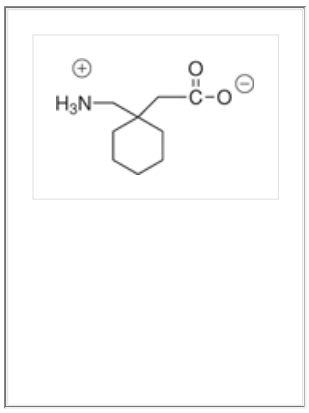
P.538

in the development of toxicity during felbamate therapy. CBMA or a further product has been shown to provoke an immune response in mice (69). Evidence for in vivo atropaldehyde formation was confirmed with the identification of its mercapturic acid conjugates in human urine after felbamate administration. This is consistent with the hypothesis that atropaldehyde reacts rapidly with thiol nucleophiles, such as glutathione, to form mercapturates (see Chapter 10). More recently, a fluorine analogue of felbamate was synthesized in which the benzylic C_2 hydrogen of the propane chain was replaced with fluorine, preventing the formation of atropaldehyde and confirming that the acidic benzylic hydrogen plays a pivotal role in its formation (70). This analogue is presently undergoing drug development. Felbamate administration exhibited linear kinetics, with a half-life of 20 to 23 hours in the absence of enzyme-inducing AEDs. Approximately 50% of an oral dose of felbamate is excreted unchanged.

Adverse effects

Felbamate has exhibited the rare occurrence of aplastic anemia and of severe hepatotoxicity, which may be associated with the in vivo formation of reactive metabolites. Felbamate increases phenytoin and valproate serum levels but decreases the level of CBZ. The increase in valproate plasma concentrations by felbamate is through the inhibition of β-oxidation. No clinically relevant pharmacokinetic interactions have been noted between felbamate and lamotrigine, clonazepam, vigabatrin, or the active monohydroxy metabolite of oxcarbazepine. The enzyme inducers phenytoin, phenobarbital, and CBZ decrease felbamate plasma levels by increasing its clearance.

Gabapentin (Neurontin)



Mechanism of action

Gabapentin is a water-soluble amino acid originally designed to be a GABA-mimetic analogue capable of penetrating the CNS. Surprisingly, it has no direct GABA-mimetic activity, nor is it active on sodium channels. The mechanism of action remains unknown, although it has been suggested that gabapentin may alter the metabolism or release of GABA (Fig. 20.2). Gabapentin raises brain GABA levels in patients with epilepsy (71). Recent studies have demonstrated gabapentin binding to calcium channels in a manner that can be allosterically modulated (72).

Gabapentin is indicated as an adjunct for use against partial seizures with or without secondary generalization, in patients older than 12 years, and as adjunct for the treatment of partial seizures in children 3 to 12 years of age. It also is approved for the treatment of postherpetic neuralgia.

Pharmacokinetics

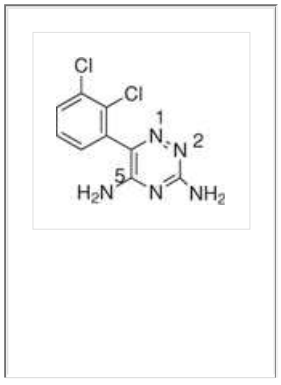
The pharmacokinetic properties for gabapentin generally are favorable, with a bioavailability of 60% when given in low doses and somewhat less when given at higher doses because of saturable intestinal uptake by the L-amino-acid transporter (73). The L-amino-acid transporter is very susceptible to substrate saturation (low K_m value). Its absorption and distribution into the CNS appears to be dependent on this amino acid transporter. Following the administration of an oral dose, gabapentin reaches peak plasma concentration in 2 to 3 hours. Additionally, it exhibits linear pharmacokinetics. Moreover, it is not extensively metabolized, nor is it an inducer of hepatic metabolizing enzymes. The elimination of unmetabolized gabapentin occurs by the renal route. Although its therapeutic range is not well characterized, gabapentin has a broad therapeutic index. This implies that a wide range of doses can be used, based on individual patient needs, without significant limitation because of dose-dependent side effects. Protein binding is negligible. Its elimination half-life of 5 to 7 hours is not affected by the dose or by other drugs, and its short half-life necessitates multiple daily administration.

Adverse effects

Adverse effects of gabapentin are uncommon and not serious. The CNS effects include mild to moderate sedation, fatigue, ataxia, headache, dizziness, and diplopia. Gabapentin may exacerbate myoclonus, but the effect is mild and does not require discontinuance of the drug (53,74). It has been associated with the development of neuropsychiatric adverse events in children.

Drug interactions are infrequent with gabapentin. It does not induce hepatic metabolizing enzymes, nor do other AEDs affect its metabolism and elimination. Antacids may decrease absorption. Gabapentin dosage may need to be decreased in patients with renal disease or in the elderly.

Lamotrigine (Lamictal)



Lamotrigine is a 5-phenyl-1,2,4-triazine derivative indicated as monotherapy or as an adjunct for partial seizures in adults, as adjunct in patients with Lennox-Gastaut syndrome, and as adjunct for partial seizures in children 2 years of age and older. Lamotrigine may have additional benefit in combating myoclonic and typical absence seizures. It is approved for use in the maintenance treatment of bipolar disorder.

Mechanism of action

The most probable explanation for lamotrigine's efficacy is its ability to produce a blockade of sodium channel repetitive firing. In addition, lamotrigine appears to reduce glutaminergic excitatory transmission, although the mechanism for this action remains unclear (75,76).

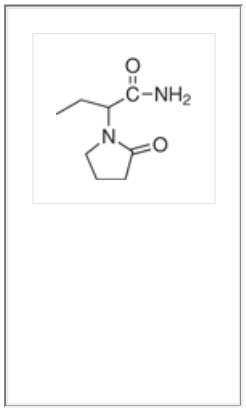
Pharmacokinetics

Following oral administration, lamotrigine is absorbed rapidly and completely, exhibiting linear pharmacokinetics and modest protein binding (55%). Lamotrigine is metabolized predominantly by N-glucuronidation and subsequent urinary elimination of its major metabolite, the quaternary 2-N-glucuronide (80–90%), the minor 5-amino-N-glucuronide (8–10%), and unchanged drug (8–10%) (77). Lamotrigine's usual elimination half-life of 24–35 hours is reduced to 13–15 hours in patients taking enzyme-inducing AEDs. The presence of valproate increases the lamotrigine half-life substantially by inhibiting N-glucuronidation, necessitating a reduction in dose to avoid toxicity. Hepatic disease patients may demonstrate a reduced capacity to for lamotrigine glucuronidation, thus reducing its rate of clearance.

Adverse effects

The usefulness of lamotrigine is limited by the increased incidence of serious rashes, particularly in children or patients taking valproate (53). This increase, however, may be attenuated by very slow dose escalation, because most rashes appear within the first 8 weeks of treatment. The drug should be discontinued if a rash appears at any time. Additionally, lamotrigine may be associated with development of myoclonus after 2 to 3 years of drug treatment (78). Additional common side effects associated with lamotrigine therapy include dizziness, diplopia, headache, ataxia, blurred vision, somnolence, and nausea.

S-(–)-levetiracetam (Keppra)



S-(–)-levetiracetam is a pyrrolidone derivative unrelated to the structures of other AEDs. It is indicated as an adjunct in the treatment of partial onset seizures in adults, and it has shown some benefit in clinical trials for generalized tonic-clonic seizures (GTC) and myoclonic seizures in adults and children (79,80).

Mechanism of action

The mechanism of action for S-(–)-levetiracetam is unknown. It does not appear to interact with any of the recognized excitatory or inhibitory neural mechanism. A CNS-specific binding site for S-(–)-levetiracetam has been identified as the synaptic vesicle protein (SV2A). Knockout animals without SV2A proteins accumulated presynaptic Ca^{2+} during consecutive action potentials that destabilized synaptic circuits and induced epilepsy. Thus, it appears that SV2A plays a major role in the antiepileptic properties of S-(–)-levetiracetam, which acts by modulating the function of SV2A and the regulation of Ca^{2+}-mediated synaptic transmission. These data support previous indications that S-(–)-levetiracetam possesses a mechanism of action distinct from that of other antiepileptic drugs. Three SV2 isoforms (SV2A, SV2B, and SV2C) have been identified, each of which has a unique distribution in brain, suggesting synapse-specific functions (81) as well as antagonism of neuronal synchronization (74,82).

Pharmacokinetics

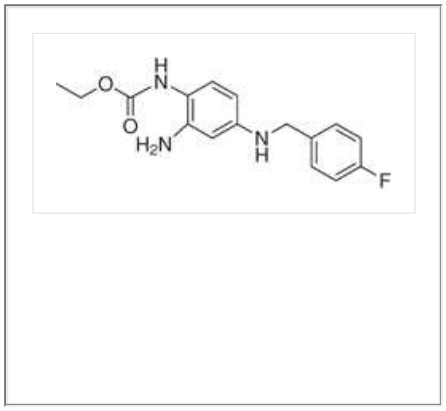
S-(–)-levetiracetam displays rapid and complete absorption, although food slows the rate but not the extent of absorption. It

exhibits linear pharmacokinetics and is minimally protein bound (83). Approximately 60% of an oral dose is excreted into the urine unchanged and 24 to 30% as its carboxylic acid metabolite, with an elimination half-life in adults of approximately 7 hours. Although S-(–)-levetiracetam is not metabolized by hepatic CYP450, UGT, or epoxide hydrolase, it is esterase hydrolyzed to its carboxylic acid metabolite (loss of amido group), which is not affected by the hepatic metabolizing enzymes.

Adverse effects

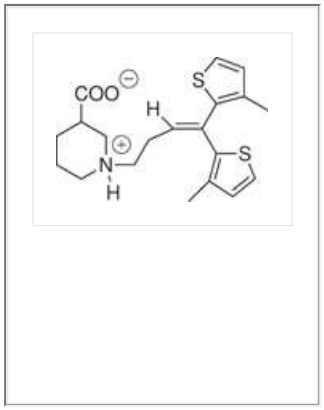
The risk of clinically relevant drug interactions is minimal with S-(–)-levetiracetam, because it does not alter the pharmacokinetics of coadministered drugs by inhibition or induction of hepatic enzymes (84). Toxic effects include mild to moderate somnolence, asthenia, ataxia, and dizziness; these effects seldom require discontinuance. An increase in the incidence of behavioral abnormalities in children and in adults having a previous history of neuropsychiatric problems has been noted (85). Its use in the elderly or in patients with renal impairment will require an individualization of dose, and an additional dose is needed after renal dialysis. Levetiracetam was associated with developmental toxicity in the offspring of pregnant animals.

Retigabine



Retigabine is an investigational antiepileptic drug with a novel mechanism of action that involves opening of neuronal voltage-activated K^+ channels that serves to stabilize the membrane potential and to control neuronal excitability. Thus, retigabine also may prove to be useful in the treatment of other diseases associated with neuronal hyperexcitability.

Tiagabine (Gabitril)



Mechanism of action

Tiagabine is a nipecotic acid derivative with an improved ability to cross the blood-brain barrier. It was rationally designed to be a GABA uptake inhibitor based on the fact that nipecotic acid (piperidine-3-carboxylic acid) inhibits GABA uptake by glial

cells. Tiagabine binds to the GABA transporter GAT1, blocking the uptake of GABA into both neurons and glia, thus enhancing GABA-mediated inhibition (Fig. 20.2) (52,86). Tiagabine is presently approved for adjunct use in patients with epilepsy who are older than 12 years and have partial seizures not controlled by first-line drugs.

Pharmacokinetics

Tiagabine is well absorbed, with an oral bioavailability of 90 to 95%. It displays linear pharmacokinetics, with a plasma half-life of 5 to 8 hours, necessitating a multiple daily dosing regimen (87). It also is highly protein bound (96%). The major pathway of metabolism for tiagabine is oxidation by CYP3A4, followed by glucuronidation. Its pharmacokinetics are altered by the

coadministration of enzyme-inducing AEDs, even though tiagabine does not appear to induce or inhibit hepatic microsomal metabolizing enzymes.

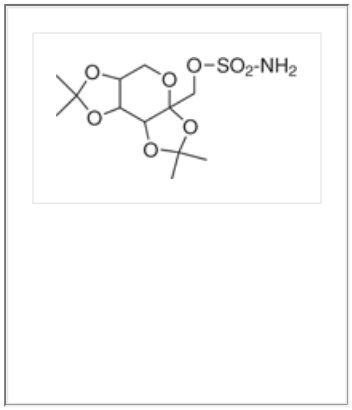
Adverse effects

Side effects are more common with tiagabine than with other adjunct drugs and most often involve the CNS. They include somnolence, headache, dizziness, tremor, abnormal thinking, depression, and psychosis. Furthermore, recent reports have implicated tiagabine in the development of nonconvulsive status epilepticus (88,89). There is an increased risk of seizure in patients being treated for off-label psychiatric indications. Tiagabine may interfere with visual color perception (90).

Tiagabine does not affect the hepatic metabolism of other AEDs, but its half-life is decreased by enzyme-inducing AEDs, such as CBZ, phenytoin, and barbiturates. Other CYP3A4-inducing drugs may act similarly. Valproate decreases the protein binding of tiagabine. increasing its plasma concentration in these patients.

Hepatic disease causes decreased clearance of tiagabine, and a dose reduction may be required. Renal disease does not affect elimination.

Topiramate (Topamax)



Topiramate is a sulfamate-substituted monosaccharide derived from fructose with a broad spectrum of AED activity. It is approved for monotherapy or as an adjunct drug for partial or primary generalized tonic-clonic seizures in patients older than 10 years, as adjunct therapy in children aged from 2 to 10 years with partial-onset seizures, and in persons older than 2 years with Lennox-Gastaut syndrome (40,53). Topiramate also is approved for the prophylaxis of migraine headaches.

Mechanism of action

The mechanism of action for topiramate is unknown, but several actions are thought to contribute to its AED activity (91). It blocks repetitive firing by acting on sodium channels, may enhance $GABA_A$-mediated chloride flux, and appears to be an antagonist at the AMPA and KA receptors, thus blocking the effect of glutamate (Fig. 20.2) (92,93). In addition, recent evidence suggests inhibition of L-type calcium currents (94).

Pharmacokinetics

Topiramate is rapidly absorbed, with at least an 80 to 95% oral bioavailability that is unaffected by food. Following an oral dose of topiramate, peak plasma concentration is reached in 1 to 4 hours, exhibiting linear pharmacokinetics (95). Protein binding is minimal (<20%), and the usual elimination half-life is 20 to 30 hours, allowing a twice-daily dosing regimen. In the absence of enzyme-inducing drugs, approximately 70 to 80% of the drug is excreted unchanged in the urine, with the remainder as metabolites resulting from oxidation and hydrolysis. Enzyme-inducing AEDs alter the pharmacokinetics of topiramate by reducing its plasma levels and increasing its rate of elimination.

In children from 4 to 17 years of age, topiramate exhibits linear pharmacokinetics, with a 50% increase in clearance rate compared to adults (95). Topiramate may require up to a 50% dose reduction in patients with renal insufficiency, and a replacement dose may be needed after renal dialysis. Topiramate has demonstrated teratogenicity in animal studies.

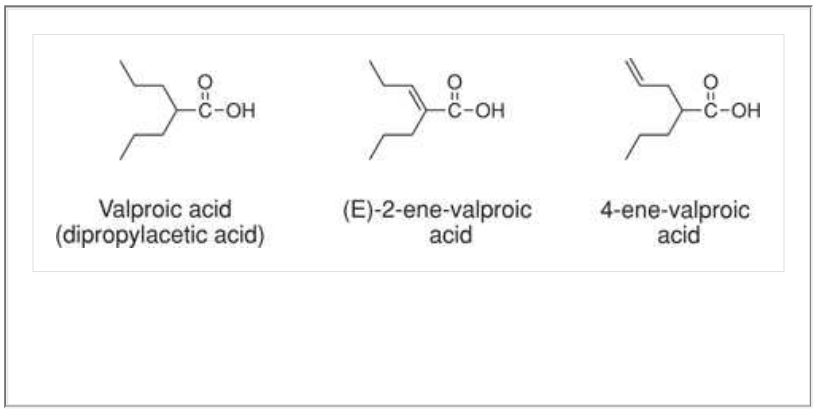
Adverse effects

Common CNS side effects associated with topiramate therapy include drowsiness, dizziness, impaired concentration and memory, speech and language difficulties, and confusion. These effects develop during the first weeks of therapy and may decline over time. Acute closed-angle glaucoma caused by topiramate requires immediate evaluation (96). Only rare hepatic or bone marrow effects have been noted thus far; however, an increased incidence of renal stones is troublesome and probably related to the drug's activity as a carbonic anhydrase inhibitor, reducing citrate excretion and increasing urinary pH. Use of additional carbonic anhydrase inhibitors, a ketogenic diet, or a family history of nephrolithiasis may be considered as contraindications for using topiramate.

Topiramate is not devoid of potential interaction properties: It induces CYP3A4 and inhibits CYP2C19, thus significantly

increasing plasma phenytoin levels. Topiramate also may decrease the effectiveness of oral contraceptives.

Valproic acid and its derivatives



Valproate is available as valproic acid (Depakene), divalproex sodium (Depakote), and valproate sodium (Depacon) for IV use. Its AED properties were discovered

serendipitously when it was used as a solvent for potential new AEDs undergoing testing. It is effective against both MES test- and pentylenetetrazole-induced seizures in animals and possesses a satisfactory margin of safety. Because the pK_a of valproic acid is 4.7, the drug is completely ionized at physiologic pH; thus, the valproate ion is almost certainly the pharmacologically active species.

Mechanism of action

Although its mechanism of action is not clearly established, valproate appears to increase the inhibitory effect of GABA, possibly by activation of glutamic acid decarboxylase or inhibition of GABA-transaminase (Fig. 20.2). The high drug concentrations required, however, cast doubt on the clinical relevance of this effect. Furthermore, valproate recently has been shown to decrease the uptake of GABA into cultured astrocytes; this action may contribute to the AED efficacy (97). Valproate is known to produce a blockade of high-frequency repetitive firing by slowing the rate of Na^+ recovery from inactivation, a mechanism consistent with the actions of phenytoin and CBZ. Valproate blocks the low-threshold T-type Ca^{2+} channel. Consequently, the overall therapeutic utility of valproate is likely caused by multiple effects.

Valproate is indicated for initial or adjunct treatment of absence seizures or as an adjunct when absence seizures occur in combination with either tonic-clonic seizures, myoclonic seizures, or both. For patients with unambiguous idiopathic generalized epilepsy, valproate often is the drug of choice, because it controls absence, myoclonic, and generalized tonic-clonic seizures well (98). It also is approved by U.S. FDA for use in complex partial seizures, occurring with or without other seizure types in adults or children 10 years of age or older. In new patients with typical absence seizures, ethosuximide is preferred to valproate because of the latter drug's risk of producing hepatotoxicity. In a comparative trial, sodium valproate and ethosuximide were equally effective when either drug was given alone or in combination with other AEDs in children with typical absence seizures. In atypical absence seizures (Lennox-Gastaut syndrome), sodium valproate is more effective, whereas in myoclonic seizures, it is less effective than clonazepam. Valproate is approved by the U.S. FDA for use in bipolar disorder and against migraine headaches.

Pharmacokinetics

Valproate undergoes rapid and complete absorption, which is only slightly slowed by food. It is 90% protein bound, and its clearance is dose-dependent because of an increase in the free fraction of the drug at higher doses. It is metabolized almost entirely by the liver, with 30 to 50% of an orally administered dose being eliminated in the urine as its acyl glucuronide conjugate, 40% from mitochondrial β-oxidation, approximately 15 to 20% by ω-oxidation, and less than 3% is excreted unchanged in urine. Its major active metabolite is (E)-2-ene valproate (*trans* 2-ene valproate). Its 4-ene metabolite has been proposed to be a reactive metabolite responsible for the hepatotoxicity of valproate (see Chapter 10). Other metabolites found in the urine include 3-oxo- and 4-hydroxyvalproate. The elimination half-life for valproate ranged from 9 to 16 hours following oral dosing regimens of 250 to 1,000 mg. Patients who are not taking enzyme-inducing AEDs (carbamazepine, phenytoin, and phenobarbital) will clear valproate more rapidly; therefore, monitoring of AED plasma concentrations should be intensified whenever concurrent AEDs are introduced or withdrawn.

Adverse effects

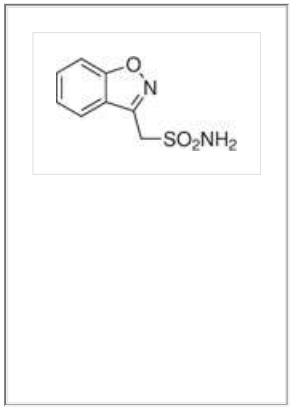
The most commonly observed side effects for valproate are gastrointestinal (anorexia, nausea, and indigestion). These effects can be minimized by selecting divalproex sodium, which is enterically coated, and by initiating therapy at a low dose. More importantly, however, valproate is associated with the development of fatal hepatotoxicity, especially in children or when coadministered with other AEDs. Frequent monitoring of liver function tests is mandatory for determining the onset of toxicity,

particularly during the first 6 months of treatment. Tremors, hematologic dyscrasias, pancreatitis, stupor, depression, behavioral anomalies, and coma also have been observed with valproate therapy.

Valproate, a substrate for hepatic CYP2C19 and CYP2C9, has an extensive pattern of drug interactions. It increases the plasma concentrations of lamotrigine, CBZ, and phenobarbital and the free fraction of phenytoin by either displacing these drugs from plasma proteins or inhibiting their metabolism. Phenytoin, phenobarbital, and CBZ cause decreased plasma concentrations of valproate, whereas felbamate increases valproate levels.

Because of its propensity for causing liver damage, valproate therapy should be avoided in persons with liver disease. It should be used with caution before surgery, because it can produce thrombocytopenia and inhibition of platelet aggregation. In pregnancy, it has been associated with an increased risk of fetal epilepsy syndrome and spina bifida.

Zonisamide (Zonegran)



Mechanism of action

Zonisamide is a sulfonamide derivative that is indicated as an adjunct for partial seizures in patients older than 16 years whose seizures are not controlled by first-line drugs. In Japan, it is used for myoclonic seizures as well. Apparently, it has more than one mechanism of action—all as yet unidentified. It is known to produce blockade of both sodium and T-type calcium channels (Fig. 20.2) (99,100). Because it also affects dopaminergic transmission, bipolar or schizoaffective disorder patients may improve.

Pharmacokinetics

The absorption for orally administered zonisamide is slow but nearly complete. Its

pharmacokinetics are nonlinear, with a half life of 50 to 70 hours when administered alone or 27 to 46 hours when administered concurrently with enzyme-inducing AEDs. Protein binding is moderate (<50%). An oral dose of zonisamide is completely absorbed, with peak plasma concentration occurring in 2 to 6 hours. Although the presence of food will delay the attainment of its peak plasma concentration, oral bioavailability does not appear to be altered. More than one-third of each oral dose is excreted in the urine in an unchanged form. The routes of metabolism for zonisamide include acetylation to form its N-acetyl metabolite, reduction by CYP3A4/CYP2D6, and the formation of an open-ring metabolite, 2-sulfamoylacetyl phenol. These metabolites subsequently are eliminated unconjugated or glucuronidated in the urine, with an elimination half-life of 63 hours. Its coadministration with enzyme-inducing AEDs, such as phenytoin, CBZ, or phenobarbital, and with valproate will alter its pharmacokinetics by reducing its half-life and serum concentration. The half-life for zonisamide is decreased to 27 hours in the presence of phenytoin, to 38 hours in the presence of either CBZ or phenobarbital, and to 46 hours with valproate. Other drugs that inhibit or induce CYP3A4 could affect the metabolism of zonisamide.

Zonisamide should be used with caution in patients with hepatic or renal disease. It also has shown to be teratogenic in animal studies.

Adverse effects

Zonisamide is contraindicated in patients with a history of allergy to sulfonamides. The most frequent side effects include somnolence, anorexia, dizziness, agitation, confusion, headache, cognitive impairment, and memory loss. In addition, an incidence of drug-induced psychosis has been noted (101). Reports from both the United States and Europe have indicated that development of renal stones may occur with use of this drug. A family history of nephrolithiasis may be a contraindication, and urinary monitoring for hypercalciuria may be warranted in bedridden patients or those receiving multiple AEDs (102). Although the incidence of severe rashes attributable to zonisamide is low, sulfonamides are associated with Stevens-Johnson syndrome. Thus, it is recommended to discontinue the drug immediately should a rash occur.

Drugs Effective Against Absence Seizures

Drugs that are effective against absence seizures include the 5-membered ureides, the oxazolidinediones and the succinimides

(Fig. 20.11), and clonazepam and lamotrigine, which have been previously discussed. An examination of the structure–activity relationship for the 5-membered heterocyclic ureides (Fig. 20.4) reveals that a small substructural difference between ring N (hydantoins), ring O (oxazolidinediones), and ring CH_2 (methylene and succinimides) results in switching from AEDs effective against partial and generalized tonic-clonic seizures to those effective against absence seizures.

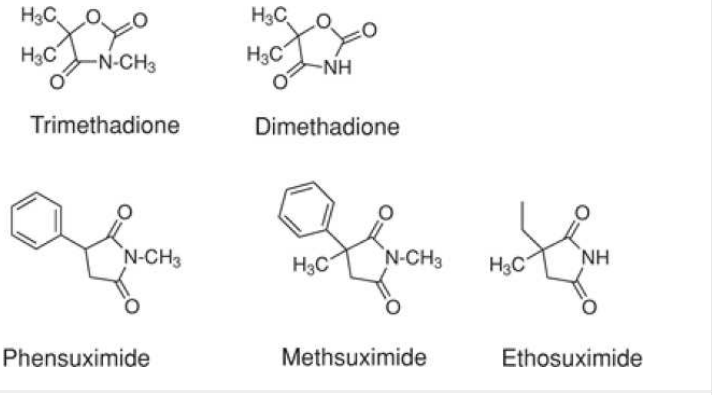


Fig. 20.11. Drugs effective against absence seizures.

Oxazolidinediones

These compounds are some of the oldest AEDs in use, having been introduced into antiseizure therapy between 1946 and 1948. At that time, no effective drugs were available to control absence seizures (petit mal disorders). Therefore, the acceptance of trimethadione in 1946 and of paramethadione in 1948 for the control of absence seizures was rapid. At present, trimethadione (Tridione) (Fig. 20.11) is indicated only for control of absence seizures refractory to treatment with other AEDs. It is ineffective against other seizure types. Trimethadione is a pro-drug and is metabolized by N-demethylation to dimethadione, which is effective in the pentylenetetrazole test, which acts by decreasing T-type calcium currents. Trimethadione is rapidly absorbed, is not protein bound, and has a half-life of 16 to 24 hours. The half-life of dimethadione, however, is substantially longer (i.e., 6–13 days), and dimethadione accumulates to concentrations greater than the parent drug. Because of its potentially fatal side effects. including aplastic anemia, nephrosis, idiosyncratic rashes, and exfoliative dermatitis, trimethadione rarely is used today. It causes malformations or fetal death in up to 87% of pregnancies. Paramethadione is no longer clinically available in the United States.

Succinimides

Because oxazolidinediones are toxic, an extensive search was undertaken to replace them with less toxic drugs. Substituting the ring O in the oxazolidinediones with a methylene group gave the antiseizure succinimides. The clinically used succinimides include ethosuximide, methsuximide, and phensuximide, which were introduced between 1951 and 1958 (Fig. 20.11) and widely accepted for the treatment of absence seizures.

Mechanism of action

Succinimides suppress the paroxysmal 3-Hz spike-and-wave activity associated with the lapses of consciousness associated with absence (petite mal) seizures, thus reducing the frequency of seizures and raising the threshold to seizures. The proposed mechanism of action involves a decrease in T-type calcium channel activity (Fig. 20.2).

Succinimides are indicated for the monotherapy of absence seizures or with concomitant therapy when additional forms of seizures occur in combination with absence seizures. These drugs are readily absorbed from the gastrointestinal tract and display very low protein binding. The drug interactions for the succinimides are less extensive than with the oxazolidinediones. They may increase plasma phenytoin levels, decrease plasma primidone levels, and either increase or decrease valproate levels, although the changes may not be clinically significant.

Renal/hepatic disease does not appear to enhance their toxicity. Extreme caution is advised, however, because succinimides can cause morphological changes to kidneys and liver. Periodic monitoring of the blood count, hepatic function, and urinalysis are recommended with the use of succinimides.

Ethosuximide (Zarontin)

Although ethosuximide is the drug of choice for treatment of simple absence seizures, it is not effective against partial complex or tonic-clonic seizures and may increase the frequency of grand mal attacks. Thus, it must be administered in combination with other AEDs when treating persons with mixed seizure types. Ethosuximide is a substrate for both CYP3A4 and CYP2E1. The major metabolite for ethosuximide is 3-(1-hydroxyethyl) succinimide, which is inactive and excreted unconjugated into the urine.

Several additional metabolites have been characterized recently (103). Approximately 20% of an oral dose is excreted unchanged.

Although ethosuximide is thought to be the least toxic of the succinimides, it can cause gastrointestinal disturbances and dose-related CNS effects, such as drowsiness, dizziness, ataxia, sleep disturbances and depression. Idiosyncratic hypersensitivity reactions include severe rashes, leukopenia, agranulocytosis (some fatal), systemic lupus erythematosus, and parkinsonian-like symptoms. In addition to being less toxic than trimethadione, ethosuximide offers a wider range of protection against different kinds of absence seizures.

Methsuximide

Although methsuximide is less commonly used, it may be indicated for the control of absence seizures refractory to other drugs. Although it does not precipitate tonic-clonic convulsions, it often is combined with phenytoin or phenobarbital when absence seizures coexist with tonic-clonic symptoms. Much of the efficacy of methsuximide is attributed to its desmethyl metabolite. The half-life of methsuximide is between 2.6 and 4.0 hours, but the half-life for N-desmethylsuximide is 25 hours, causing it to accumulate substantially. Concentrations of greater than 40 g/mL may be associated with toxicity. Methsuximide is considered to be more toxic than ethosuximide.

Phensuximide

Phensuximide occasionally is used for the treatment of absence seizures refractory to other drugs, although it is considered to be less effective than ethosuximide. It is excreted in both urine and bile, and it may cause harmless pink to red discoloration of the urine. It should be used with caution in patients with acute intermittent porphyria.

Drugs Effective Against Myoclonic Seizures

Clonazepam and valproate commonly are used to control myoclonic seizures. Studies suggest that lamotrigine and topiramate may be effective as well, although neither is approved by the U.S. FDA for this indication.

Drugs for Status Epilepticus

Diazepam, administered IV or IM, is a drug of choice for rapid control of status epilepticus. Lorazepam, although not approved by the U.S. FDA for the purpose, is preferred by some clinicians for its longer duration of action (40), and midazolam is preferred for its more rapid onset of action (67). Because of its high lipid solubility, IV diazepam enters the CNS rapidly. The initially high brain concentration is quickly reduced, however, because of its redistribution, increasing the chance of recurring status epilepticus (62). Concomitant IV injection of diazepam and phenobarbital or fosphenytoin has been suggested to overcome this difficulty (104).

Antiepileptic Drugs in Phase III Clinical Trials

Antiepileptic drugs in Phase III clinical trials are shown in Figure 20.12. Talampanel is a 2,4-benzodiazepine that is a AMPA/KA receptor antagonist. RWJ-333369 is a monocarbamate antagonist at KA receptors. Rufinamide is a 1,2,3-triazole carboxamide that blocks sodium channels. Soretilide has a mechanism of action similar to that of CBZ, and brivaracetam and seletracetam are derivatives of S-(–)-levetiracetam for treatment of myoclonic seizures.

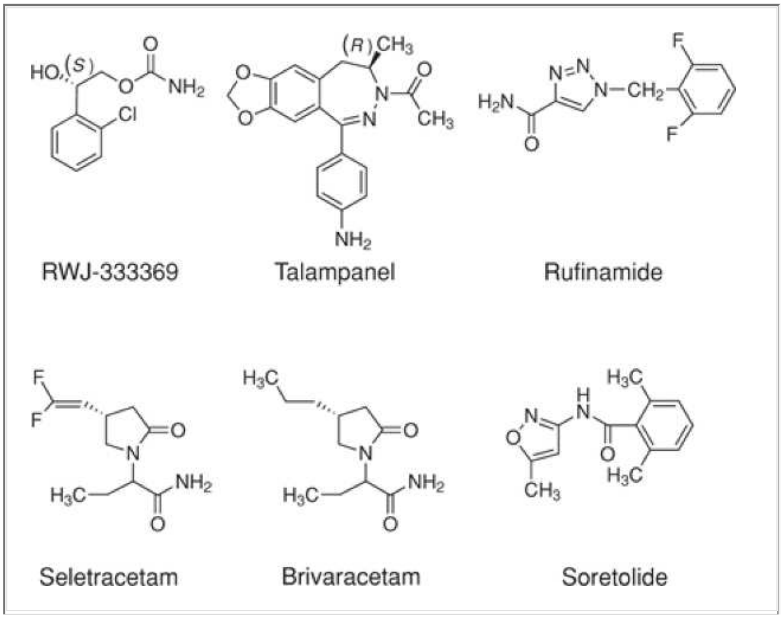

Fig. 20.12. Antiepileptic drugs in Phase III clinical trials.

Case Study

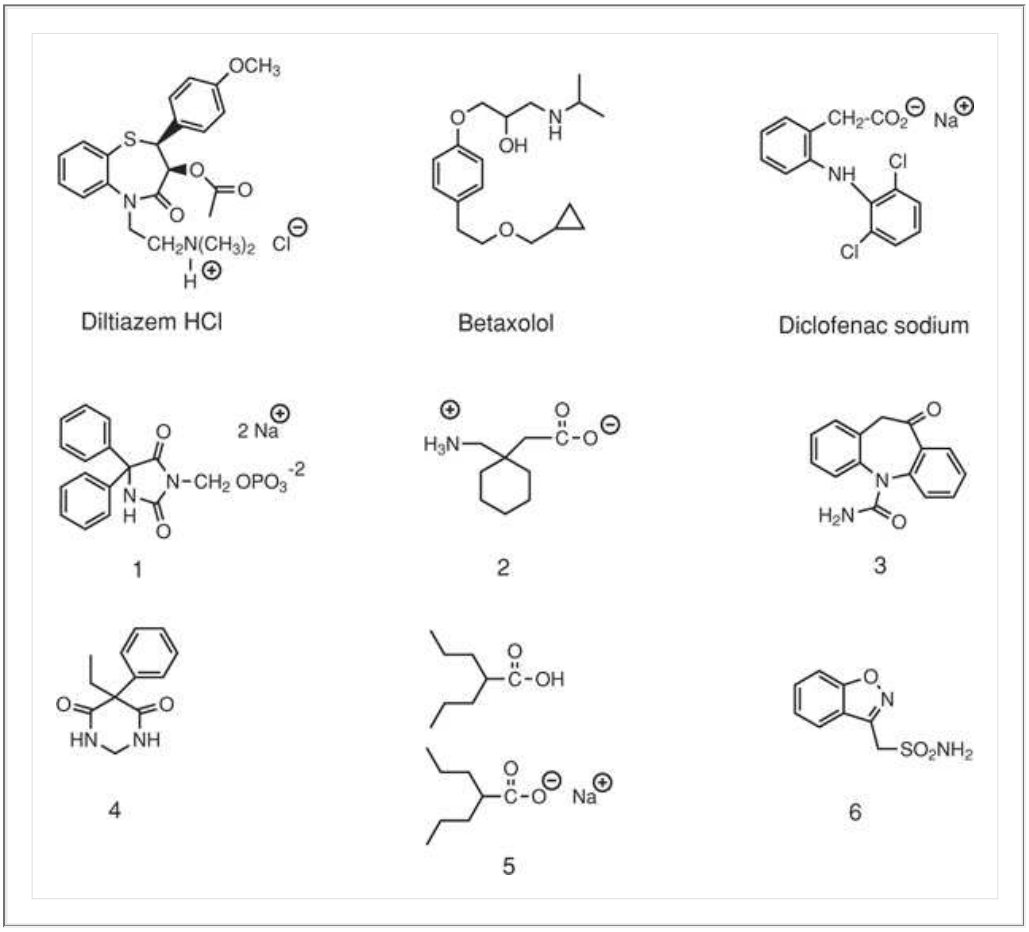
Victoria F. Roche

S. William Zito

FP is a 63-year-old physician practicing in a rural, sparsely populated county in northeast Arkansas. Although he works two days a week out of a clinic in one of his county's larger communities, he is on the road the other three days, often driving long distances to see patients who live in the more remote areas. Despite his health issues and advancing years, FP will not retire, because the patients he treats have very few alternatives for care.

FP has a history of cardiovascular disease, having survived a myocardial infarction that occurred in his mid-50s and, more recently, a stroke. Currently, he is on extended-release diltiazem (Cardiazem, 420 mg q.i.d.) and betaxolol HCl (Kerlone, 10 mg q.i.d.) for chronic stable angina coupled with hypertension. He also takes one baby aspirin each day. FP is troubled by rheumatoid arthritis, for which he takes diclofenac (Voltaren, 50 mg t.i.d.), and he has a documented allergy to sulfonamides.

FP is now facing a diagnosis of complex partial seizure disorder. The etiology of his newly acquired epilepsy is unknown, but he believes that it is related to the stroke he recently experienced. An animal lover, he is trying to acquire a “seizure dog” (a dog that can sense the onset of seizures and warn patients in time to seek care or safety) to take with him on his rural rounds. Regarding antiseizure therapy, FP has his opinions (of course) but is seeking you out to select an anticonvulsant for oral maintenance therapy. Consider the choices below, and advise this practitioner colleague.



1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all structures provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic

outcomes, and make a therapeutic decision.

5. Counsel your patient.

Chapter 21

Antidepressants

David A. Williams

Drugs covered in this chapter:

Selective norepinephrine reuptake inhibitors (SNRIs)

- Desipramine
- Nortriptyline
- Amoxepine
- Protriptyline
- Maprotiline
- Reboxetine
- Nisoxetine
- R-(2)-Atomoxetine

Selective 5-HT reuptake inhibitors (SSRIs)

- Fluoxetine
- Paroxetine
- Citalopram
- Escitalopram
- Sertraline
- Fluvoxamine

Nonselective reuptake inhibitors (NSRIs)

- Amitriptyline
- Imipramine
- Doxepin
- Clomipramine
- Trimipramine
- Dothiepin
- Lofepramine
- Venlafaxine
- Milnacipran
- Duloxetine

Dopamine and norepinephrine reuptake inhibitors (DNRIs)

- Bupropion

Serotonin antagonist/reuptake inhibitors (SARIs)

- Trazodone

Noradrenergic specific serotonergic antidepressants (NaSSAs)

- Mirtazapine

Monoamine oxidase inhibitors (MAOIs)

- Phenelzine
- Tranylcypromine
- Moclobemide

Mood stabilizers

- Lithium carbonate

Canst thou not minister to a mind diseas'd Pluck from the memory a rooted sorrow, Raze out the written troubles of the brain And with some sweet oblivious antidote Cleanse the stuff'd bosom of that perilous stuff Which weighs upon the heart?

—William Shakespeare

Introduction

Depression is an ancient and prevalent mental condition that has been referenced throughout history in song, poetry, and literature. In a depressed state, one feels hopeless and experiences an overwhelming sense of despair. Depression immobilizes a person, afflicting men and women, rich and poor, and young and old alike. Depression makes one feel exhausted, worthless, helpless, and hopeless. It is an illness that involves the body, mood, and thoughts and affects the way one eats and sleeps, the way one feels about oneself, and the way one thinks about things. It often interferes with normal functioning, causing pain and suffering not only to themselves but also to those around them. Serious depression can destroy family life as well as the life of the person who is ill. A depressive disorder is not the same as a passing blue mood. Without treatment, symptoms can last for weeks, months, or years. Appropriate treatment, however, can help most people who suffer from depression. Negative thinking fades as treatment begins to take effect. Unfortunately, many people do not recognize that depression is a treatable illness. Much of this suffering is unnecessary, because *depression is one of the most treatable mental illnesses*.

"Depression is the flaw in love. The meaninglessness of every enterprise and every emotion, the meaninglessness of life itself, becomes self-evident. The only feeling left in this loveless state is insignificance."

"My depression had grown on me as that vine had conquered the oak; it had been a sucking thing that had wrapped itself around me, ugly and more alive than I. It had a life of its own that bit by bit asphyxiated all of my life out of me. My moods belonged to the depression as surely as the leaves on that oak tree's high branches belonged to the vine."

"Drug therapy hacks through the vine. You can feel it happening, how the medication seems to be poisoning the parasite so that bit by bit it withers away. You feel the weight going, feel the way that the branches can recover much of their natural bent. But even with the vine gone, you may still have a few leaves and shallow roots, and the rebuilding of your self cannot be achieved with any drugs that now exist. Rebuilding of the self in and after depression requires love, insight, and most of all, time."

—Andrew Solomon, The Noonday Demon: An Atlas of Depression

Clinical Significance

The antidepressant class of drugs are well-known and widely used today not only for the treatment of mood disorders, such as depression and bipolar disorders, but also for the treatment of neuropathic pain, smoking cessation, and obsessive-compulsive disorders, among others. The application of medicinal chemistry in the development of newer antidepressants, such as selective serotonin uptake inhibitors

(SSRIs), in the past 20 years has significantly affected the treatment of depression. The SSRIs have become first-line therapy in the treatment of major depressive disorder, and they also are used as adjunct treatment in other mood disorders. This new generation of antidepressants has more favorable side effect and pharmacokinetic profiles than the older generations of antidepressants, such as tricyclic antidepressants (TCAs) and monoamine oxidase inhibitors (MAOIs). This has resulted in improved patient compliance and therapeutic outcomes for patients with major depressive disorder.

Modifications of the structure–activity relationships of the antidepressant drugs have produced medications with multiple indications. For example, both duloxetine and buproprion are indicated for major depressive disorder, but duloxetine also is used for diabetic neuropathic pain and buproprion for smoking cessation. With a growing number of antidepressants on the market, it is more important than ever for the clinician to be knowledgeable about the drug's structure–activity relationships, adverse effects, drug interactions, and pharmacokinetic properties to properly select the optimal drug regimen for the patient.

Nancy Ordonez Pharm.D.
Clinical Assistant Professor, University of Houston, College of Pharmacy

Depression affects approximately 10 to 12% percent of the Western population (United States, ~10%; Europe, 9–12%; Australia, ~18%), with females outnumbering males 2:1: One in four women and 1 in 10 men can expect to develop depression during their lifetime. Thus, depression ranks among the Top 5 diseases in these countries. In the United States alone, approximately 19 million adults will be afflicted yearly with depression, and at least 50% of those with major depression will suffer one or more repeated episodes of depression during their adult lifetime (1,2,3). Depression affects at least 1 in 50 children under the age of 12 years and 1 in 20 teenagers, mostly girls. The increase in the rate of depression among adolescent girls is related more to physical changes that occur during puberty, suggestive of hormonal changes. Premenstrual syndrome (PMS) and postpartum depression are additional conditions involving depression that specifically affect women and are suggestive of hormonal involvement in the pathogenesis of depression. About half of all cases of depression go unrecognized and untreated, and approximately 10 to 15% of those with depression will take their own lives yearly.

Depression in the elderly (17–35%) often is dismissed as a normal part of aging and may go undiagnosed and untreated, causing needless suffering for the family and for the individual who could otherwise live a fruitful life. Often, the symptoms described usually are physical, and the older person often is reluctant to discuss feelings of hopelessness, sadness, loss of interest in normally pleasurable activities, or extremely prolonged grief after a loss. Some symptoms may be the result of adverse (side) effects of medication that the elderly person is taking for other physical problems, or they may be caused by a concurrent illness. Improved recognition and treatment of depression will make life more enjoyable and fulfilling for the depressed elderly person, the family, and the caretakers.

The economic cost for depressive illnesses in the United States is estimated to be $53 billion per year, (2005), but the cost in human suffering cannot be estimated. In 2005, antidepressants drugs (primarily selective serotonin reuptake inhibitors [SSRIs]) ranked in the Top 50 drugs dispensed, first in total prescriptions written and third in total dollar prescription sales, at approximately $12.5 billion (~5% of total prescription drug sales) (4).

Types of Depressive Disorders

Why are some people more susceptible to depression than others? Hippocrates, the father of medicine, theorized that we are born into one of four primary temperament styles and that each style has its own unique outlook on life: Choleric (aggressive), Sanguine (emotional), Phlegmatic (passive), and Melancholy (analytical). Of these four styles, the introverted Melancholy is the most perfection driven and depression prone. The analytical Melancholy influence gives one tremendous attention to detail, but it also can create stress, anxiety, and depression. In fact, the term “melancholy” has become synonymous with depression. People with the Melancholy temperament style are by their very nature sensitive, judgmental, and critical. This temperament style becomes depressed primarily from the fact that they fail to reach their own incredibly high standards. This depression often leads to suicide, violence against others, or both.

Major Depression (MDD)

Major depression (also called unipolar depression) is the most serious type of depression; is manifested by a combination of symptoms that interfere with the ability to work, study, sleep, eat, and enjoy once-pleasurable activities; and may reoccur several times during a lifetime (5). Many people with major depression cannot continue to function normally. Major depression seems to run in families, suggesting that depressive illnesses can be inherited. Early signs (prodromal symptoms) of major depression include changes in brain function in those individuals having low self-esteem, who consistently view themselves and the world with pessimism or who are readily overwhelmed by stress. The treatments for major depression are medication, psychotherapy, and in extreme cases, electroconvulsive therapy.

Dysthymia

This is a mild, chronic depression that lasts for 2 years (1 year for children and adolescents) or longer and is characterized by chronic symptoms that do not disable but that keep one from functioning well or from feeling good about themselves (5). Many of those with dysthymia also experience major depressive episodes at some point in their lives. Most people may not realize that they are depressed and continue to function at work or school, but often with the feeling that they are “just going through the motions.” Antidepressants or psychotherapy can help.

Bipolar Disorder (Manic-Depressive Illness)

Bipolar disorders can be divided into bipolar I (manic-depressive episodes), bipolar II (hypomanic-depressive episodes or cyclothymia [low grade bipolar II]) (5). Clinical studies over the years have provided evidence that monoamine signaling and hypothalamic-pituitary-adrenal axis disruption are integral to the pathophysiology of bipolar disorder (6). Bipolar disorders also appear to run in families and affect men and women equally. Not nearly as prevalent as the other forms of depressive disorders, bipolar disorders are characterized by cyclical periods of depression (lows) with periods of abnormal behavior (highs) known as hypomanic or mania. Sometimes, the mood switches are dramatic and rapid, but most often, they are gradual. When in the depressed cycle, an individual can exhibit the symptoms of a depressive disorder. When in the hypomanic manic cycle, the individual may be overactive, overtalkative, and have a great deal of energy. The hypomanic/manic cycle often affects thinking, judgment, and social behavior in ways that cause serious problems and embarrassment. For example, the individual in the hypomanic/manic cycle may feel elated, full of grand schemes that might range from unwise business decisions to romantic sprees. Lithium, carbamazepine, topiramide, and valproic acid are effective mood-stabilizing treatments for bipolar disorders. Also, the atypical antipsychotic, olanzepine (see Chapter 22) is used as a mood stabilizer for acute bipolar mania or in conjunction with antidepressants (e.g., Symbyax, a combination of olanzepine and fluoxetine).

Other Types of Depressive Disorders

Other, less common types of depression include seasonal affective disorder, a popular name that describes a type of depression that happens during particular seasons of the year (seasonal pattern) but that it is not a Diagnostic and Statistical Manual of Mental Disorder (DSM IV) (5) diagnosis. This disorder involves symptoms of depression that occur during the fall and winter seasons, when the days are shorter and there is less exposure to natural sunlight. When the spring and summer seasons begin and there is greater exposure to longer hours of daylight, the symptoms of depression disappear. Adjustment disorder with depressed mood is a type of depression that results when a person has something bad happen that depresses them (e.g., loss of one's job can cause this type of depression). It generally fades as time passes and the person gets over whatever it was that happened (5). Additional factors involved in its onset include stresses at home, work, or school, and symptoms may persist for as long as six months.

Biological Basis of Depression

Current theories regarding the causes of depression support the role of the neurotransmitters serotonin (also known as 5-HT) and norepinephrine (NE) in depression and their interrelationships with each other and with dopamine (Fig. 21.1). Although the precise nature of the depression is not fully understood at the level of the chemistry in the brain, several theories explain the role of NE and 5-HT in the causes of depression (7).

Monoamine Hypothesis

The monoamine hypothesis proposes that depression results from a deficiency in 5-HT and/or NE (8,9) and that antidepressant therapy aims to correct these deficiencies. The role of dopamine in depression remains

unclear. Schildkraut et al. (8) postulated that depression arises as a consequence of a deficiency of NE and that the effects caused by catecholamine depletion can be reversed by the tricyclic antidepressants (TCAs). Depression in animals following reserpine administration can be reversed by TCAs, suggesting that the stimulating effects for desipramine (a secondary amine TCA) and monoamine oxidase inhibitors (MAOIs) were NE based.

During the late 1960s, Kielholz, a Swiss psychiatrist, argued that different antidepressants did quite different things and that it was important to select the right antidepressant for the right patient. He differentiated the TCAs based on whether they possessed the ability to sedate (e.g., trimipramine), to stimulate (e.g., desipramine or nortriptyline),

or to improve mood (e.g., clomipramine). By the end of the decade, the broad consensus was that secondary amine TCAs (like desipramine or nortriptyline) inhibited the reuptake of NE into noradrenergic neurons and that blocking 5-HT reuptake by tertiary amine TCAs (such as clomipramine), gave an explanation for the mood elevation of some antidepressants.

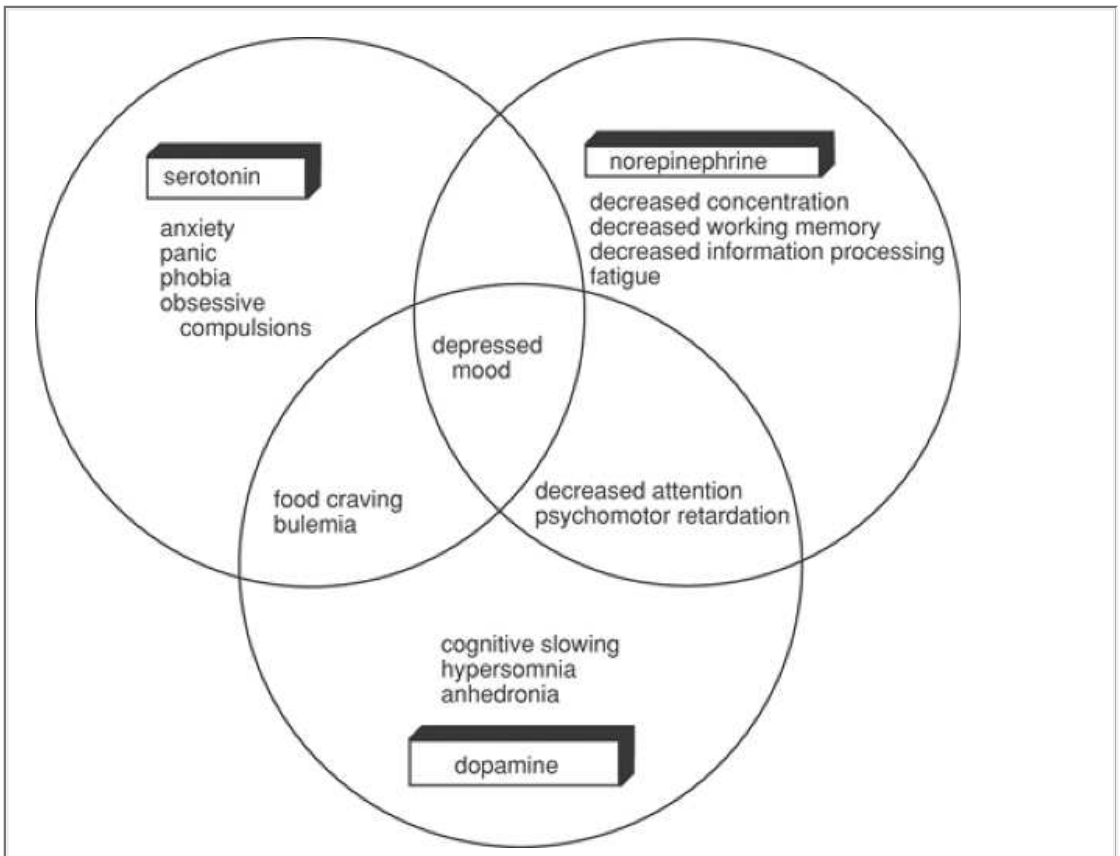

Fig. 21.1. Neurotransmitter deficiency syndromes and their interactions.

The catecholamine hypothesis was then modified to include 5-HT in the etiology of depression (9,10). It should be noted, however, that not all inhibitors of monoamine reuptake are antidepressants, because cocaine, a potent inhibitor of NE and dopamine reuptake, is not an antidepressant but, rather, an addictive stimulant. Subsequent studies with inhibitors of monoamine biosynthesis appear to confirm Kielholz's opinion and Schildkraut's modified theory that clinical depression is the result of a deficiency in both 5-HT and NE and that the antidepressive mechanism of action most likely affects levels of both.

Inhibition of 5-HT biosynthesis reverses the therapeutic effects of treatment with antidepressants that have predominantly 5-HT reuptake inhibitory activity (e.g., fluoxetine) but less so with those that have predominantly NE reuptake inhibitory activity (e.g., desipramine) (11,12). Also, inhibition of 5-HT biosynthesis produced a relapse in depressed patients who had their depression successfully treated with imipramine or

tranylcypromine, whereas inhibitors of dopamine or NE synthesis had no effect on these depressed patients (13,14). A depletion of catecholamines reverses the therapeutic effects of desipramine more than that of fluoxetine or sertraline. These studies appear to confirm that the antidepressive action of antidepressants is, indeed, a function of their monoamine activity.

Kielholz further reasoned that because NE reuptake inhibitors (activating antidepressants) were likely to trigger suicide, the greatest hazard of an antidepressant, such as the 5-HT reuptake inhibitors would be less likely to lead to suicide. These observations led to the proposition that it would be worth developing drugs that selectively inhibited the reuptake of 5-HT, producing agents more useful for the treatment of depression.

Changes in NE and 5-HT levels do not affect mood in everyone. Some evidence also suggests that for a subset of patients, dopamine plays a role in depression. Dopaminergic substances have been used as antidepressants when other measures have failed. The dopamine hypothesis of schizophrenia and the emphasis on other neurotransmitters, most notably NE and 5-HT, in the pathogenesis of depression have focused attention away from dopamine and its role in affective disorders. Recent clinical evidence suggests the involvement of dopamine in several subtypes of depression, psychomotor retardation and diminished motivation, and in seasonal mood disorder (11). The biochemical evidence in patients with depression indicates diminished dopamine turnover. In addition, a considerable amount of pharmacological evidence exists regarding the efficacy of antidepressants with dopaminergic effects in the treatment of depression. However, the role of dopamine in depression must be understood, in the context of existing theories involving other neurotransmitters that may act independently and interact with dopamine and other neurochemicals to contribute to depression (12).

Receptor Sensitivity Hypothesis

The receptor sensitivity hypothesis proposes that it is not simply the level of NE or 5-HT in the synapse that matters but, rather, the sensitivity of the postsynaptic receptors to these neurotransmitters. Those with depression, it is speculated, possess postsynaptic receptors that have grown hypersensitive to NE and 5-HT because of their depletion in the synaptic cleft. Thus, a low level of NE and 5-HT at their respective receptors can lead to changes in the receptors themselves, even if there are no clinical signs of depression. Increased receptor sensitivity (hypersensitivity) and an increase in receptor numbers on the neuronal cell membrane are events that may correlate with the start of depression. This theory is an important step toward understanding the long delay between administration of antidepressant drugs and their clinical response. According to this hypothesis, relief from the symptoms of depression following chronic administration of antidepressants comes from a normalization of receptor sensitivity (reducing receptor hypersensitivity) by increasing the concentration of NE and 5-HT in the synaptic cleft. Therefore, the use of reuptake inhibitors and the MAOIs as antidepressants increases the concentration of NE and/or 5-HT in the synaptic cleft and, over time, causes the postsynaptic neuron to compensate by decreasing receptor sensitivity (desensitization) and the number of receptor sites (decrease in the expression of NE and 5-HT receptors: downregulation). About one-third of depressed patients, however, fail to respond to antidepressant therapy. For some unknown reason, the increased concentration of NE and/or 5-HT fail to desensitize the postsynaptic receptors.

Permissive Hypothesis

The permissive hypothesis (10) emphasizes the importance of the balance between 5-HT and NE in regulating mood, not the absolute levels of these neurotransmitters or their receptors. If 5-HT levels are too low, the balanced control of the NE system is lost, permitting abnormal levels of NE to cause mania, as seen in bipolar disorders. If the NE levels fall, the balanced control of the 5-HT system is lost, allowing abnormal levels of 5-HT to cause the person to exhibit the symptoms of depression.

Hormonal Hypothesis

The hormonal hypothesis suggests that changes in the hypothalamus-pituitary-adrenal axis (HPA) can influence the levels of 5-HT and NE released by nerve cells in the brain and, subsequently, their function (15). In the event of stress, the hypothalamus produces a hormone locally in the brain called corticotrophin-releasing factor, which in turn stimulates the pituitary gland to secrete adrenocorticotropic hormone into the blood, where it stimulates the adrenal glands to release hydrocortisone (cortisol), which prepares the body for dealing with stress. Stress also directly stimulates the adrenal gland to secrete epinephrine and NE. Hydrocortisone can cause depression, especially when released in higher-than-usual amounts. The release

of hydrocortisone may push the individual over the edge into depression or contribute to the component of anxiety, which so often accompanies depressive illnesses. Approximately 50% of those with major depression have elevated hydrocortisone levels.

Living organisms operate in a state of imbalance, and the neural (autonomic) and endocrine systems have evolved to modify the rates of biochemical pathways to maintain homeostasis. One of the hallmarks of these regulatory systems is the short-lived nature of the nerve signals produced. The half-life of neurotransmitters is measured in seconds, whereas those of the circulating hormones may be minutes or hours. A rationale for the short-lived nature of the neurotransmitters is to permit these signaling pathways to quickly reset themselves to meet the next challenge. Readjustments (i.e., plasticity) in these systems include uncoupling of receptor responses from signaling events, degradation of receptors, and up- and downregulation of signaling molecules that affect the primary signaling pathway. These hypotheses are not mutually exclusive and in each it is assumed that the more extreme the event, the more severe the clinical outcome.

General Approaches to Treatment of Depression

Before 1950, there were no antidepressants—at least not as we know them today. The two treatments for depressive illness were either amphetamine stimulants, which often were ineffective and had the general affect of increasing energy and activity (16), or electroconvulsive therapy, which was effective but had the disadvantage of terrifying and often endangering the patient. Not until the late 1950s were the first generation of antidepressants discovered (the TCAs and MAOIs), not by design but by chance. While searching for “chlorpromazine-like” compounds to treat schizophrenia, imipramine was recognized by Kuhn (16) for its antidepressant properties, thus becoming the forerunner for the tricyclic class of monoamine reuptake inhibitor antidepressants (i.e., the TCAs). The second compound to be discovered was the antitubercular drug isoniazid (17), which proved to have powerful mood-enhancing properties, becoming the forerunner of the MAOIs. With the introduction of imipramine and isoniazid, the theory and treatment of depression changed. These early studies still summarize much of our current knowledge regarding the therapeutic effects of antidepressant treatments.

Between 1960 and 1980, TCAs were the major pharmacological treatment for depression (18). The TCAs, however, have many other actions in addition to blocking monoamine reuptake, including anticholinergic, antihistaminergic, and cardiotoxic side effects that are related to their affinity for muscarinic, histamine, and α_1-adrenergic receptors as well as their action on cardiac and central

nervous system (CNS) Na^+ channels in membranes. The improved safety, tolerability, and reuptake selectivity of the newer antidepressants (i.e., SSRIs, selective NE reuptake inhibitors [SNRIs], and nonselective NE and 5-HT reuptake inhibitors [NSRIs]) have resulted in displacement of the TCAs as the first choice for prophylactic treatment of major depression. The TCAs occupy a narrower—but still important—role in the psychopharmacological therapy.

The early MAOIs irreversibly inhibited the oxidative deamination of the neurotransmitter monoamines, the proposed mechanism of their antidepressant activity. The biggest liability for these MAOIs was their potential to cause life-threatening hypertensive reactions, resulting from the nonselective irreversible inhibition of MAO-A and MAO-B, which decreases the intestinal and hepatic degradation of dietary sources of tyramine. This inhibition of MAO allows excessive amounts of dietary tyramine, a weak sympathomimetic vasoconstrictor, to be absorbed from the food, resulting in increased blood pressure (refer to the section of MAOIs in this chapter for more details). Inhibition of monoamine oxidases also can alter the pharmacokinetics of monoamine over-the-counter and prescription drugs, allowing them to accumulate in the blood and, thus, increasing their potential for causing adverse drug effects and drug–drug interactions. Minimizing drug and food interactions of these early MAOIs inspired the development of a new generation of MAOIs that are both reversible and selective for MAO-A. The demise of the early MAOIs allowed the TCAs to become the gold standard for the treatment of depressive disorders.

The discovery that certain antihistaminic agents without the condensed aromatic ring systems are selective inhibitors of 5-HT reuptake with little affinity for the other neuroreceptors and almost devoid of cardiotoxicity questioned the need for the 10,11-ethylene bridge for the TCAs. Thus, the search for inhibitors that selectively blocked 5-HT reuptake without the 7-membered central ring of the TCAs resulted in the synthesis of the diarylpropylamine analogues of the TCAs (Fig. 21.2). Thus, during the late 1960s and early 1970s, antihistamine molecules were structurally manipulated in the search for compounds that selectively inhibited 5-HT reuptake with greater potency. The initial breakthrough came with the synthesis of *Z*-zimeldine (the

cis-isomer) (a.k.a., zimelidine, Zemid, patented in 1971), the first SSRI that selectively inhibited the presynaptic reuptake of 5-HT without the adverse events associated with the multireceptor activities of the TCAs (19,20). Zimeldine was synthesized from the manipulation of the antihistamine pheniramine into a diary allylamine, the *cis*-isomer (rigid analogue) of the propylamine group (Fig. 21.2).

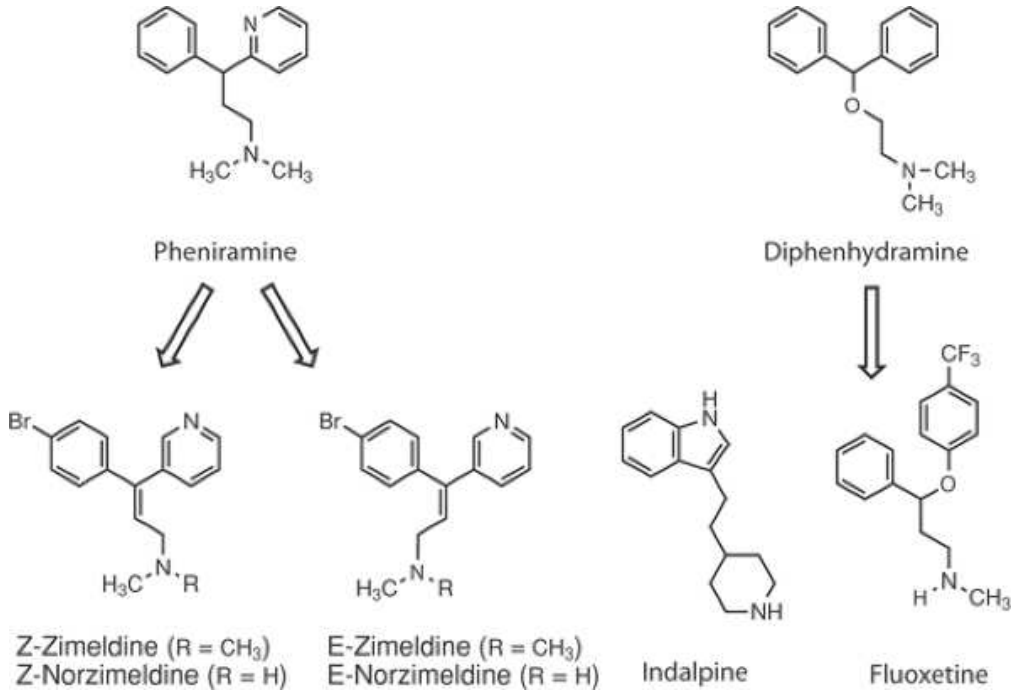

Fig. 21.2. Structural relationship between antihistamines and antidepressants that block the reuptake of 5-HT.

Other structural changes that enhanced its potency and selectivity for blocking 5-HT reuptake was moving the regional position of the 2-pyridyl ring of pheniramine to the 3-pyridyl position and substitution of a halogen into the 4-position of the phenyl ring (2-substitutions selectively block NE reuptake). The secondary amine and primary metabolite, norzimeldine, was 15 times more potent than zimeldine for blocking 5-HT reuptake. On the other hand, (*E*)-zimeldine (the *trans*-isomer) is a nonselective inhibitor of 5-HT and NE reuptake, whereas its corresponding secondary amine is a potent and selective inhibitor of NE reuptake. It is not unusual for geometric isomers to differ markedly from each other with regard to their receptor

or transporter selectivity, affinity, and pharmacodynamic properties. Thus, zimeldine became the first SSRI to be marketed as an antidepressant, but unfortunately, several cases of Guillain-Barre syndrome (an autoimmune disorder attacking the peripheral nervous system) were associated with the use of this drug and led to its withdrawal from the market in 1983. During postmarketing clinical studies, zimeldine showed an increase in the number of suicide attempts than had been expected—this adverse event was to become a major issue with the SSRIs 20 years later.

The success of zimeldine as an SSRI, however, led to the discovery and marketing of several nontricyclic SSRIs from multiple pharmaceutical companies worldwide. Another manipulation of the antihistamines produced indalpine (patented 1977 by Rhône Poulenc) (Fig. 21.2). It produced responses in patients who had not responded to the TCAs or MAOIs but then ran into trouble, because clinical trials suggested that it might cause agranulocytopenia (a lowering of the white blood cell count). For the most part, this is not a serious problem, but in rare cases, if undetected, it can be fatal. It was removed from the European market in 1985 and was never marketed in the United States.

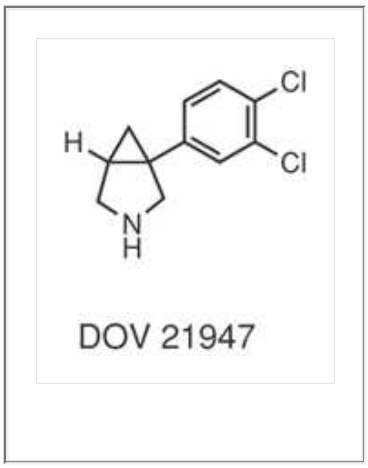
Other SSRIs developed during this period that have become household words include paroxetine (patented 1975 by Ferrosan to SmithKlineBeecham to GlaxoKline), citalopram (patented 1979 Lindberg, licensed to

Forest Labs), fluoxetine (patented 1982 Lilly), and sertraline (patented 1985 Pfizer).

Scientists at Lilly Research Laboratories synthesized more than 50 phenoxypropylamines derived from the antihistamine diphenhydramine (Benadryl) before discovering fluoxetine (21,22) (Fig. 21.2). The first of these compounds was nisoxetine, a potent SNRI (see Fig. 21.8) that was clinically developed but never marketed. Other derivatives that have since been marketed by Lilly include atomoxetine (a SNRI) and duloxetine (a NSRI).

Fluoxetine (Prozac) was heralded as the prototype for the next generation of SSRI antidepressants possessing fewer adverse effects and with a greater margin of safety when overdoses are consumed compared with the TCAs and also lacking the food-interaction toxicity of MAOIs. Fluoxetine was marketed in 1987, and within a few years, it boasted worldwide sales of nearly $1.2 billion a year. During the past 20 years, nontricyclic selective and nonselective NE and 5-HT reuptake inhibitors as well as reversible selective MAOIs have been approved for use in depression. These newer additions allow exploration of the roles of NE versus 5-HT using treatments that are devoid of confounding receptor activities. Conscious targeting of more than one neurotransmitter activity (e.g., of serotonergic and noradrenergic mechanisms or of NE and dopamine), while retaining specificity, is the target for the development of the next generation of antidepressants.

The majority of antidepressants in current use selectively inhibit the reuptake of 5-HT and/or NE. Based on the previously neglected role proposed for dopamine in depression, it has been hypothesized that a “broad-spectrum” antidepressant will produce a more rapid onset and/or higher efficacy than agents inhibiting the reuptake of 5-HT and/or NE (23). Broad-spectrum antidepressants are compounds that inhibit the reuptake of NE, 5-HT, and dopamine, the three biogenic amines most closely linked to depression. The pharmacological profile of one such compound, DOV 21947, an azabicyclo[3.1.0]hexane, has recently been described and is in Phase III clinical trials (23,24). It is a potent inhibitor of NE, 5-HT, and dopamine reuptake by their corresponding membrane transporter proteins. The plasma concentrations of DOV 21947, following both single and multiple doses, appear to be sufficient to inhibit NE, 5-HT, and dopamine reuptake.



The antiobesity agent, racemic (*R*, *S*)-sibutramine is a 5-HT and NE reuptake inhibitor and has an antidepressant profile similar to that of a “triple-acting” antidepressant in animals (25). It has two active metabolites, desmethylsibutramine and didesmethylsibutramine (the terms “desmethyl” and “demethyl” are used interchangeably). The IC50 for the R-enantiomers of these metabolites were more potent as in vitro inhibitors of dopamine and NE reuptake than 5-HT (25). Both *R*-enantiomers had significantly greater anorectic effects than those of their respective *S*-enantiomers as well as that of (*R*,*S*) sibutramine. The results suggest that these enantioselective metabolites of sibutramine could be safe and effective treatments for binge-eating disorder in obese patients.

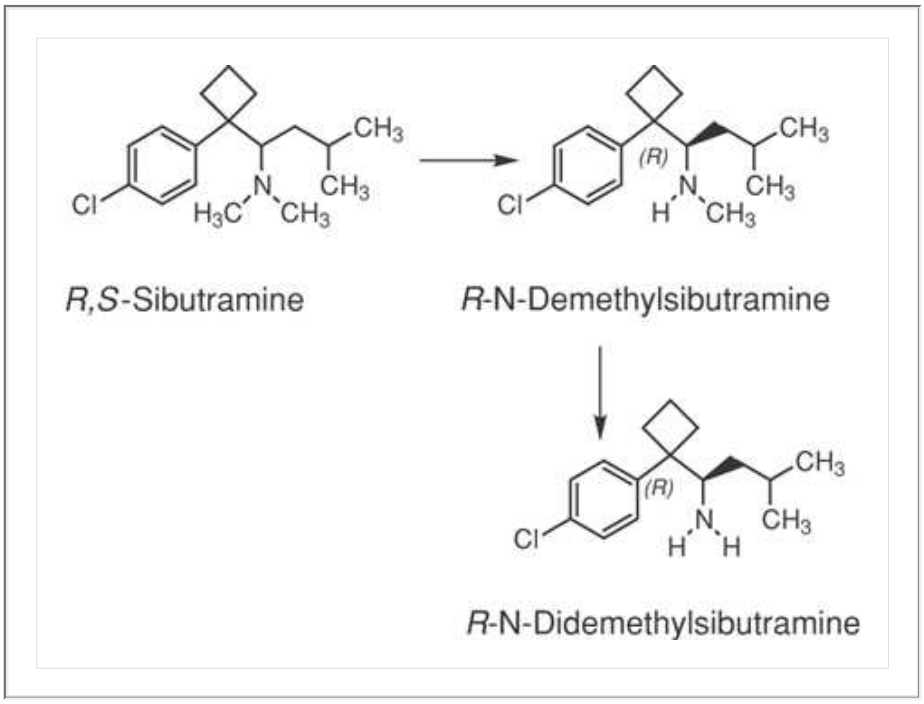


Table 21.1. Antidepressant Classes with Examples of Generic and Trade Names

Drug Classes	Abbreviation	Drug Examples	Trade Names
Selective norepinephrine reuptake inhibitors	SNRIs	Amoxapine	Asendin
		Desipramine	Norpramin
		Maprotiline	
		Nortriptyline	Aventyl, Pamelor
		Roboxetine	Vestra
		Atomoxetine	Strattera
Selective serotonin reuptake inhibitors	SSRIs	Citalopram	Celexa
		Escitalopram	Lexapro
		Fluoxetine	Prozac

		Fluvoxamine	
		Paroxetine	Paxil
		Sertraline	Zoloft
Norepinephrine and serotonin reuptake inhibitors	NSRIs	Amitriptyline	Elavil
		Clomipramine	Anafranol
		Doxepine	Sinequan
		Imipramine	Tofranil
		Milnacipran	Ixel
		Trimipramine	Surmontil
		Venlafaxine	Effexor
		Duloxetine	Cymbalta
Dopamine and norepinephrine reuptake inhibitors	DNRIs	Bupropion	Wellbutrin, Zyban
Serotonin receptor modulators	SRMs		
Serotonin-2 antagonists/serotonin reuptake inhibitors	SARIs	Trazodone	Desyrel
α_2–Noradrenergic antagonists/serotonin antagonists	NaSSAs	Mirtazepine	Remeron
Monoamine oxidase inhibitors	MAOIs	Meclobemide	

		Phenelzine	
		Nardil	
		Tranylcypramine	Parnate
Mood stabilizers		Lithium	Eskalith, Lithobid
		Valproic acid	Depakote, Depakene, Depacon
		Carbamazepine	Tegretol

Traditionally, antidepressants have been classified according to their structure (i.e., secondary or tertiary amine TCAs) or their principal mechanism of action (i.e., MAOIs and SSRIs). With the appearance of increasing numbers of second- and third-generation antidepressants, however, a better way of classifying and describing the antidepressants was necessary. For the purposes of this chapter, the antidepressants are organized into eight classes (Table 21.1) and discussed according to their distinct and different mechanisms of action (Fig. 21.3). Considerable overlap exists in their mechanism of actions and uses, but these different classes of antidepressants work by distinct mechanisms, have different side-effect profiles, and may be favored for different types of depressive illnesses.

A key step that determines the intensity and duration of monoamine signaling at synapses is the reuptake of the released neurotransmitter into nerve terminals through high-affinity plasma membrane transporters (26). Reuptake is the process of rapidly removing the monoamine neurotransmitters from the synaptic cleft and allowing most of the released neurotransmitter to be recycled for further use. The advantage of reuptake is that it is faster than passive diffusion through the membrane. Any monoamine neurotransmitter remaining in the synaptic cleft is then absorbed and metabolized into inactive metabolites. The monoamine reuptake transporter protein binds the released neurotransmitter in the extracellular fluid and transports the monoamine across the presynaptic plasma membrane back into the intracellular fluid of the presynaptic neuron (Fig. 21.4). Monoamine transporters (Fig. 21.5 and sidebar for more detail) are embedded in the plasma membrane of the nerve terminals (perisynaptically) of dopaminergic, noradrenergic, and serotonergic neurons rather than intrasynaptically (along the portion of the nerve terminal forming the synapse). They are members of a larger sodium-dependent transporter family and represent a major mechanism terminating the action of released monoamine neurotransmitters in the synaptic cleft. These transporters are important targets for many antidepressive drugs and substances of abuse (i.e., cocaine). Transporter proteins are specific to their respective neurotransmitter: SERT for 5-HT (serotonin reuptake transporter), NET (NE reuptake transporter) for NE, and DAT for dopamine. None of the reuptake antidepressants

exhibit significant affinity for dopamine transporters, which may be related to their ineffectiveness in types of depression that is resistant to the SNRIs, SSRIs, and NSRIs. The TCAs and nontricyclic NSRIs nonselectively block the reuptake transporters for both NE and 5-HT, the SSRIs selectively block SERT, and SNRIs selectively block NET. The antidepressant reuptake inhibitors also may contribute to relief of depression by decreasing the expression of their respective transporter proteins.

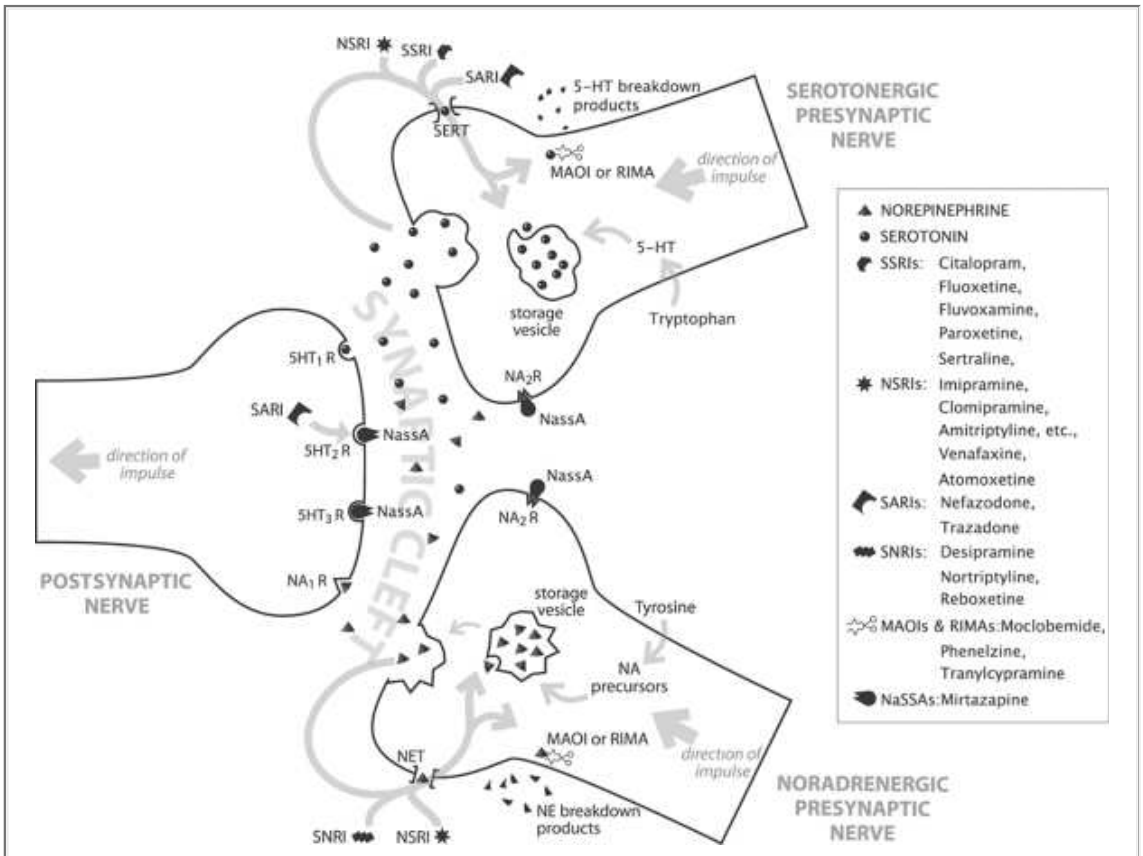

Fig. 21.3. Sites of action of the antidepressants.

Figure 21.6 graphically illustrates the selectivity of the reuptake inhibitors for their respective transporters. The selectivity ratios for inhibiting SERT (ratio, >1) is obtained by dividing the affinity of the inhibitor (K_i) for inhibiting SERT with its affinity (K_i) for inhibiting NET, whereas the selectivity ratio for inhibiting NET (ratio <1) is obtained by dividing its affinity (K_i) for inhibiting NET with the affinity (K_i) for inhibiting SERT. For example, a value of approximately one for amitriptyline means that amitriptyline will inhibit both NET and SERT at the same concentration (i.e., no selectivity with regard to their mechanism of antidepressant activity). The value of -30 for desipramine means that desipramine is 30 times more potent at inhibiting the NET than the SERT, although the SSRIs with selectivity ratio values of greater than 100 are more than 100 times more potent at inhibiting the SERT than the NET. Furthermore, because the selectivity ratio for most SSRIs is more than 100, a plasma concentration of any SSRI that will produce inhibition of the SERT will produce no physiologically meaningful inhibition of NET (27,28,29). The converse will be true regarding selectivity for the NET. Clinically, such selectivity ratios of greater than 100 translate into being able to produce all the physiological effects mediated by inhibiting one transporter without causing any effects that will be produced by inhibiting the other uptake transporter. When the selectivity ratio is less than 30, such as with fluoxetine, the difference is small enough that inhibition of both reuptake transporters may occur under therapeutic doses and, thus, can contribute to the broad antidepressant activity of the drug.

Transporter Proteins

The monoamine transporter protein (molecular weights, 60-80 kDa) is a string of amino acids that weaves in and out of the presynaptic membrane 12 times (Fig. 21.4)—that is, 12 transmembrane domains (TMs) with a large extracellular loop between TM3 and TM4. Both the N- and C-termini of the transporters are located within the cytoplasm. There are six potential sites of phosphorylation by protein kinase A and protein kinase C, which regulate the transporters. The large extracellular loop and the cytoplasmic parts of the N- and C-termini do not appear to be the target sites for the transporter inhibitors (i.e., antidepressants). Rather, the areas important for selective monoamine

affinity appear to be localized within TM1 to TM3 and TM8 to TM12 that project into the synapse, and these areas of the transporters have a common binding site for the monoamine and many of its inhibitors (Fig. 21.4). To transport protonated 5-HT^+, SERT cotransports a sodium ion and a chloride ion while countertransporting a potassium ion (Fig. 21.5). The SERT then flips inside the cell, releasing the 5-HT^+ and the ions into the cytoplasm of the neuron. On releasing the 5-HT^+ and the ions, SERT flips back out, with the unoccupied binding site exposed to the synaptic cleft, ready to receive and transport another 5-HT^+ molecule. To transport protonated NE^+, NET also cotransports sodium and chloride ions with intracellular potassium stimulation and no potassium efflux. The initial complex of the monoamine, Na^+, and Cl^2 with the transporter protein creates a conformational change in the transporter protein. The driving force (electrical potential) for the energetically unfavorable transport of the monoamine is the Na^+ concentration gradient. The Na^+, K^+ transporter (Na^+, K^+-ATPase) maintains the extracellular Na^+ concentration as well as the intracellular K^+ concentration. The Na^+, K^+-ATPase transport three Na^+ ions for each two K^+ ions pumped into the cell. Unlike channels that stay open or closed, transporters undergo conformational changes (changes in their three-dimensional shape) and move one monoamine molecule in each cycle.

Most scientists agree that MAOIs, SSRIs, SNRIs, and NSRIs improve depression by boosting the levels of NE and/or 5-HT in the brain, but what is not established is how increased concentrations of NE and 5-HT translate into reducing depression. One problem with the original monoamine model was that whereas plasma concentrations of the antidepressant and binding to the monoamine transporter occur almost immediately, chronic administration of antidepressants is needed before clinical efficacy is attained (18). The therapeutic effect of an antidepressant is almost always observed after a period of 3 to 6 weeks of treatment. This suggests that certain adaptive changes are occurring with chronic administration of these drugs that may be important for their antidepressant action (see Receptor Sensitivity Hypothesis). This concept has been the motivating force for much of the refinement of the monoamine theory. Over the years, mechanisms such as downregulation of β-adrenergic receptors, desensitization of presynaptic α_2-adrenoceptors, increased postsynaptic 5-HT receptor sensitivity, downregulation of 5-HT_2 receptors, and desensitization of presynaptic 5-HT_{1A} receptor have been cited either as the final common pathway or as one of many possible final common pathways.

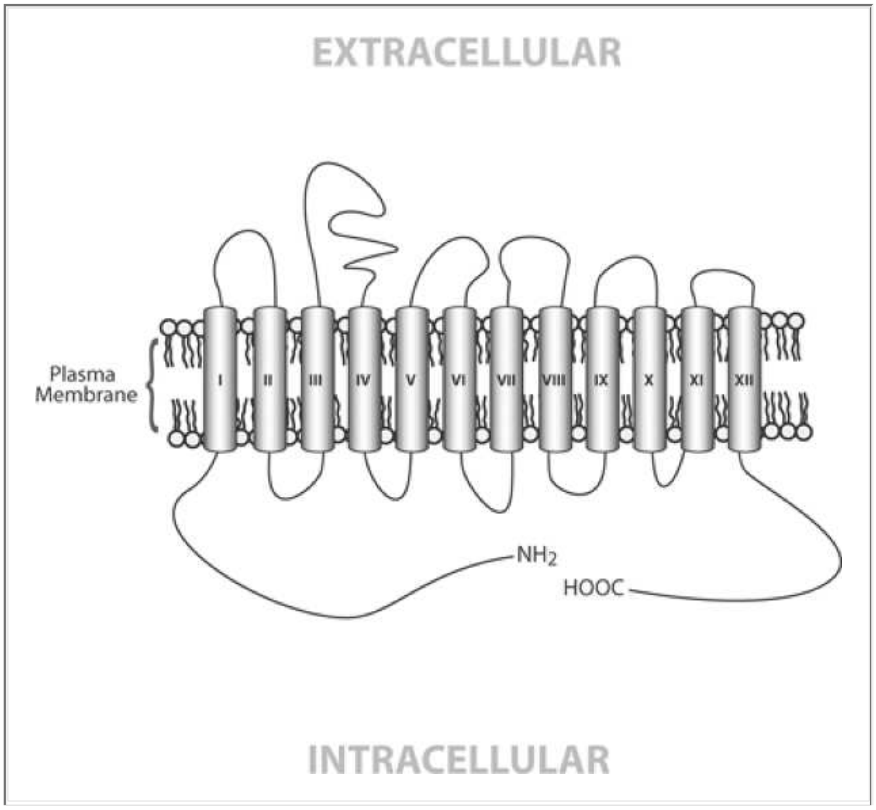

Fig. 21.4. Monoamine reuptake transporter.

It should be remembered that the neurotransmitter and downregulation hypotheses are incomplete explanations for how antidepressants work. Antidepressants most likely set off an intricate chain of reactions that occur

between the time the patient first takes them and the following few weeks, when they finally produce their effect. What the neurotransmitter and downregulation hypotheses do provide are useful—if simplistic—models for comprehending at least some of the basic biochemical processes triggered by antidepressants.

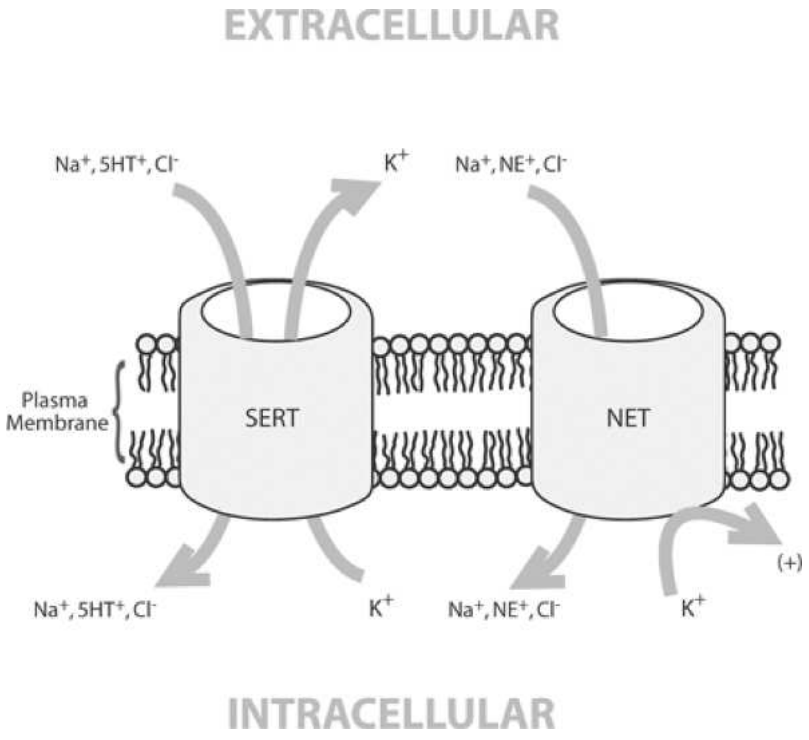

Fig. 21.5. Model of the NET and SERT and the ion-coupled NE and 5-HT reuptake. Reuptake of 5-HT is dependent on the cotransport of Na^+ and Cl^- and countertransport of K^+. Reuptake of NE is dependent on the cotransport of Na^+ and Cl^- with intracellular K^+ stimulation but without K^+ efflux.

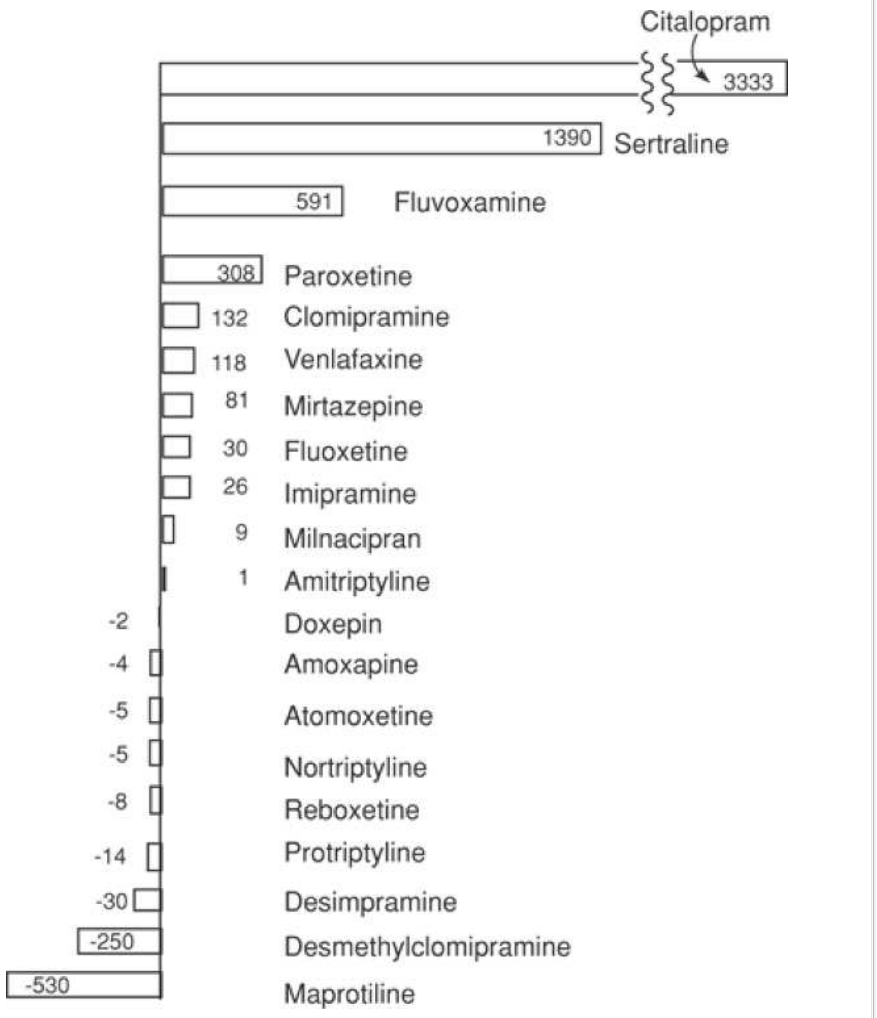

Fig. 21.6. In vitro selectivity ratios for reuptake inhibitors.

Antidepressants in Psychotherapy

The introduction of the second-generation classes of antidepressants in the 1980s and 1990s (SSRIs, SNRIs, NSRIs, and serotonin receptor modulators [serotonin antagonist/reuptake inhibitors (SARIs) and noradrenergic specific serotonergic antidepressants (NaSSA)]) (Table 21.1) has been regarded as the major pharmacological advance in the treatment of depression since the appearance of the TCAs and MAOIs. The SSRIs, SNRIs, and NSRIs have proven to be effective for a broad range of depressive illnesses, dysthymia, several anxiety disorders, and bulimia. The SSRIs are the most widely prescribed antidepressant drugs and rank in the Top 50 drugs in terms of total United States sales for 2004. In addition to being the usual first-line treatments for major depression, the SSRIs also are first-line treatments for panic disorder, obsessive-compulsive disorder, social phobia, posttraumatic stress disorder, and bulimia. They also may be the best medications for treatment of dysthymia and generalized anxiety disorder.

Differences in general tolerability of the different classes of antidepressants and in their side-effect profiles are well known and generally accepted. Compared with the TCAs, the SSRIs cause significantly more nausea, diarrhea, agitation, sexual dysfunction, anorexia, insomnia, nervousness, and anxiety, whereas the TCAs cause more cardiotoxicity, dry mouth, constipation, dizziness, sweating, and blurred vision (18). Consistent evidence also indicates that SSRIs, as a group, are better tolerated than TCAs. Despite pharmacological differences in their mechanisms of actions, the general view has been that all antidepressants are of equal efficacy. Only within the last 10 years has this general assumption come under serious challenge from comparisons of antidepressants with dual mechanisms of action versus those with a single mechanism of

action (11).

Often, a variety of antidepressants will be prescribed and the dosage adjusted before the most effective antidepressant or combination of antidepressants is found. Although some improvements may be seen during the first few weeks, the antidepressants must be taken regularly for 3 to 4 weeks (and, in some cases, for as many as 8 weeks) before the full therapeutic effect occurs. Patient compliance can become an issue, because they often are tempted to stop medication too soon as a result of feeling better and, thus, thinking they no longer need the medication. Additionally, they may have problems with the adverse effects, or they may think the medication is not helping at all. It is important for the patient to keep taking the antidepressant until it has a chance to work, although side effects often appear before antidepressant activity does. Once the individual is feeling better, it is important to continue the medication for at least 4 to 9 months (or longer) to prevent a recurrence of the depression. Antidepressants alter the brain chemistry; therefore, they must be stopped gradually to give the brain time to adjust. For some individuals with bipolar disorder or chronic major depression, antidepressant therapy may need to be maintained indefinitely (30). All patients who are prescribed antidepressants should be informed that although the drugs are not associated with tolerance and craving, discontinuation/withdrawal symptoms may occur on stopping, missing doses, or occasionally, on reducing the dose of the drug. These symptoms usually are mild and self-limiting, but occasionally, they can be severe, particularly if the drug is stopped abruptly. Symptoms of antidepressant withdrawal include nausea, vomiting, anorexia, headache, restlessness, agitation, “chills,” insomnia, and sometimes, hypomania, panic-anxiety, and extreme motor restlessness, especially if an antidepressant (particularly an MAOI) is stopped suddenly after regular administration for 8 weeks or more.

Clinical trials have concluded that 2 or 3 of every 100 children and teenagers treated with antidepressants might be at higher risk of suicidal behavior. Data regarding suicidal behavior varies among the antidepressants, which leads to the conclusion that no antidepressant is free from risk at this time. Most of the suicides have occurred with the SSRIs, especially paroxetine (Paxil)

and fluoxetine (Prozac); only fluoxetine has been proven to be effective and is approved for treating pediatric depression. Approximately 7% of antidepressant prescriptions are written for children. Thus, the U.S. Food and Drug Administration (FDA) in 2007 approved that “black box labeling” be included on antidepressant product packaging, alerting physicians to avoid prescribing antidepressants to children because of possible risks of suicidal behavior and to watch for signs of worsening depression or suicidal thoughts in children who are taking any antidepressant.

Guidelines for Managing Depression

The following guidelines apply to all antidepressants, including SSRIs, SNRIs, and NE/serotonin reuptake inhibitors (NSRIs):

- For most SSRIs used for treating depression, recommended daily dosages should not be exceeded, because no evidence indicates any additional benefit from higher amounts.
- Patients who are taking antidepressants should be monitored carefully and frequently during the early stages of treatment, especially if symptoms worsen or if new symptoms appear.
- Adverse drug reactions should be considered if a patient does not do well after treatment begins; if restlessness or agitation occur, increasing antidepressant doses can be detrimental.
- Although the relationship between suicidality and increasing or decreasing antidepressant doses is not clear, patients should be monitored during such periods for changes in symptoms. Data supporting a link with suicidality have come from studies of patients younger than 18 years of age; however, because people mature at different rates, young adults who are being treated with these agents should be monitored especially carefully.
- Pharmacists should expect to hear questions from patients regarding the safety and continued use of their antidepressant medication. Pharmacists can help patients and other health care professionals to evaluate the situation to determine the most appropriate action for the patient.
- Patients should talk to their pharmacist or physician about any concerns they may have before making any changes to the way they take their medication.
- Patients should not abruptly stop taking or lower the dosage of their antidepressant medication and

should continue with their current medication plan until a decision is made with their health care provider because of the possibility of withdrawal symptoms, especially if the patient has been on extended therapy for 6 weeks or more. If a patient is taken off antidepressant medication, he or she should be advised of a tapered approach and should watch for increased dizziness, restlessness, agitation, anxiety, nervousness, headache, nausea and vomiting, mood changes, and fatigue. If a patient feels that these symptoms are severe or there is a reemergence of depression, the patient should immediately contact the health care provider. Patients should be carefully monitored for reemergence of depression or severe symptoms. If antidepressant therapy is discontinued, the dosage should be tapered gradually, over at least a 2-week time frame, to minimize withdrawal reactions.

Effect of Physicochemical Properties and Stereochemistry on Antidepressant Efficacy

Small substituent changes in molecular structure can affect the pharmacokinetic and pharmacodynamic (clinical) properties of antidepressant drug molecules, resulting in profound differences between their transporter selectivity and their antidepressant effect—for example, a difference of a 2-chloro group between the structurally related antidepressants imipramine and clomipramine or the *o*- versus *p*-substituents between duluoxetine (NSRI) and atomoxetine (SNRI) (Fig. 21.7). Furthermore, a seemingly simple isosteric replacement of a sulfur atom in the central ring of chlorpromazine with an ethylene group to give a 7-membered azepine ring (clomipramine), or the replacement of the methylpiperidylidene at the 5-position for the antihistamine/5-HT antagonist cyproheptadine with a dimethylaminopropylidene for the antidepressant reuptake inhibitor amitriptyline, has profound effects on the physicochemical properties, pharmacokinetics, mechanisms of action, and therapeutic activities (Fig. 21.7). On the other hand, the physicochemical differences can translate into differences in in vitro and in vivo pharmacological and clinical properties, as exemplified between mianserin and mirtazapine (Fig. 21.7) (31). The isosteric replacement of a benzene ring (mianserin) with a pyridine (mirtazapine) resulted in significant changes in their dipole moments, lipophilicity (log P), pK_a values, and electronegativity, resulting in different mechanisms of action and regioselectivity in formation of hydroxylated metabolites.

Many antidepressants are stereoisomers and contain either a chiral center or a center of unsaturation by which chiral metabolites could result (32,33). Often, such drugs are marketed as a mixture of the resultant enantiomers (racemates) or of geometric isomers. These enantiomers or geometric isomers may differ markedly from each other with regard to their pharmacodynamic and/or pharmacokinetic properties. Increased knowledge about the molecular structure of specific drug targets and an awareness of several possible advantages to using single enantiomers rather than racemic mixtures of drugs have led to an increased emphasis on understanding the role of chirality in drug development of antidepressant drugs. Several notable examples of antidepressants (the SSRIs) currently are available in which the individual enantiomers or geometric isomers differ considerably with regard to factors such as binding to SERTs and NETs, interactions with receptors and metabolizing enzymes, and clearance rates from the body.

Examples of the effects of chiral centers or geometric centers on such properties include racemic mixtures (e.g., fluoxetine, citalopram, bupropion, and trimipramine), single enantiomers (e.g., (+)-sertraline, (–)-paroxetine, (–)-escitalopram, and (–)-atomoxetine), or geometric isomers (e.g., *Z*-zimeldine, *Z*-dioxepin, *E*-dothiepin, and *E*-fluvoxamine). Recent developments in analytical and preparative resolution of racemic and geometric drug mixtures as well as increased interest in developing new drugs that interact with specific targets, which have been described in detail at the molecular level, have resulted in increased emphasis on stereochemistry in antidepressant drug development.

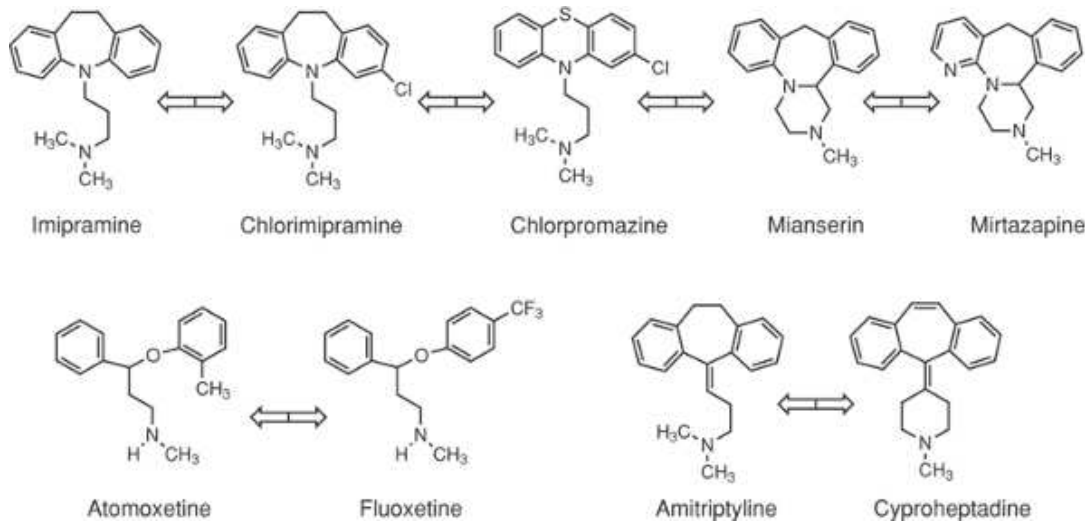

Fig. 21.7. Structural relationship between selected molecular structures.

Drug Metabolism and Drug–Drug Interactions

Antidepressant treatment carries increased risks of adverse drug events because of age-related physiologic changes, polypharmacotherapy, and individual variability in drug metabolism (e.g., genetic factors, concurrent disease, diet, and eating habits). Pharmacokinetic drug–drug interactions occur when one medication (the precipitant drug) significantly affects the plasma concentration, half-life, or both of another medication (the object drug) by altering its absorption, distribution, metabolism, or elimination. For object drugs with narrow therapeutic indices, even small elevations in plasma drug concentration can cause potentially serious adverse reactions. Pharmacodynamic drug–drug interactions occur when the precipitant drug affects the ability of the object drug to bind with its therapeutic target (e.g., transporter protein) or receptor. Some compounds compete directly for binding to a receptor; others indirectly affect the ability of an object drug to interact with its site of action. Many medications can bind to multiple receptor types (e.g., first-generation TCAs), causing diverse adverse reactions. Thus, before adding a new drug to an existing antidepressant regimen, it is wise to determine whether any medications can be eliminated. Reduction of total drug burden, adjustment of dose levels, and careful selection of an appropriate agent are important steps toward avoiding adverse drug interactions. In addition, the documented and potential drug interactions of the various classes of antidepressants—and of the specific drugs within each class—should be considered. Each patient should be treated individually and monitored carefully during the initiation and maintenance of antidepressant therapy.

The infamous drug–drug interactions between mibefradil (Propulsid) and terfenadine (Seldane) and other drugs metabolized by cytochrome P450 (CYP) 3A4 resulted in these drugs being withdrawn from the market, which placed a spotlight on hepatic drug metabolism as a significant participant in drug–drug interactions. Nearly all the antidepressants are metabolized by at least one CYP isoform, and these drugs and their metabolites may be substrates or inhibitors for the CYPs (Table 21.2).

When an antidepressant is metabolized by more than one CYP isoform in parallel, it is unlikely to be affected by drug interactions or genetic polymorphisms and to cause clinically significant drug interactions via CYP isoform inhibition (34). However, if the drug is metabolized primarily by CYP3A4 or the polymorphic CYP2C18 or CYP2D6 isoforms, the potential for drug–drug interactions increases. Therefore, knowledge regarding the metabolic pathways of antidepressants as well as knowledge about substrates and inhibitors of the CYP isoforms can assist in the selection of a proper drug and its dose, thus minimizing the risks of drug–drug interactions (37).

Table 21.2. Cytochrome P450 (CYP) Metabolisma

Antidepressant	Major CYP	Minor CYP	Metabolism Pathway	CYP Inhibito
Amitriptyline	2D6	3A4, 2C19, 2C9, 1A2, and 2B6	2D6, 3A4, 2C19, and 1A2 N-demethylation 2D6 and 2B6 E-10-hydroxylation	2D6, 2C19, 1A2, and 2C9b
Clomipramine	2D6	3A4, 2C19, 1A2, and 2C9	2D6, 3A4, 2C19, 2C9, and 1A2 N-demethylation 2D6 2- and 8-hydroxylation	2D6
Desipramine	2D6	1A2 and 2C19	1A2 and 2C19 N-demethylation 2D6 and 2C19 2-hydroxylation	2D6 and 2C19b
E-Doxepine	2D6 and 2C9	3A4, 1A2, and 2C19	2D6 and 2C9 hydroxylation 3A4 and 1A2 N-demethylation	
Z-Doxepine	2C19	2C9, 3A4, and 1A2	2C19 and 2C9 N-demethylation 3A4 and 1A2 N-demethylation	
Imipramine	2D6	3A4, 2C19, 1A2, 2B6, and 2C9	1A2 and 2C19 N-demethylation 2D6, 1A2, 3A4, and 2C19 2- and 10-hydroxylation	1A2, 2D6, and 2C19
Maprotiline	2D6	1A2	2D6 and 1A2 N-demethylation	
Nortriptyline	2D6	3A4, 2C19, and 1A2 N-demethylation 2D6 E-10-hydroxylation	2D6, 3A4, 2C19, and 1A2	2D6 and 2C19b
Trimipramine	2D6	2C9 and 2C19	2-hydroxyl, 10-hydroxyl, and N-demethylation	2D6

(±)-Citalopram	2D6	1A2 and 2C19	2D6, 2C19, and 3A4 N-demethylation 2D6 N-oxidation	1A2b and 2D6b
Escitalopram	2D6	1A2 and 2C19 2D6 N-oxidation	2D6, 2C19, and 3A4 N-demethylation	
(±)-Fluoxetine	2D6	3A4, 2C9, 2C19, and 1A2	2D6 and 2C19 N-dealkylation 1A2 and 2C9 O-dealkylation	2D6 (S-fluoxetin 1A2,b 2C19,b 3A4,b, 2C9, and 2D6b
Sertraline	3A4	2D6 and 2C19	3A4, 2C19, 2D6, and 2C9 N-demethylation	2C19,b 3A4,b and 2D6b
Fluvoxamine	1A2	3A4, 2C19, and 2D6	2D6 and 1A2 O-dealkylation	2C19, 1A2,I and 3A4b
Paroxetine	2D6	3A4, 1A2, and 2C9	2D6 cleavage methylene dioxy	2D6,c 2C19,b and 3A4b
Venlafaxine	2D6	3A4, 2C19, and 2C9	2D6, 2C19, and 2C9 O-demethylation 2C19, 2C9, and 3A4 N-demethylation	2D6b
Reboxetine	3A4		O-dethylation, aromatic ring hydroxylation	2D6 and 3A
Atomoxetine	2D6	3A4, 2C19, and 1A2	2D6, 1A2, 2B6, and 2C19 4-hydroxylation 2C19, 3A4, and 2B6 N-demethylation	
Duloxetine	2D6		4- and 6-hydroxylation	2D6
Mirtazepine	2D6	3A4 and 1A2	2D6 and 1A2 8-hydroxylation 3A4 N-demethylation 3A4 and 1A2 N-oxidation	3A4b and 2D6b

Bupropion	2B6	2E1, 3A4, and 2D6	Hydroxylation t-butyl group	2D6b
Trazodone	3A4	2D6	N-dealkylation to chlorophenylpiperazine Aromatic ring hydroxylation	
Trancypromine		3A4, 2A6, 2D6, 2C19, and 2C9	Aromatic ring hydroxylation	2A6c
Meclobemide	2C19	2D6 and 1A2	Aromatic ring hydroxylation Morpholine ring oxidation	2D6b

[b]Weak CYP inhibitor.

[c]Mechanism-based inhibition.

P-Glycoprotein Transporters

P-glycoprotein (P-gp) is a member of the ATP-binding cassette superfamily of membrane transport proteins responsible for the efflux of many drugs. It represents a major component of the blood-brain barrier and the intestinal barrier, and contributes to renal and biliary elimination of drugs. At the blood-brain barrier, P-gp is localized in the apical membrane of brain capillary endothelial cells and transports substrates into the blood. Therefore, P-gp limits the penetration into and retention of numerous compounds, including the antidepressants, within the brain and, thus, modulate their effectiveness and CNS toxicity.

P.561

Inhibition of P-gp could significantly increase drug concentrations in the CNS. Additionally, P-gp is highly expressed in the apical membrane of epithelial cells in the small and large intestine, where it transports drugs out of the cells into the intestinal lumen, thus limiting the bioavailability of compounds such as paclitaxel and HIV protease inhibitors.

The role of P-gp for affecting the pharmacokinetic parameters of antidepressants and contributing to numerous pharmacokinetic drug–drug interactions with coadministered drugs has not been thoroughly elucidated. Antidepressants, particularly TCAs, have a significant potential for inducing adverse drug reactions and, therefore, are subject to numerous drug–drug interactions. The role of P-gp in causing clinically relevant drug interactions is becoming more and more obvious (35). Concentrations of paroxetine and venlafaxine increased two to three times in the brains of mice without P-gp (i.e., knockout mice) after single-dose administration and after treatment for 11 days (34), suggesting that these antidepressants are P-gp substrates and that their pharmacokinetics might be influenced by coadministered P-gp inhibitors. In contrast, fluoxetine exhibited no P-gp substrate characteristics (34), indicating that not all antidepressants share these properties. For citalopram, the results are contradictory.

The potency of sertraline and its N-demethylated metabolite, desmethylsertraline, and paroxetine for inhibiting P-gp was comparable with that of quinidine (35). Fluoxetine, norfluoxetine, fluvoxamine, reboxetine, and O-demethylparoxetine showed intermediate inhibition, and citalopram, desmethylcitalopram, venlafaxine, and N-desmethylvenlafaxine showed only weak inhibition. No inhibition was found for O-desmethylvenlafaxine.

Inhibition of P-gp by drugs may play an important role in drug safety by increasing plasma and brain concentrations of coadministered drugs and, thus, causing adverse drug reactions. No evidence for a potent drug–drug interaction was found with fluoxetine, although sertraline and paroxetine exhibited the greatest potential for affecting the pharmacokinetics of coadministered drugs at the level of P-gp (35,36). At usual therapeutic doses of paroxetine and sertraline, however, the IC50 for the inhibition of P-gp is approximately 250 times higher than the plasma concentration for paroxetine and approximately 500 times higher than that for sertraline (36), suggesting that even if the accumulation of sertraline within the cell (e.g., in the biliary or renal system) is taken into account, the P-gp inhibition observed in vitro might not be clinically relevant. This is substantiated by the fact that neither sertraline, fluvoxamine, nor citalopram had a clinically relevant influence on the pharmacokinetic parameters of digoxin, a P-gp prototype substrate. On the other hand, in addition to being an inhibitor of CYP2D6, paroxetine is a substrate for this same isoform, the activity of which is regulated by a genetic polymorphism. In individuals who lack this active enzyme (i.e., poor metabolizers), plasma paroxetine concentrations are up to 25 times higher than those in individuals who are extensive metabolizers. Therefore, one cannot exclude that in patients who are poor metabolizers, administration of high doses of paroxetine may translate into clinically relevant changes in the pharmacokinetics of concomitantly administered P-gp substrates.

It remains to be studied whether the inhibition of P-gp by the newer antidepressants might lead to drug–drug interactions in patients. Such interactions might, for instance, be relevant when drugs with low oral bioavailability because of substantial transport back into the gut lumen are to be coadministered, as has been shown for loperamide when given in combination with quinidine (38).

Specific Drugs

Selective Norepinephrine Reuptake Inhibitors (SNRIs)

Despite the current popularity of the SSRIs for the treatment of depression, the noradrenergic neurons should not be overlooked, because they also influence the depressed mood (39). The noradrenergic system appears to be associated with increased drive, whereas the serotonergic system relates more to changes in mood (Fig. 21.1). Thus, the different symptoms of depression may benefit from drugs acting mainly on one or other of the neurotransmitter systems (18). The SNRIs (Fig. 21.8) seem to be at least as effective as the SSRIs in the treatment of depressive illness (39) by acting specifically at noradrenergic sites. Thus, the SSRIs and SNRIs influence depression by parallel, independent pathways. The SNRIs have a role in the treatment of depression, either alone or as adjunct therapy. The SNRI antidepressants are well tolerated but possess different adverse-event profiles.

The selectivity ratios (Fig. 21.6) show that the SNRIs, as a group, are potent selective inhibitors of the NET and that the secondary amine TCAs are substantially more potent with regard to their inhibition of NE reuptake in comparison to the SSRIs. Their in vitro affinity for inhibiting the NET essentially mirrors more or less their clinical efficacy as SNRIs (11): desipramine > protriptyline > amitriptyline = nortriptyline > reboxetine > maprotiline > amoxapine > imipramine > paroxetine. The level of affinity of the SNRIs for NET is not predictive for antidepressant activity.

Tricyclic Secondary Amine Antidepressants

Structure–activity relationship of the TCAs

The tricyclic ring structure can be found in a variety of different drugs and, for the most part, represents a method for medicinal chemists to restrict the conformational mobility of two phenyl rings attached to a common carbon or hetero atom. The tricyclic ring structure is formed by joining the two phenyl rings into 6-6-6 or 6-7-6 ring systems, in which the central ring is either a 6–membered or

7-membered carbocyclic or heterocyclic ring, respectively. Small molecular changes, such as ring flexibility, substituents, or heteroatoms in the tricyclic ring structure, can bring about significant changes in physicochemical, electronegativity (dipole moments), and pharmacodynamic properties (e.g., anticholinergics [antimuscarinic], cholinesterase inhibitors, antihistamine, antipsychotics, and antidepressants). This suggests that the tricyclic structure is not associated with affinity for any particular receptor but, rather, contributes to a range of multiple CNS pharmacodynamic (adverse) effects because of increased lipophilicity. The most common tricyclic ring found in drugs is the near-planar phenothiazine ring common to most of the

antipsychotic drugs (Fig. 21.9). The TCAs are classified as such because they contain a 6-7-6 ring arrangement in which the central 7-membered ring is either carbocyclic or heterocyclic, saturated or unsaturated, which is fused to two phenyl rings (Fig. 21.8; also see Fig. 21.15 for NSRIs). The side chain may be attached to any one of the atoms in the central 7-membered ring, but it must be three carbon atoms, either saturated (propyl) or unsaturated (propylidine), and have a terminal amine group (secondary or tertiary). The TCAs differ structurally from the antipsychotic phenothiazines in that the two phenyl (aromatic) rings are connected by a 2-carbon link to form a central 7-membered ring instead of a sulfur bridge.

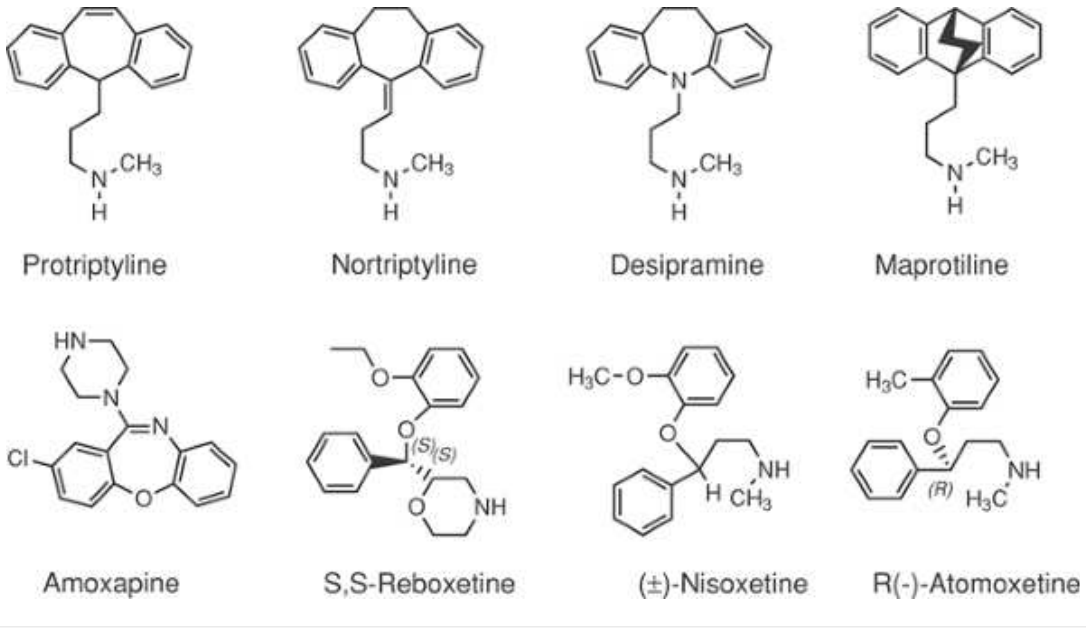

Fig. 21.8. Selective norepinephrine reuptake inhibitors (SNRI).

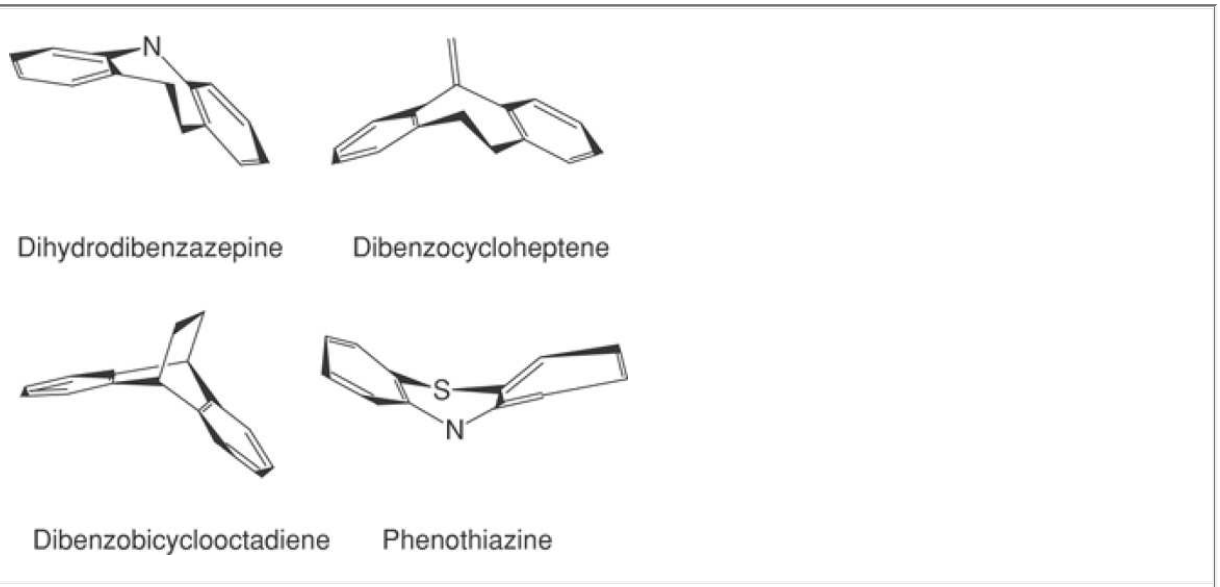

Fig. 21.9. Three-dimensional models of the tricyclic and tetracyclic ring systems.

The TCAs are subdivided into a dihydrodibenzazepine ring (a.k.a., iminodibenzyl, from which the name

imipramine is derived), a dibenzocycloheptene ring (e.g., amitriptyline), a dibenzoxepin ring (e.g., doxepin), a dibenzocycloheptriene ring (e.g., protriptyline), or a tetracyclic (bicyclic ring, e.g., maprotiline) derivatives. The tricyclic ring system has little significance regarding selectivity for inhibiting the NET or SERT, but it appears to be important for dopamine transporter inhibition.

The secondary and tertiary amine TCAs differ markedly with regard to their selectivity ratios (Fig. 21.6) and their pharmacodynamic and/or pharmacokinetic properties (Table 21.3; see Table 21.8). Substituting a halogen (i.e., chlorine; clomipramine) or cyano group into the 3-position of the dihydrodibenzazepine ring enhances preferential affinity for SERT. 3-Cyanoimipramine was investigated as a potent, SSRI but was never marketed as an antidepressant agent. It is used as a research probe for studying 5-HT transporters. Branching the propyl side chain with a 2-methyl group (as in trimipramine) significantly reduces the affinity (~100 times) of imipramine for both the SERT and NET. The *Z* (*cis*) geometry for the propylidine group in chiral TCAs appears to be important for transporter selectivity and affinity (e.g., doxepin).

Studies correlating the binding of the TCAs with the SSRIs found that the TCAs and SSRIs bind to different

sites on the transporter and that the TCAs may act as a modulator of monoamine reuptake by producing conformational changes in the transporter, affecting affinity of the monoamine neurotransmitter (40).

Table 21.3. Pharmacokinetics of the Selective Norepinephrine Reuptake In

Parameters	Desipramine	Nortriptyline	Amoxapine	Protriptyline	Maprotiline	Robo
Oral bioavailability (%)	60–70	32–79	ND	77–93	66–75	95
Protein binding (%)	91	92	92	92	88	>97

Time to steady-state concentration	ND	ND	ND		7 days	ND

ND, not determined.

Although similar in a two-dimensional plane to the antipsychotic (neuroleptic) phenothiazines, the ethylene bridge linking the two phenyl rings of the TCAs causes the two phenyl rings to be twisted out of the plane, leading to a less rigid and more conformationally mobile molecular structures than the phenothiazines (Fig. 21.9). The conformational mobility for the TCAs, including ring inversion of the tricyclic ring system, flexing of the CH_2-X bridge (X= CH_2, O, N, or S) in the central 7-membered ring, and flexibility of the alkyl side chain, can result in substantial changes in the overall shape of the molecules, affecting transporter affinity and selectivity, diverse neuroreceptor affinity, and their physicochemical properties. The rate of ring flexibility seems to be correlated with their differences in clinical potency. A dibenzazepine ring system exhibits a greater degree of conformational ring flexing, whereas the dibenzocycloheptene ring system and inserting heteroatoms into the benzylic position reduces the rate of ring flexing in TCAs and their potency (41). Thus, the differences in the pharmacological activity between these TCAs allows selective binding to their respective transporter proteins. The angle between the two aromatic rings ranges from 106 to 110° for the TCAs, and the large lipophilic ring enhances the affinity of TCA to block the CNS muscarinic, H_1-, and α_1-adrenergic receptors and to block sodium channels, contributing to its multiple pharmacodynamic effects.

Pharmacokinetics common to secondary amine TCAs

The secondary amine TCAs are rapidly and well absorbed following oral administration. Although the pharmacokinetics are approximately similar within the tertiary and secondary amine groups, the pharmacokinetics are different between the two groups (Table 21.3; also see Table 21.9 for NSRIs). The secondary amine TCAs have relatively high bioavailability. Their primary routes of hepatic metabolism are N-demethylation to inactive primary amine metabolites and aromatic ring hydroxylation (Table 21.2). Despite the fact that serum plasma levels are reached with 1 to 2 days, their onset of antidepressant action typically is at least 2 to 3 weeks or longer. Their volume of distribution is very high, suggesting distribution into the CNS and protein binding. Elimination is primarily as metabolites and their conjugates via renal elimination. Renal and liver function can affect the elimination and metabolism of the parent secondary amine TCA and its metabolites, leading to increased potential for adverse effects, especially in those patients (i.e., the elderly) with renal disease.

Mechanisms of action common to secondary amine TCAs

The exact mechanism of action for the secondary TCAs is unclear, but the secondary amine TCAs exhibit substantially more affinity than the SSRIs and the tertiary TCAs for inhibiting the NE transporter. None of the secondary TCAs has significant affinity for the dopamine transporter. Blocking the reuptake of NE increases its concentration in the synaptic cleft and its ability to interact with synaptic NE receptors. When drugs are selective for a transporter, differences in potency become clinically irrelevant, because the plasma concentration can be dose-adjusted to achieve inhibition of the desired transporter without affecting the other

transporters. During chronic therapy with the TCAs, adaptive changes at the noradrenergic receptor occur (i.e., downregulation) as a result of neurotransmitter hypersensitivity from low concentrations of NE at the postsynaptic receptor. These changes involve the α_1-adrenergic receptor.

Therapeutic uses common to all TCAs

The efficacy of the secondary and tertiary amine TCAs in the clinical treatment of depressive illness is recommended for various conditions, including major depressive episodes, dysthymia, panic disorder, social phobia, bulimia, narcolepsy, attention-deficit disorder with or without hyperactivity, migraine headache and various other chronic pain syndromes, enuresis in children, and obsessive-compulsive disorder (clomipramine). The TCAs possibly are useful as well for a broader range of depressive conditions described as dysthymia or depressive neurosis and even for prolonged or pathological mourning, agoraphobia without panic attacks, and some of the symptoms (e.g., nightmares) in posttraumatic stress disorder.

Adverse effects common to all TCAs

The family of TCAs has many undesirable side effects and behaves like “five drugs wrapped into one.” They not only block the reuptake of NE and 5-HT but also block muscarinic receptors (anticholinergic), α_1-adrenergic receptors, H_1-receptors (antihistamine), and sodium channels. The common side effects and appropriate responses are given in Table 21.4.

Drug–drug interactions common to the secondary amine TCAs

The secondary amine TCAs were once first-line therapy for depression because of their efficacy in a broad range of depressive disorders. Today, however, these agents generally are reserved for second-line treatment because of their narrow therapeutic-to-toxicity ratios and troublesome adverse-effect profiles. Even the better-tolerated nortriptyline is fatal in overdose and may have significant adverse effects at therapeutic dose levels. Most TCAs are metabolized by multiple CYP enzymes and, thus, are likely to be object drugs for many common medications. Because these TCAs have narrow therapeutic indices, any interference with their metabolism can lead to serious adverse reactions resulting from increased plasma concentrations (e.g., arrhythmias, seizures, and confusion). Such reactions are both more common and more likely to be life-threatening in elderly patients because of age-related pharmacokinetic alterations. Therefore, although specific secondary amine TCAs are useful for some conditions (e.g., major depression), coadministration with other drugs should be done cautiously.

Table 21.4. Common Side Effects with Secondary Amine Tricyclic Antidepressants and Recommendations

Side Effects	Treatment Recommendations
Dry mouth	Drink sips of water; chew sugarless gum; clean teeth daily
Constipation	Diet rich in bran cereals, prunes, fruit, and vegetables
Bladder complaints (weak urine stream, emptying difficulty, painful urination)	Consult physician
Sexual problems	Consult physician
Blurred vision	Should pass with time

Dizziness	Rise slowly from the bed or chair
Daytime drowsiness	Do not drive; take medication at bedtime; commonly will pass with time

Concurrent administration of these TCAs and MAOIs is contraindicated, and at least two weeks should elapse between discontinuance of TCA therapy and initiation of MAOI therapy, and vice versa, to allow washout. Coadministration of SNRIs, TCAs, and MAOIs is potentially hazardous and may result in severe adverse effects associated with hypertension.

Because protein binding of secondary amine TCAs is high, displacement interactions with other highly protein-bound drugs with narrow therapeutic indices, although not yet fully evaluated, may be important. Concurrent use of the secondary amine TCAs with anticholinergic or sympathomimetic drugs requires close supervision and careful adjustment of the dosage because of potential additive anticholinergic effects (i.e., spastic colon) and increased blood pressure and heart rate. An additional disadvantage of these TCAs is their toxicity from overdosage, especially in those being treated for depression who may have suicidal thoughts.

In addition, the secondary amine TCAs are inhibitors of sodium channels and, thus, can slow ventricular conduction at therapeutic doses. If the patient overdoses or drug interactions result in increased plasma concentration of the TCA, severe conduction block contributing to cardiotoxicity may result in ventricular arrhythmias. Also, changes in CNS conduction can result in seizures. Patients who are sensitive to one TCA may be sensitive to other TCAs.

The effect of smoking on the activity of CYP1A2 does not appear to have an affect on the plasma concentrations of the secondary TCAs. This is because CYP1A is not involved with the N-dealkylation to their primary amine metabolites.

For common patient information and recommendations, see Table 21.5.

Unique properties for the specific secondary amine TCAs

Desipramine

Desipramine is a dihydrodibenzazepine secondary amine TCA that also is the active metabolite of imipramine (Fig. 21.8). Desipramine appears to have a bioavailability comparable to the other secondary TCAs (Table 21.3). Desipramine is distributed into milk in concentrations similar to those present at steady state in maternal plasma. This drug is metabolized primarily by CYP2D6 to its 2-hydroxy metabolite and by CYP1A2 and CYP2C19 to its N-demethylated (primary amine) metabolite (Table 21.2).

Desipramine exhibits a greater potency and selectivity for the NET than the other secondary TCAs do (Fig. 21.6). Its antidepressant effect results from increases in the level of NE in CNS synapses, and long-term administration

causes a downregulation of α_1-adrenoceptors and desensitization of presynaptic α_2-receptors, equilibrating the noradrenergic system and, thus, correcting the dysregulated output of depressed patients. The SSRIs do not produce this effect. Desipramine also downregulates the NET, but not the 5-SERT. Substantial loss of NE transporter–binding sites takes 15 days to occur and is accompanied by a marked reduction of NET function in vivo. Desipramine has weak effects on 5-HT reuptake.

Table 21.5. Patient Information and Recommendations for Secondary Amines Tricyclic Antidepressants (TCAs)

Patient Information	Recommendations

Potential drug–drug and drug–health interactions	Share medical conditions, other medicines (including over-the-counter and herbal medicines), allergies to TCAs, fertility status, or breast-feeding with pharmacist
Seizures, breathing difficulties, fever and sweating, loss of bladder control, muscle stiffness, unusual weakness or tiredness	Discontinue therapy, and consult physician (TCAs may increase risk of seizures)
Course of therapy	Complete full course of therapy
Discontinuance of therapy	Consult physician; abrupt discontinuance not recommended, because it may cause nausea, headache, and malaise
Alcohol use	Avoid alcohol
Central nervous system depressants	May exacerbate TCAs
Drowsiness, dizziness, blurred vision	Avoid driving or performing tasks requiring alertness and coordination
Sun/sunlamp exposure	Avoid prolonged exposure because of photosensitivity

Nortriptyline

Nortriptyline is a secondary amine dibenzocycloheptene TCA (Fig. 21.8) as well as the major metabolite of amitriptyline. Similar to desipramine, nortriptyline appears in mother's milk and is metabolized by CYP2D6 to the primary amine and by ring hydroxylation to its E-10-hydroxy metabolite (Table 21.2). Approximately one-third of a dose of nortriptyline is excreted in urine as metabolites within 24 hours, and small amounts are excreted in feces via biliary elimination.

Amoxepine

Amoxapine is a dibenzoxazepine TCA (Fig. 21.8) with antidepressant and antipsychotic effects that has shown therapeutic effectiveness in patients with delusional depression. Additionally, it is the N-desmethyl metabolite of the antipsychotic loxapine. Amoxapine differs structurally from the other secondary TCAs in that it has both a nitrogen and an oxygen atom in its 7-membered central ring and a piperazinyl ring rather than a propylamino side chain attached to the central ring.

Amoxapine is a less potent inhibitor of neuronal NE reuptake compared with the other secondary TCAs, with a mechanism of action similar to that of desipramine. Amoxapine shares the toxic potentials of the TCAs, and the usual precautions of TCA administration should be observed. Amoxapine resembles the atypical

antipsychotic drugs in its intermediate affinity as an antagonist of dopamine-2 and of 5-HT_2 receptors.

Amoxapine is rapidly and almost completely absorbed from the gastrointestinal (GI) tract. Its pharmacokinetics are shown in Table 21.3. Amoxapine and its 8-hydroxyamoxapine metabolite have been detected in human milk at concentrations below steady-state therapeutic concentrations. Amoxapine has the shortest elimination time (~8 hours) of the secondary TCAs. It is metabolized in the liver principally to 8-hydroxyamoxapine and to 7-hydroxyamoxapine. Both of these metabolites are pharmacologically active and have half-lives of 30 and 6.5 hours, respectively. The hydroxylation of amoxapine is inhibited by ketoconazole, suggesting the involvement of CYP3A4.

Protriptyline

Protriptyline is a dibenzocycloheptriene TCA that differs from the other tricyclics by having an unsaturated ethylene bridge joining the two aromatic rings and a secondary aminopropyl side chain (Fig. 21.8). Protriptyline is completely absorbed from the GI tract and slowly eliminated. Its pharmacokinetics are shown in Table 21.3. Metabolism data are limited for protriptyline, but it is most likely to be metabolized via the same pathways as the other TCAs are (Table 21.2). Very little drug is excreted in the feces via the bile.

Protriptyline exhibits high selectivity for the NE transporter, but with less potency than desipramine. Its mechanism of action is similar to that of desipramine. Minimal effect on 5-HT reuptake has been observed.

Maprotiline

Maprotiline is a secondary amine dibenzobicyclooctadiene (a tetracyclic antidepressant) that differs structurally from the TCAs by having an ethylene bridge in its central ring, resulting in a rigid bicyclo-molecular skeleton (Fig. 21.8).

Maprotiline exhibits the highest affinity and selectivity for the NE transporter (Fig. 21.6). Its antidepressant mechanism of action is similar to that of desipramine, with an onset of action of up to 2 to 3 weeks.

Maprotiline is slowly but completely absorbed from the GI tract, and like the other TCAs, it is metabolized by the polymorphic CYP2D6 and CYP2C19 isoforms in the liver, primarily to pharmacologically active N-desmethylmaprotiline and to maprotiline-N-oxide. Its pharmacokinetics are shown in Table 21.3. Maprotiline is distributed into breast milk at concentrations similar to those found at steady state in maternal blood. The elimination half-life of maprotiline averages 43 hours (60–90 hours for its N-desmethyl metabolite).

Maprotiline shares the toxic potentials of the TCAs, and the usual precautions of TCA administration should be observed. Although most of the TCAs have been

reported to induce seizures, it is generally recognized that maprotiline may be associated with a higher incidence of dose-dependent seizures compared with the other secondary TCAs. Maprotiline has been reported to produce sedation in depressed patients and to reduce aggressive behavior in animals. Maprotiline also shares the anticholinergic and cardiovascular effects of the secondary TCAs and may cause electrocardiographic changes, tachycardia, and postural hypotension.

Nontricyclic Secondary Amine Antidepressants

Reboxetine

Reboxetine is a nontricyclic SNRI in which the propylamine side chain of the TCAs is constrained into a morpholine ring (Fig. 21.8). It is a potent and selective ligand for the NET, with a mechanism of action is similar to that of desipramine. Reboxetine is used for the treatment of major depressive disorders. It is a chiral compound that is marketed as a racemic mixture of *R*,*R*- and *S*,*S*-reboxetine. The antidepressant activity for reboxetine appears to reside with the *S*,*S*-(+)-enantiomer, which has approximately twofold the inhibition potency of the *R*,*R*-enantiomer (42). It is well tolerated, with different adverse-event profiles, and it appears to be at least as effective as the SSRIs in the treatment of depressive illness. Currently, it is available only in Europe and is under U.S. FDA review. It preferentially inhibits the reuptake of NE (5-HT:NE ratio, 8). Reboxetine is not metabolized by the polymorphic isoforms, CYP2D6 or CYP2C19, and may offer a valuable alternative to the secondary amine TCAs in the treatment of major depression. Reboxetine is likely to become a promising alternative for patients who have failed treatment with or do not tolerate serotonergic antidepressants. Reboxetine has been shown to be effective and well tolerated in the treatment of panic

disorder.

Reboxetine's oral bioavailability is greater than 90% for both *R*,*R*-(–)-reboxetine and *S*,*S*-(+)-reboxetine, indicating that stereoisomerism has no significant effect on absorption and first-pass metabolism. The pharmacokinetics of reboxetine are linear following multiple oral doses of 12 mg/day (Table 21.3). Food affects the rate but not the extent of absorption. In human liver microsomes, each reboxetine enantiomer was metabolized to one primary metabolite, O-desethylreboxetine, and three minor metabolites, two arising via oxidation of the ethoxy aromatic ring and a third yet-unidentified metabolite (43). The metabolism of both reboxetine enantiomers in humans is mediated principally via CYP3A4 and are a competitive inhibitors of CYP2D6 and CYP3A4. Less than 10% of the unmetabolized drug is cleared renally, with the other 90% being excreted hepatically.

After a single, 4-mg dose, the plasma concentration in the elderly (mean age, 81 years) was twice that of younger subjects, although in both groups, the plasma concentration was similar after 2 hours. The area under the curve (AUC) was nearly four times greater in the elderly than in the younger subjects, and the elimination half-life was twice as long (24 ± 6 vs. 12 ± 3 hours). Renal clearance also was reduced. The increased plasma concentrations of reboxetine observed in elderly subjects supports a reduction of the starting dose to 4 mg/day (in two divided doses) for elderly patients (44). Because of reduced metabolic clearance, reboxetine plasma concentrations also are increased in those patients with hepatic or renal dysfunction. In these populations, reboxetine should be used with caution, and a dosage reduction is indicated. No ethnic differences have been observed with *R*,*R*-(–)- or *S*,*S*-(+)-reboxetine.

Drug interactions

Reboxetine seems to be an antidepressant that has negligible interference with the pharmacokinetics of other drugs; thus, fewer drug–drug interactions are expected. It also may be possible to use reboxetine in combination with MAOIs, because it has no inhibitory effect on this enzyme, which would avoid tyramine-induced hypertensive reactions.

Adverse effects

Reboxetine is relatively well tolerated, with insomnia, sweating, constipation, and dry mouth being commonly reported adverse events. Hypotension and urinary hesitancy occur at lower rates than with the TCAs. When compared with the SSRIs, reboxetine is associated with lower rates of nausea, somnolence, and diarrhea.

Structure–activity relationships for the phenoxyphenylpropylamines

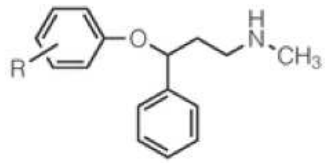
(±)-Nisoxetine

Nisoxetine (Fig. 21.8) was the initial phenoxyphenylpropylamine synthesized in the Lilly research laboratories during the early 1970s from the rearrangement of an oxygen atom in diphenyhydramine, a diphenylmethoxyethylamine, to a phenoxyphenylpropylamine (Figs. 21.2). Nisoxetine was discovered to be a potent and very selective SNRI, with little affinity for other receptors. It underwent clinical studies as an alternative to Lilly's best-selling antidepressant, nortriptyline, but without the adverse effects associated with the tricyclic secondary amines. It was never marketed, however, because of a greater interest in developing its 4-trifluoromethyl analogue, fluoxetine, an SSRI.

The type and position of the ring substitution plays a critical role in the mechanism of action for these phenoxyphenylpropyamines (see Table 21.6 for structure–activity relationships of the phenoxypropylamines). The unsubstituted molecule is a weak SSRI. However, 2-substitutions into the phenoxy ring (except for the 2-trifluoromethyl) yields compounds with high potency and selectivity for blocking NE reuptake (an SNRI), whereas the 4-substitution results in compounds having potent SSRI activity, with the 4-trifluormethyl group (fluoxetine) being the most potent and selective for SERT (28,29). The substantial changes in transporter selectivity for NET and SERT and the differences in affinity is more likely attributed to the bulky 2-(ortho)-substituted groups, which restricts the flexibility of the aromatic rings, thereby enhancing alignment of the hydrogen-bond acceptor group (the methoxy)

with a donor group on the binding site on the NET for NE that is not available for the 5-HT binding site. The *R*-isomer of nisoxetine has 20 times greater affinity than its *S*-isomer for NET. The NET K_i for nisoxetine is 0.8 nM and is 40 times more selective for NET than for SERT. Its tertiary amine is approximately 100 times

less effective at inhibiting NET. Increasing the size of the dimethylamino with ethyl or larger alkyl eliminates all activity. The 2- and 4-analogues exhibited weak effects on neuronal uptake of dopamine and lack affinity for other neuroreceptors at therapeutic concentrations. Substituting the 2-methoxy with the isosteric 2-methylthio (thionisoxetine) produced a more potent SNRI (K_i = 0.2 nM for the *R*-enantiomer) and 600 times more selective for NET than for SERT. Thionisoxetine is approximately 10 times more potent than nisoxsetine at inhibiting NET, and unlike nisoxetine, it reduces food consumption in rodents and has been studied for the treatment of obesity and eating disorders. Substitution of the phenoxy group with a naphthyloxy group and the phenyl ring with the isosteric thienyl (thiophene) group results in a drug with dual inhibition of NE and 5-HT reuptake (i.e., duloxetine) (see Fig. 21.18 and the discussion of nonselective inhibitors of NE and 5-HT for a description of duloxetine).



R (drug)	Inhibition of Re-Uptake (Ki nM) (20)	
	5-HT	NE
H	102	200
2-OCH_3 (nisoxetine)	1371	2.4
2-SCH_3 (thionisoxetine)	130	0.2

4-OCH_3	71	1207
4-Cl	142	568
4-F	638	1276

Table 21.6. Structure Activity Relationships for Phenoxyphenyl-propylamines

R-(–)-atomoxetine

R-(–)-atomoxetine, a 2-methylphenoxyphenylpropylamine, was marketed in 2003 as a "nonstimulant" treatment for attention-deficit hyperactivity disorder (ADHD) in both adults and children and for treatment of adult depression. The 2-methyl substitution (c.f., nisoxetine) (Fig. 21.8) confers selectivity for inhibiting NE reuptake (Table 21.6) (21,22,45). The *R*-enantiomer is 10 times more potent than the *S*-enantiomer as a NET reuptake inhibitor. Atomoxetine has a low propensity for anticholinergic and adverse cardiovascular effects.

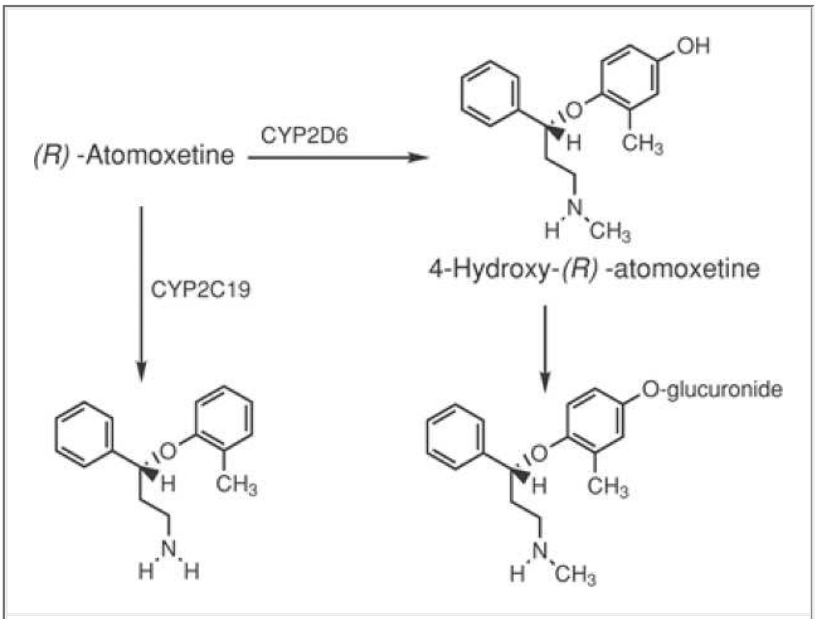

Fig. 21.10. Metabolism of *R*-atomoxetine.

Pharmacokinetics

Atomoxetine is well absorbed from the GI tract and cleared primarily by metabolism, with the majority of the dose being excreted into the urine. Atomoxetine is metabolized primarily by CYP2D6 to its major active metabolite, 4-hydroxyatomoxetine, which is eliminated as its glucuronide (Fig. 21.10). Peak plasma concentrations of atomoxetine occur 1 to 2 hours after oral administration. Significant differences are seen in the elimination half-life between normal metabolizers, extensive metabolizers, and poor metabolizers (Table 21.3). Atomoxetine exhibited an elimination half-life of 3 to 6 hours for normal and extensive metabolizers and 17 to 21 hours for poor metabolizers (46). CYP2C19 is the other enzyme primarily responsible for the formation of its minor metabolite N-desmethylatomoxetine (46).

Adverse effects

At therapeutic doses, no serious drug-related adverse effects have been encountered. Adverse effects have included modest increases in diastolic blood pressure and heart rate, anorexia, weight loss, somnolence, dizziness, GI effects (nausea), dry mouth, and skin rash.

Therapeutic uses

Atomoxetine is used as a safe and well-tolerated “nonstimulant” treatment of ADHD in both adults and children and of depression. Among children and adolescents aged 8 to 18 years, atomoxetine was superior to placebo in reducing symptoms of ADHD and in improving social and family functioning symptoms. Oral atomoxetine is promoted as an alternative to conventional ADHD therapy with methylphenidate, dextroamphetamine, and pemoline. It also can be a replacement for bupropion or for TCAs. Onset of action is approximately 7 days.

Selective 5-HT Reuptake Inhibitors (SSRIs)

Serotonin Hypothesis of Depression

5-HT is a major player in depressive illness, and serotonergic pathways are closely related to mood disorders, especially depression (Fig. 21.1) (11,47). Thus, drugs affecting the 5-HT levels in the neural synapse and serotonergic pathways may lead to effective therapy of depression.

5-HT is synthesized from tryptophan, packaged into vesicles, and released into the synaptic cleft following an

action potential (see Chapter 14). Once in the synaptic cleft, 5-HT interacts with both the pre- and postsynaptic serotonergic receptors. Evidence implicating multiple abnormalities in serotonergic pathways as a cause of depression include:

1. Low urinary concentrations of 5-HT's major metabolite, 5-hydroxyindoleacetic acid.
2. A low density of brain and platelet 5-HT transporters in depressed individuals.
3. A high density of brain and platelet 5-HT binding sites.
4. A low synaptic concentration of tryptophan, which is used in 5-HT synthesis.

Of these, the low level of SERTs in depressed patients has received the most attention in the development and synthesis of the SSRIs. The precise antidepressant mechanism of action for the SSRIs eludes neuroscientists, but the SSRIs have been shown to alleviate depression and are the most commonly used drugs in the therapy for depression. Claims of decreased adverse effects (adverse drug reactions) and less toxicity in overdose than both the MAOIs and the TCAs, together with increased safety, have led to their extensive use, and several are ranked in the Top 50 prescription drugs dispensed in the United States during the year 2005.

The SSRIs are proven treatments for depression, obsessive-compulsive disorder, and panic disorder and are helpful in a variety of other conditions as well. The most substantial benefit to the SSRIs compared with the TCAs is their reduced adverse-effect profile and the fact that they are better tolerated. Although the SSRIs have become the most commonly prescribed drugs for depression, there are clinical situations in which TCAs may be more appropriate (e.g., melancholic depression). Meaningful differences between the individual SSRIs are largely related to their pharmacokinetics, metabolism to active metabolites, inhibition of CYP isoforms, effect of drug–drug interactions, and the half-life of the individual SSRI.

The SSRIs are expensive, and it has been common to have noncompliant patients (especially elderly) relapse because they cannot afford their medications. Persuading the patient to take his or her medication as prescribed is extremely important for potentially suicidal patients with depression. Because of this, it is exceedingly important that patients receive the lowest effective (and, thereby, the most cost-effective) dose of any drug they are prescribed. Also, the SSRIs have a history of increased risk of suicide for reasons that are not clearly understood.

The Discovery of SSRIs

Although the TCAs, as a group, are effective antidepressants, their adverse-event profile and high potential for toxicity have limited their use. The early antidepressants indicated that 5-HT might play a significant role in depression. Therefore, medicinal chemists set out in search of the ideal SSRI with the goal for developing drugs with:

- High affinity and selectivity for the 5-HT uptake transporter.
- Ability to slow or inhibit the transporter when bound to it.
- Low affinity for the multiple neuroreceptors known to be responsible for many of the adverse effects of the TCAs (e.g., acetylcholine, histamine, and adrenergic receptors).
- No inhibition of the fast sodium channels. which cause the cardiotoxicity problems associated with TCAs.

Initial success occurred with the synthesis of zimeldine, in which the central ring of amitriptyline was opened to form a diphenylpropylidine analogue. *Z*-zimeldine displayed selective inhibition of 5-HT reuptake, with minimal inhibition of NE reuptake. Most importantly, zimeldine was without the adverse-event profile exhibited by the TCAs. Thus, zimeldine became the template for the second-generation SSRIs shown in Figures 21.11 to 21.13.

Mechanisms of Action Common to the SSRIs

The SSRIs preferentially act to inhibit SERT (the reuptake transporter for 5-HT) with minimal or no affinity for

NE and dopamine transporters (11). These drugs have a high and selective affinity for SERT (Fig. 21.6) and, therefore, block 5-HT from binding to SERT and being absorbed into presynaptic cells. The excess 5-HT in the synaptic cleft means overactivation of the postsynaptic receptors. Over an extended period of time, this causes downregulation of pre- and postsynaptic receptors, a reduction in the amount of 5-HT produced in the CNS, and a reduction in the number of SERTs expressed. Long-term administration of SSRIs causes downregulation of the SERT, but not the NET. Substantial loss of 5-HT transporter binding sites takes 15 days to occur and is accompanied by a marked reduction of SERT function in vivo. These compensatory responses at receptors and transporters are thought to produce the antidepressant effects of SSRIs. This onset delay may, in part, explain the delayed onset of action of SSRIs in the treatment of depression (48). Similar to the binding of 5-HT, SSRIs likely bind to SERT at the same site as 5-HT does, although it has not been determined conclusively. Although not as selective as the SSRIs, drugs of abuse, such as cocaine, fenfluramine, and 3,4-methylenedioxymethamphetamine (“Ecstasy”), are inhibitors of SERT.

The affinity data for the SSRIs show that the SSRIs, as a group, are very potent and selective inhibitors for SERT compared with their affinity for NE and dopamine reuptake transporters (Fig. 21.6) and are more potent inhibitors of 5-HT reuptake than are the tertiary amine TCAs, with the exception of clomipramine. None of the SSRIs has substantial effect on the NET or dopamine transporter. Of the SSRIs, sertraline exhibits the most potent inhibition of dopamine reuptake transporter, although it is still 100 times less potent in terms of inhibiting the dopamine versus the SERT. Therefore, the plasma concentration of sertraline would have to be increased by as much as 100 times to inhibit the dopamine reuptake transporter. When drugs are this selective for the reuptake transporters, differences in potency become clinically irrelevant, because the plasma concentration can be dose-adjusted to achieve inhibition of the desired transporter without affecting the other transporters. Clomipramine displays less affinity for SERT than citalopram, fluvoxamine, paroxetine, or sertraline does and is more potent than fluoxetine. In terms of the ability to inhibit the NET, the SSRIs are two to three times less potent than the SNRI TCA, desipramine.

Their in vitro potency for selectively inhibiting the 5-HT transporter more or less mirrors their clinical efficacy as SSRIs (11): paroxetine> sertraline> clomipramine> fluoxetine> citralopram> fluvoxamine> imipramine> amitriptyline> roboxetine> venlafaxine = milnacipran> desipramine. Clinically, however, all the SSRIs are equally effective over time, suggesting that these variations in potency do not affect efficacy or adverse effects. The SSRIs have less affinity for α_1, α_2, H_1, and muscarinic receptors, which may explain the adverse-effect profile differences between TCAs and SSRIs.

The results in Table 21.7 show the therapeutic doses that produce approximately 70 to 80% inhibition of the SERT (48). The inhibition of SERT is relevant to the antidepressant efficacy of the SSRIs and suggests that approximately 70 to 80% inhibition of this transporter usually is necessary to produce an antidepressant effect. Higher doses of these drugs do not produce a greater antidepressant response on average (i.e., a flat dose–response curve for antidepressant efficacy) but do increase the incidence and severity of adverse effects mediated by excessive 5-HT reuptake inhibition. Obviously, the results shown in Table 21.7 pertain to the average patient. A patient who has a rapid clearance of the SSRI may need a higher-than-average dose to achieve an effective concentration, whereas a patient who has a slow clearance may do better in terms of the ratio of efficacy to adverse effects on a minimum dose.

The β-adrenergic blocker pindolol blocks the presynapatic 5-HT_{1A} receptors, thereby increasing 5-HT neuronal transmission. The 5-HT_{1A} receptors do not require prolonged exposure (several weeks) to excessive amounts of 5-HT to promote downregulation. This results in augmentation and acceleration of the antidepressant effect of the SSRIs when combined with a 5-HT_{1A} inhibitor. Bordet et al. (49) demonstrated the accelerated antidepressant response of pindolol with paroxetine.

Table 21.7. Relationship Between Dose, Plasma Level, Potency, and Serotonin Uptake

SSRI	Dose (mg/day)	Plasma Level	In Vitro Potency (IC50)	Inhibition of SERT
Citalopram	40	85 ng/mL	1.8	60%

		(260 nM)		
Fluoxetine	20	200 ng/mL (300 nM)a	3.8	70%
Fluvoxamine	150	100 ng/mL (300 nM)	3.8	70%
Paroxetine	20	40 ng/mL (130 nM)	0.29	80%
Sertraline	50	25 ng/mL (65 nM)	0.19	80%

[a]Plasma level for fluoxetine represents the total of fluoxetine plus norfluoxetine given comparable effects on SERT; parent SSRI alone shown for all others. Also, plasma levels are a total of both enantiomers for citalopram and fluoxetine. Values for the parent drug and for the respective major metabolite are in parentheses.

Pharmacokinetics Common to the SSRIs

The SSRIs share a number of pharmacokinetic characteristics (48,50) (Table 21.8). They are well absorbed orally, although the presence of food in the stomach may alter the absorption of some SSRIs. Food, however, does not affect the AUC and does not appear to affect clinical efficacy. The SSRIs are highly lipophilic and are highly plasma protein bound.

Current SSRIs tend to be characterized by high volumes of distribution, which results in relatively long plasma concentration (typically 4–8 hours). The SSRIs display a range of elimination half-life values for the parent drugs, from half-life values of approximately 20 hours for paroxetine and fluvoxamine to 2 days for fluoxetine. Only sertraline and citalopram exhibit linear pharmacokinetics, whereas fluvoxamine, fluoxetine, and paroxetine exhibit nonlinear pharmacokinetics (i.e., changes in plasma concentration are not proportional to dose) as a result of their longer plasma half-lives within the usual therapeutic ranges (Table 21.8). Sertraline stands out as having the best effects on depression among all antidepressants. Fluoxetine and fluvoxamine are least likely to penetrate into breast milk. Thus, the SSRI antidepressants best suited for pharmacokinetic optimization of therapy are the following: sertraline, fluvoxamine, and citalopram. All the SSRIs are extensively metabolized by CYP isoforms to pharmacologically active N-demethylated metabolites, which are then excreted in urine and feces. Except for sertraline, the drugs fluoxetine, paroxetine,

and fluvoxamine are metabolized by polymorphic CYP isoforms, a matter of concern for poor and extensive metabolizers who may need dose adjustments. Citalopram is metabolized almost equally by CYP2C19, CYP2D6, and CYP3A4 (Table 21.7). Peak plasma levels usually are reached in approximately 6 to 8 hours and steady-state plasma levels in approximately 7 to 10 days except for fluoxetine (~4 weeks). The half-lives are variable depending on the specific SSRI and the presence and plasma concentration of an active metabolite, but the half-lives tend to be prolonged. No evidence indicates that serum drug monitoring of SSRIs is a useful strategy to predict response. The SSRIs in general exhibit a flat, dose-independent antidepressant response curve (i.e., the antidepressant activity does not improve with increasing dose, only side effects increase) (50).

Table 21.8. Pharmacokinetics of the Selective Serotonin Reuptake Inhibit

Parameters	(±)-Fluoxetine	(–)-Sertraline	(–)-Paroxetine	E-Fluvoxamine	(±)-Citalo[(+)-Esci

(days)					

Some of the key differences among the SSRIs are the result of differences in their pharmacokinetic properties and metabolism to active metabolites (Table 21.8). Fluoxetine is unique because of its long half-life and the long half-life of its active metabolite norfluoxetine (48,50). Although sertraline also has an active metabolite, it is 10 times less potent than sertraline and probably is not clinically relevant (51). Fluvoxamine and paroxetine have no active metabolites. Because of the differences in half-lives and activities of metabolites, a much longer washout period is necessary when switching from fluoxetine (a long-acting SSRI) to another SSRI or MAOI. These differences can cause considerable therapeutic delays in the treatment of refractory patients.

Adverse Effects Common to the SSRIs

The SSRIs are reported to have fewer side effects than the TCAs, which have strong anticholinergic and cardiotoxic properties (50). Among the SSRIs, there are few differences in adverse effects. The adverse effects observed for the SSRIs include nausea, diarrhea, anxiety, agitation, insomnia, and sexual dysfunction. Fewer patients have discontinued SSRIs than TCAs (amitriptyline and imipramine, and not nortriptyline, desipramine, doxepin, and clomipramine).

Sexual dysfunction is reported in both men and women, such as of decreased libido, anorgasmia, ejaculatory incompetence, ejaculatory retardation, or inability to obtain or maintain an erection. The basic pharmacological similarities among the SSRIs suggest that the effects on sexual function should be similar for each drug and that no one SSRI was more likely to cause the reported sexual adverse effects than another. Moreover, evidence suggests that SSRI-induced sexual dysfunction may be dose-related and may be treated by simply lowering its dose. In patients who cannot have their SSRI dosage reduced, another option is simply to wait and reassess sexual function after several months. If the above measures are ineffective in managing SSRI-induced sexual dysfunction, the next step is to consider an alternative antidepressant without serotonergic activity (e.g., bupropion). Orgasm difficulties and impotence occurred more frequently with paroxetine as compared with sertraline and fluoxetine. The addition of amantadine, cyproheptadine, yohimbine, or sildenafil has been reported to be effective in some patients with SSRI-induced sexual dysfunction.

Drug Interactions Common to the SSRIs

The most serious drug–drug interaction for the SSRIs is their potential to produce the “serotonin syndrome” (i.e., hyperserotonergic effect), which typically develops within

hours or days following the addition of another serotonergic agent to a drug regimen that already includes serotonergic-enhancing drugs. Symptoms of the 5-HT syndrome include agitation, diaphoresis, diarrhea, fever, hyperreflexia, incoordination, confusion, myoclonus, shivering, or tremor.

The 5-HT syndrome interaction between MAOIs and SSRIs is the most important drug interaction for the SSRIs, necessitating a washout ranging from 2 to 5 weeks depending on the plasma half-life of the SSRI. These differences in washout times for the SSRIs when switching to an MAOI are key differences between SSRIs and should be remembered if an MAOI is planned as a possible subsequent treatment in the event of SSRI failure. The differences among SSRIs are not important, when a patient is switched from an MAOI to an SSRI. However, in this case, a 10- to 14-day washout for the MAOI is necessary, regardless of which SSRI is used, to allow regeneration of monoamine oxidase. The drug interaction between TCAs and SSRIs is of particular importance because of the potential for the development of toxic TCA concentrations, 5-HT syndrome, and subsequent adverse effects (48,50).

Coadministration of the antihistamine cyproheptadine or other 5-HT antagonists with SSRIs might be expected to result in a pharmacodynamic interaction (i.e., reduced effectiveness for the SSRI). Cyproheptadine acts to block postsynaptic 5-HT. Lack of antidepressant efficacy has been reported when cyproheptadine was given concurrently with fluoxetine and paroxetine.

Clinically, the potency of the SSRIs to inhibit CYP2D6 decreases from paroxetine to fluoxetine to

norfluoxetine and then to fluvoxamine, with sertraline and citalopram being metabolized by CYP3A4 and CYP2C19, respectively, explaining the extent of differences in pharmacokinetic interactions between the SSRIs and other CYP2D6 substrates. Fluvoxamine is associated with drug interactions from its inhibition of CYP1A2, CYP2C9, CYP2C19, and CYP3A4 (see Table 10.10 for inhibition drug interactions). Because all the SSRIs are extensively metabolized in the liver, it is possible that other drugs that inhibit or induce hepatic CYP microsomal enzyme systems may alter SSRI plasma concentrations (AUCs) (Table 21.7). The SSRIs may inhibit or interfere with the metabolism of other frequently prescribed drugs that are CYP hepatically metabolized, increasing the potential for drug–drug interactions (Table 21.2; see also Tables 10.5 and 10.6). Although similar drug interactions are possible with other SSRIs, there is considerable variability among the drugs in the extent to which they inhibit CYP2D6. Fluoxetine and paroxetine appear to be more potent in this regard than sertraline. The extent to which this potential interaction may become clinically important depends on the extent of inhibition of CYP2D6 by the SSRI and the therapeutic index of the concurrently administered drug. The drugs for which this potential interaction is of greatest concern are those that are metabolized principally by CYP2D6 and have a narrow therapeutic index. Caution should be exercised whenever concurrent therapy with fluoxetine and other drugs metabolized by CYP2D6 is considered. The clinical significance of these possible interactions with the CYP isoforms is questionable, however, because there is no known correlation between plasma concentration and therapeutic response for any of the SSRIs (50). If an interaction is suspected, the patient's SSRI dosage can be easily adjusted.

The SSRIs are highly protein bound and may affect the pharmacodynamic effect of other protein-bound drugs with narrow therapeutic indices (e.g., warfarin). The changes appear to be clinically significant, however, only for fluoxetine, fluvoxamine, and paroxetine (50). Close monitoring of prothrombin time and international normalized ratio is necessary if these drugs are used together.

The SSRIs have a high toxic to therapeutic ratio and, therefore, are safer than the TCAs or MAOIs in acute overdose. The SSRI overdoses can result in drowsiness, tremor, nausea, and vomiting, including seizures, electrocardiographic changes, and coma. Fatalities are uncommon with pure SSRI overdoses.

Therapeutic Uses Common to the SSRIs

The primary uses for the SSRIs include MMD and bipolar depression (fluoxetine, paroxetine, sertraline, and citalopram), “atypical” depression (i.e., depressed patients with unusual symptoms, e.g., hypersomnia, weight gain, and interpersonal rejection sensitivity; fluoxetine, paroxetine, sertraline, and citalopram), anxiety disorders, panic disorder (sertraline and paroxetine), dysthymia, premenstrual syndrome, postpartum depression, dysphoria, bulimia nervosa (fluoxetine), obesity, borderline personality disorder, obsessive-compulsive disorder (fluvoxamine, fluoxetine, paroxetine, and sertraline), alcoholism, rheumatic pain, and migraine headache. Among the SSRIs, there are more similarities than differences; however, the differences between the SSRIs could be clinically significant.

The SSRIs, such as paroxetine and fluoxetine, need stronger pediatric use warnings because of the possible risks of suicidal thoughts and behavior in some children and teenagers. Such risks may be unrelated to any specific SSRI. Recent clinical trials have concluded that 2 or 3 of every 100 young people treated with antidepressants might be at higher risk of suicidal behavior. Only fluoxetine has been proven to be effective and is approved for the treatment of pediatric depression

Phenoxyphenylalkylamines

(±)-Fluoxetine

Structure–activity relationship

Fluoxetine is a 3-phenoxy-3-phenylpropylamine that exhibits selectivity and high affinity for human SERT and low affinity for NET (Fig. 21.11). It is marketed as a racemic mixture of *R*- and *S*-fluoxetine. Its selectivity for SERT inhibition depends on the position of the substituent in the phenoxy ring (Table 21.6).

Mono-substitution in the 4-(para) position of the phenoxy group (with an electron-withdrawing group, e.g., trifluoromethyl group, as in fluoxetine) results in selective inhibition of 5-HT reuptake. Disubstitution (2,4- or 3,4-substitution) results in loss of SERT selectivity. Constraining fluoxetine into semirigid analogues, such as MDL28618A or a phenylpiperidine (i.e., femoxetine), maintains selectivity for SERT, but both have approximately 10% of the affinity of fluoxetine for SERT (52) (Fig. 21.12). The *trans*-(1S,2S)-MDL 28618A

stereoisomer is approximately 10 times more potent than the *cis*-(–)enantiomer (52,53). The *trans*-(3*R*,4*S*)-(+)-enantiomer of femoxetine has approximately 10% the affinity of fluoxetine for SERT (54). N-demethylation of femoxetine to its secondary amine enhances affinity for SERT by 10 times (comparable to fluoxetine). Femoxetine is not only an analogue of fluoxetine and paroxetine but also the (3*R*,4*S*)-diastereomer of a paroxetine analogue.

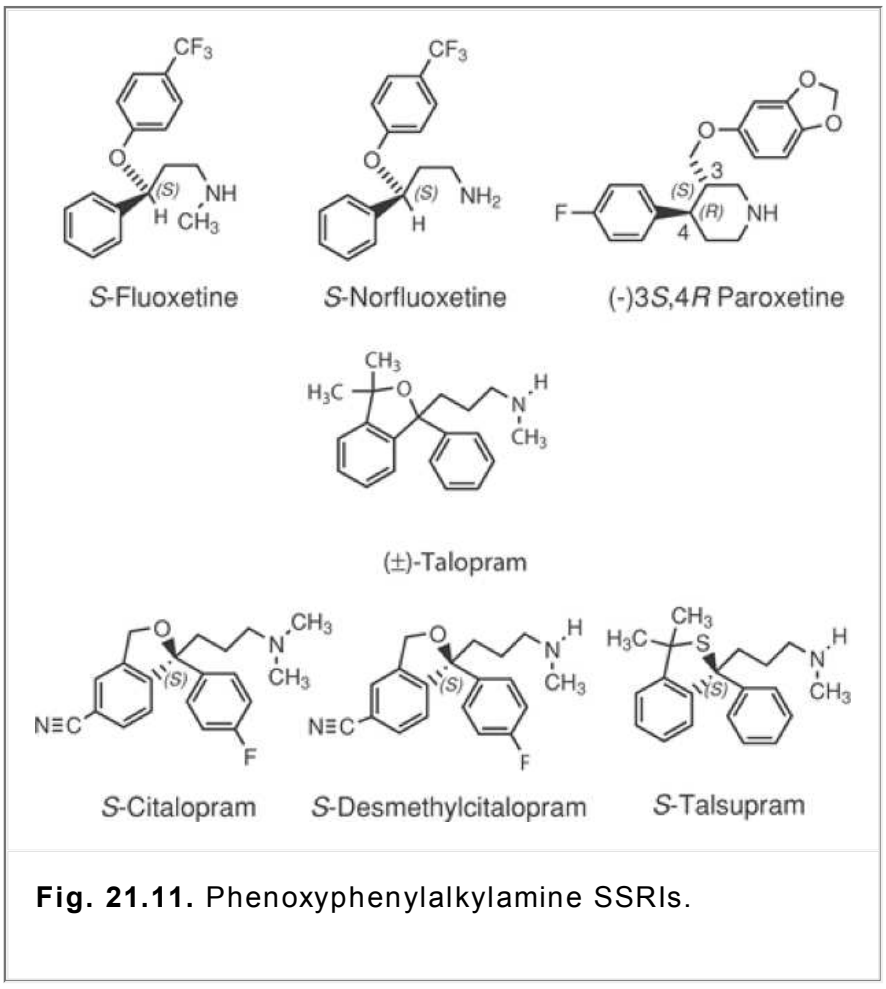

Fig. 21.11. Phenoxyphenylalkylamine SSRIs.

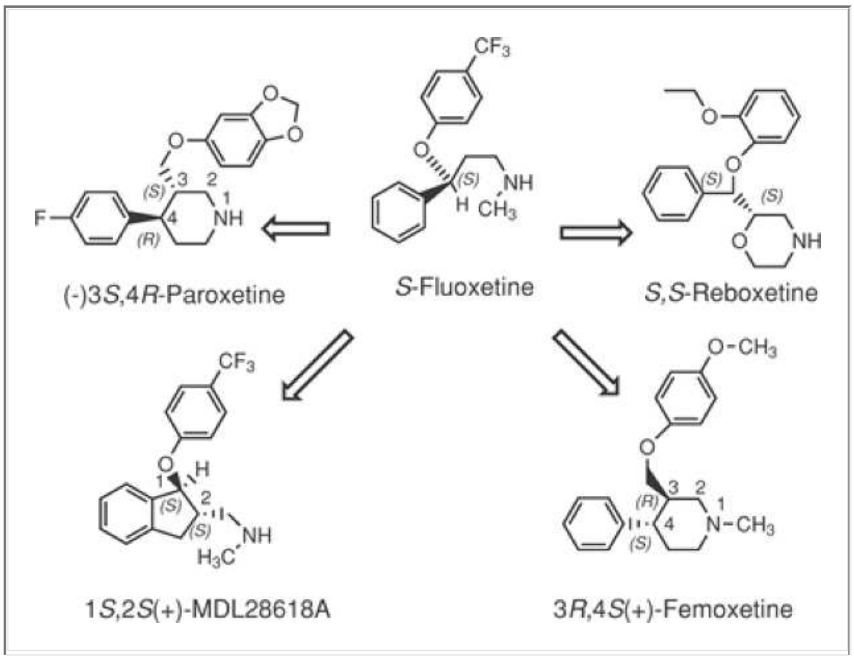

Fig. 21.12. Derivatives of fluoxetine.

Mechanism of action

Fluoxetine is a potent and selective inhibitor of 5-HT reuptake, but not of NE or dopamine uptake in the CNS. Its mechanism of action is common to the SSRIs. Fluoxetine does not interact directly with postsynaptic 5-HT receptors and has weak affinity for the other neuroreceptors. Both enantiomers of fluoxetine display similar affinities for human SERT. The NE:5-HT selectivity ratio, however, indicates that the *S*-enantiomer is approximately 100 times more selective for SERT inhibition than the *R*-enantiomer. The *R*-(+)-stereoisomer is approximately eight times more potent an inhibitor of SERT together with a longer duration of action than the *S*-(–)-isomer. However, the *S*-(–)-norfluoxetine metabolite is seven times more potent as an inhibitor of the 5-HT transporter than the *R*-(+)-metabolite, with a selectivity ratio approximately equivalent to that of *S*-fluoxetine (55,56).

Pharmacokinetics

The pharmacokinetics of fluoxetine fit the general characteristics of the SSRIs (Table 21.8). Of particular importance is its long half-life contributing to its nonlinear pharmacokinetics. In vitro studies show that fluoxetine and norfluoxetine are potent inhibitors of CYP2D6 and CYP3A4 and less potent inhibitors of CYP2C9, CYP2C19 and CYP1A2. Fluoxetine is metabolized primarily by CYP2D6 N-demethylation to its active metabolite norfluoxetine and, to a lesser extent, O-dealkylation to form the inactive metabolite *p*-trifluoromethylphenol. Following oral administration, fluoxetine and its metabolites are excreted principally in urine, with approximately 73% as unidentified metabolites, 10% as norfluoxetine, 10% as norfluoxetine glucuronide, 5% as fluoxetine N-glucuronide, and 2% as unmetabolized drug.

Both *R*- and *S*-Norfluoxetine were less potent than the corresponding enantiomers of fluoxetine as inhibitors of NE uptake. Inhibition of 5-HT uptake in cerebral cortex persisted for more than 24 hours after administration of *S*-norfluoxetine similarly to fluoxetine. Thus, *S*-norfluoxetine is the active N-demethylated metabolite responsible for the persistently potent and selective inhibition of 5-HT uptake in vivo (55).

The pharmacokinetics of fluoxetine in healthy geriatric individuals do not differ substantially from those in younger adults. Because of its relatively long half-life and nonlinear pharmacokinetics, the possibility of altered pharmacokinetics in geriatric individuals could exist, particularly those with systemic disease and/or in those receiving multiple medications concurrently. The elimination half-lives of fluoxetine and norfluoxetine do not appear to be altered substantially in patients with renal or hepatic impairment.

Drug interactions

Fluoxetine and its norfluoxetine metabolite, like many other drugs metabolized by CYP2D6, inhibit the activity of CYP2D6 and, potentially, may increase plasma concentrations of concurrently administered drugs that also are metabolized by this enzyme. Fluoxetine may make normal CYP2D6 metabolizers resemble poor metabolizers. Fluoxetine can inhibit its own CYP2D6 metabolism, resulting in higher-than-expected plasma concentrations during upward dose adjustments. Therefore, switching from fluoxetine to another SSRI or other serotonergic antidepressant requires a washout period of at least 5 weeks or a lower-than-recommended initial dose with monitoring for adverse events.

Fluoxetine is highly protein bound and may affect the free plasma concentration and, thus, the pharmacological effect of other highly protein-bound drugs (e.g., warfarin sodium).

Paroxetine

Structure–activity relationship

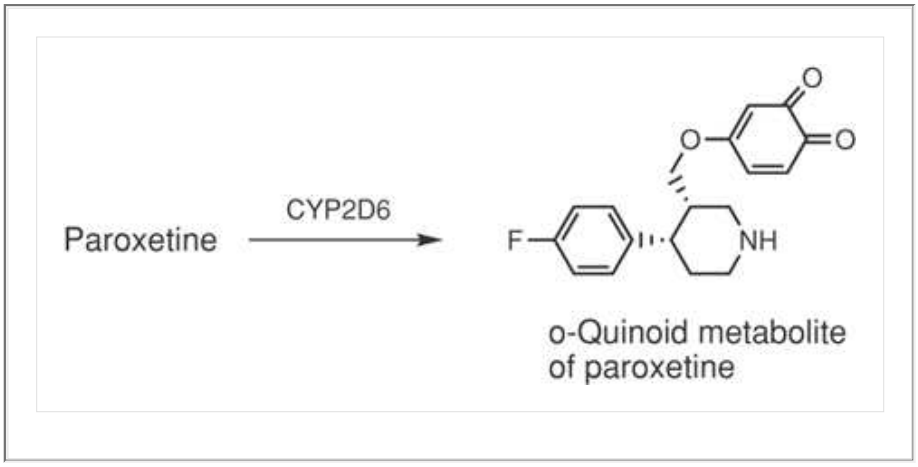
Paroxetine is a constrained analogue of fluoxetine in which the linear phenylpropylamine group has been folded into a piperidine ring (Fig. 21.11). Paroxetine contains two chiral centers, with the possibility of four stereoisomers. One of these stereoisomers, the (3*S*,4*R*)-(–)-enantiomer is marketed as paroxetine. Paroxetine

is a potent and selective inhibitor of SERT and displays high affinity for human SERT and little affinity for NE and dopamine transporters (Fig. 21.6). Converting the secondary amine of the piperidine ring into a tertiary amine with a methyl group reduces affinity for SERT by 100 times. Substituting the 4-fluoro with either a hydrogen or methyl reduces affinity for human SERT by approximately 10 times; replacing the 3,4-methylenedioxy group with a 4-methoxy group in the phenoxy ring also reduces affinity by a factor of 10. Stereochemical factors affect affinity of the paroxetine molecule for SERT. Therefore, substitution into the 2-(ortho) position of either aromatic ring decreases affinity for rat SERT by as much as 10- to 100 times, with the greatest loss occurring in the phenoxy ring. In vitro binding studies suggest that paroxetine is a more selective and potent inhibitor of 5-HT reuptake than fluoxetine. The drug essentially has no effect on NE or dopamine reuptake, nor does it show affinity for other neuroreceptors. Its onset of action is 1 to 4 weeks.

Pharmacokinetics

Paroxetine appears to be slowly but well absorbed from the GI tract following oral administration with an oral bioavailability of approximately 50%, suggesting first-pass metabolism (Table 21.8), reaching peak plasma concentrations in 2 to 8 hours. Food does not substantially affect the absorption of paroxetine. Paroxetine is distributed into breast milk. Approximately 80% of an oral dose of paroxetine is oxidized by CYP2D6 to a catechol intermediate, which is then either O-methylated or O-glucuronidated. These conjugates are then eliminated in the urine.

Paroxetine exhibits a preincubation-dependent increase in inhibitory potency of CYP2D6 consistent with a mechanism-based inhibition of CYP2D6 (56). The inactivation of CYP2D6 occurs via the formation of an o-quinonoid reactive metabolite.



The methylenedioxy has been associated with mechanism-based inactivation of other CYP isoforms (57,58). In contrast, fluoxetine, a potent inhibitor of CYP2D6 activity, did not exhibit a mechanism-based inhibition of CYP2D6. As a result of mechanism-based inhibition, saturation of CYP2D6 at clinical doses appears to account for its nonlinear pharmacokinetics observed with increasing dose and duration of paroxetine treatment, which results in increased plasma concentrations of paroxetine at low doses. The elderly may be more susceptible to changes in doses and, therefore, should be started off at lower doses. Following oral administration, paroxetine and its metabolites are excreted in both urine and feces.

Oral administration of a single dose resulted in unmetabolized paroxetine accounting for 2% and metabolites accounting for 62% of the excretion products. The effect of age on the elimination of paroxetine suggests that hepatic clearance of paroxetine can be reduced, leading to an increase in elimination half-life (e.g., to ~36 hours) and increased plasma concentrations. The metabolites of paroxetine have been shown to possess no more than 2% of the potency of the parent compound as inhibitors of 5-HT reuptake; therefore, they are essentially inactive.

Because paroxetine is a potent mechanism-based inhibitor of CYP2D6, this type of inhibition yields nonlinear and long-term effects on drug pharmacokinetics, because the inactivated or complexed CYP2D6 must be replaced by newly synthesized CYP2D6 protein. Thus, coadministration of paroxetine with CYP2D6-metabolized medications should be closely monitored or, in certain cases, avoided, as should upward dose adjustment of paroxetine itself.

(±)-Citalopram

In trying to create a new antidepressant to inhibit NE reuptake, Lundbeck chemists accidentally synthesized two new compounds (talopram and tasulopram) having the phenylspiro-isobenzofuran nucleus (Fig. 21.11). These compounds were potent SNRIs, but considering that a number of suicide attempts were reported during clinical studies with these compounds, Lundbeck discontinued the studies. Undeterred, the chemists subsequently converted talopram into citalopram by a single 6-cyano substitution. (±)-Citalopram

also can be viewed as a constrained analogue of paroxetine (Fig. 21.11). Therapeutic activity for (±)-citalopram resides in the *S*-(+)-isomer. Isosteric substitution of the isobenzofuran ring in citalopram with an isobenzothiophene yields talsupram which changes selectivity from an inhibitor of SERT to a potent inhibitor of NET (Fig. 21.11). Citalopram was marketed in the United States in 1996 as the most selective SSRI and, therefore, as the least likely to cause the adverse effects observed with most of the other antidepressants (Fig. 21.6).

Mechanism of action

Citalopram, primarily through its *S*-enantiomer, blocks 5-HT reuptake, leading to potentiation of serotonergic activity in the CNS. Citalopram exhibits the greatest in vitro selectivity for 5-HT reuptake inhibition compared with the other SSRIs (Fig. 21.6). The drug essentially has no effect on NE or dopamine reuptake, nor does it show affinity for other neuroreceptors.

Pharmacokinetics

The pharmacokinetics of citalopram are shown in Table 21.8. Unlike several of the other SSRIs, citalopram does not undergo first-pass metabolism; it has an oral bioavailability of approximately 80%. The drug is metabolized via hepatic N-demethylation to its major metabolite, N-desmethylcitalopram, almost equally by CYP2C19, CYP2D6, and CYP3A4 (Table 21.7). The major metabolite exhibits approximately 50% of the potency of citalopram as an inhibitor of 5-HT reuptake. Because the metabolite concentration in the plasma is lower than that of citalopram, it should not add significantly to citalopram's antidepressant effects. Citalopram exhibits dose-proportional linear pharmacokinetics in a dosage range of 10 to 60 mg/day; plasma levels increase proportionately with each increasing dose. Approximately 10 to 12% of an oral dose was recovered in the urine as unmetabolized drug. The clearance of orally administered citalopram was reduced by 37 and 17% in patients with hepatic and renal function impairment, respectively.

Citalopram and its desmethyl metabolite are weak inhibitors of the CYP isoforms, suggesting a low potential for drug interactions. Although no relevant in vivo interactions between citalopram and CYP2D6-metabolized medications have been reported, caution is advised when coadministering citalopram with potential object drugs, especially those having narrow therapeutic indices, in elderly patients. Because citalopram is metabolized in parallel by CYP2C19, CYP2D6, and CYP3A4, it would have little inhibitory effect on the metabolism of other drugs metabolized by these isoenzymes. Citalopram is less highly protein bound than the other SSRIs, reducing the potential for drug interactions with protein-bound drugs having narrow therapeutic indices.

Escitalopram

Escitalopram is the *S*-enantiomer of citalopram that binds with high affinity and selectivity to the human SERT equivalent to (±)-citalopram. It has been reported that nearly all the activity resides in the *S*-enantiomer and that *R*-citalopram actually counteracts the action of the *S*-enantiomer (59,60). Studies show that escitalopram exhibits twice the activity of citalopram and is at least 27 times more potent than the R-enantiomer. The *R*-enantiomer inhibits the *S*-enantiomer at the transporter (59,60). Escitalopram's mechanism of action is common to the SSRIs.

The pharmacokinetics for escitalopram does not exhibit stereoisomer selectivity and, therefore, is similar to that for citalopram (Table 21.7). Likewise, it exhibits linear pharmacokinetics so that plasma levels increase proportionately and predictably with increased doses, and its half-life of 27 to 32 hours is consistent with once-daily dosing. It also has been found that *R*-citalopram is cleared more slowly than the *S*-enantiomer. Therefore, when the drug is used as a racemic mixture (citalopram), the inactive isomer predominates at steady state. This is an added incentive for use of the enantiomerically pure escitalopram. Escitalopram has negligible effects on CYP isoforms, suggesting a low potential for drug–drug interactions. Escitalopram is

indicated for patients with major depressive disorder, generalized anxiety disorder, panic disorder, and social anxiety disorder.

Escitalopram is metabolized to *S*-desmethylcitalopram by CYP2C19 (37%), CYP2D6 (28%), and CYP3A4 (35%) and to *S*-didesmethylcitalopram (only by CYP2D6) in human liver microsomes and in expressed cytochromes. Escitalopram and its desmethyl metabolite were negligible inhibitors of CYP1A2, CYP2C9, CYP2C19, CYP2E1, and CYP3A and were weakly inhibited by CYP2D6. *R*-citalopram and its metabolites had properties very similar to those of the corresponding *S*-enantiomers. Because escitalopram is biotransformed by three CYP isoforms in parallel, escitalopram is unlikely to be affected by drug interactions or genetic polymorphisms and is unlikely to cause clinically important drug interactions via CYP inhibition.

Phenylalkylamine

Sertraline

Although sertraline appears to differ structurally from the other SSRIs, it is a phenylaminotetralin, in which the diphenylpropylamine nucleus is constrained into a rigid bicyclic ring system (Fig. 21.13). In the early work with the discovery of SSRIs at Pfizer, tametraline was initially synthesized in 1978. Animal studies showed it to be a stimulant and to block NE and DA uptake, a use that Pfizer was not interested in pursuing. Subsequently, one or two chlorine atoms were introduced into tametraline to produce new molecules that were potent inhibitors of 5-HT reuptake in the brain. One of the dichloro compounds was to become known as sertraline.

Sertraline contains two chiral centers, and only the *S*,*S*-(+)-diastereomer is marketed. The *R*,*R*-, *R*,*S*-, and *S*,*R*-diastereomers are significantly weaker as inhibitors of 5-HT reuptake. Sertraline was marketed in the United States in 1992, emphasizing its pharmacokinetic differences from the other SSRIs.

P.575

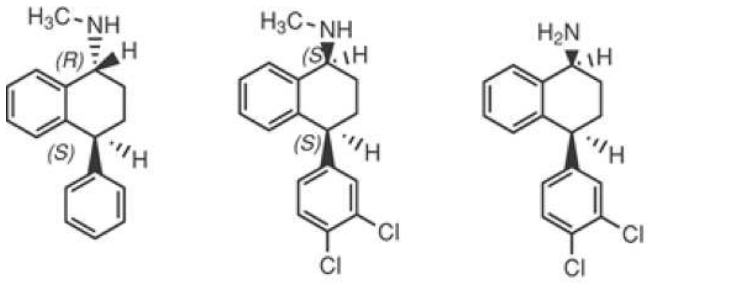


Fig. 21.13. Phenylalkylamine SSRIs.

Mechanism of Action

Sertraline is a potent and selective inhibitor of the neuronal reuptake 5-HT transporter. In vitro binding studies suggest that sertraline has a substantially higher selectivity for inhibiting 5-HT reuptake than other SSRIs or TCAs, including clomipramine (Fig. 21.6). It has only weak effects on neuronal uptake of NE and dopamine. Its mechanism of action is common to the SSRIs. Sertraline is very selective, lacking affinity for other neuroreceptors at therapeutic concentrations.

Pharmacokinetics

Sertraline appears to be slowly but well absorbed from the GI tract following oral administration. The oral bioavailability of sertraline in humans ranges from 20 to 36% (Table 21.8), suggesting extensive first-pass

metabolism to its N-desmethylated metabolite. Food enhances its oral absorption decreasing the time to achieve peak plasma concentrations from approximately 8 to 6 hours. Following multiple dosing, steady-state plasma sertraline concentrations are proportional and linearly related to dose (half-life: single dose, 24 hours; multiple dose, 24 hours). N-desmethylsertraline, sertraline's principal metabolite, exhibits dose-dependent pharmacokinetics. Sertraline and N-desmethylsertraline are distributed into breast milk. Although in elderly patients the elimination half-life is increased to approximately 36 hours, this effect does not appear to be clinically important and does not warrant dosing alterations. Sertraline is primarily metabolized by CYP3A4 N-demethylation in the intestine and liver to its principal metabolite N-desmethylsertraline and several other metabolites. N-desmethylsertraline is approximately 5- to 10 times less potent as an inhibitor of 5-HT reuptake than sertraline. Sertraline and N-desmethylsertraline undergo further metabolism via oxidative deamination and ring hydroxylation and glucuronide conjugation. N-desmethylsertraline has an elimination half-life approximately 2.5 times that of sertraline. Following oral administration, sertraline and its conjugated metabolites are excreted in both urine and feces, and unmetabolized sertraline accounts for less than 5% of oral dose. Plasma clearance of sertraline was approximately 40% lower in geriatric patients. The elimination half-life of sertraline in patients with hepatic disease was prolonged to a mean of 52 hours, compared with 22 hours in individuals without hepatic disease.

Drug Interactions

Sertraline is not a potent inhibitor of CYP3A4, and because CYP2D6 metabolism is a minor pathway for sertraline, drug–drug interactions with these isoforms is unlikely to be of clinical importance. Sertraline is metabolized by more than one CYP isoform in parallel; therefore, drug interactions or genetic polymorphisms are unlikely to cause clinically significant drug interaction via CYP isoform inhibition. Caution is advised, however, when coadministering sertraline with potential object drugs, especially those with narrow therapeutic indices in elderly patients. For example, sertraline has been shown to reduce the clearance of desipramine and imipramine as a result of CYP2D6 inhibition.

Because sertraline is highly protein bound, patients receiving it concurrently with any highly protein-bound drug should be observed for potential adverse effects associated with combined therapy.

Additional SSRIs

Fluvoxamine

Fluvoxamine is a nontricyclic SERT inhibitor that is structurally unique among the SSRIs by being the (*E*)-isomer of a 2-aminoethyl oxime ether of an aralkylketone (Fig. 21.14). The C=N double bond is isosteric with the propylidene group in amitriptyline and, thus, imparts geometric *E* or *Z* stereoisomerism to fluvoxamine. The oxime ether is found in a previously marketed analogue of amitriptyline called noxiptilin (1966 by Bayer AG [Germany]). Thus, fluvoxamine may be considered to be an open-chain analogue of the tricyclic noxipitilin. The 4-trifluoromethyl group or other electronegative group is essential for SERT affinity and selectivity. The C=N double bond also enhances the susceptibility of fluvoxamine to photoisomerization by ultraviolet (UV)-B light (290–320 nm). When fluvoxamine solutions were exposed to UV-B light, photoisomerization to the pharmacologically inactive *Z*-isomer occurred. Thus, fluvoxamine solutions should be protected from sunlight to prevent loss of antidepressant efficacy. No studies have been reported regarding its solid-state stability to UV-B light.

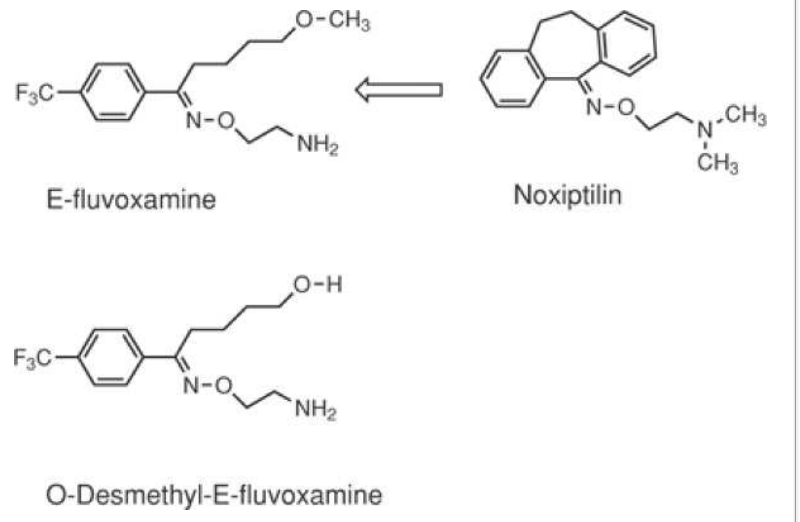

Fig. 21.14. Miscellaneous SSRIs.

Mechanism of action

Fluvoxamine is a highly selective inhibitor of 5-HT reuptake at the presynaptic membrane. Potency data from in vitro affinity studies suggest that fluvoxamine is less potent than the other SSRIs (e.g., paroxetine, sertraline, and citalopram). Its mechanism of action is similar to that of the other SSRIs. Fluvoxamine appears to have little or no effect on the reuptake of NE or dopamine. In vitro studies have demonstrated that fluvoxamine possesses virtually no affinity for other neuroreceptors. Its onset of action is similar to the other SSRIs (2–4 weeks).

Pharmacokinetics

Fluvoxamine is well absorbed, with a bioavailability of approximately 50%, probably because of first-pass metabolism (Table 21.8). At steady-state doses, fluvoxamine demonstrates nonlinear pharmacokinetics over a dosage range of 100 to 300 mg/day, which results in higher plasma concentrations at higher doses than would be predicted by lower-dose kinetics (single dose, 15 hours; multiple dosing, 22 hours). Food does not significantly affect oral bioavailability. The mean apparent volume of distribution for fluvoxamine reflects its lipophilic nature, extensive tissue distribution, and protein binding. Fluvoxamine is distributed into breast milk. Fluvoxamine is preferentially metabolized by CYP2D6 in the liver by O-demethylation to its alcohol metabolite, which subsequently is oxidized to a carboxylic acid. Oxidative deamination and nine other metabolites have been identified, none of which shows significant pharmacological activity.

Adverse effects

The adverse effects for fluvoxamine include symptoms of drowsiness, nausea or vomiting, abdominal pain, tremors, sinus bradycardia, and mild anticholinergic symptoms. Toxic doses could produce seizures and severe bradycardia.

Drug interactions

In vitro studies have shown fluvoxamine to be a potent inhibitor of CYP1A2, to inhibit CYP3A4 and CYP2C19, and to weakly inhibit CYP2D6. The bioavailability of fluvoxamine is significantly decreased in smokers compared with nonsmokers, possibly because of induction of CYP1A metabolism of fluvoxamine. Therefore, interactions with drugs that inhibit CYP1A2 also should be considered (e.g., theophylline and caffeine).

Therapeutic uses

Fluvoxamine is approved for use in obsessive-compulsive disorders.

Norepinephrine and Serotonin Reuptake Inhibitors (NSRI)

The NSRI antidepressant drugs in this class block both the NET and SERT (i.e., they combine the mechanisms of action for both the SSRIs and SNRIs), exhibiting dual affinity for NET and SERT (low NE:5-HT potency ratio). These dual inhibitors, as a group, do not show a significant separation in selectivity for the NET and SERT reuptake transporter. Historically, the tertiary amine TCAs displayed dual inhibition of 5-HT and NE presynaptic reuptake, but they also bind to other types of neuroreceptors, which is responsible for their narrow therapeutic window and adverse effects. Clinical studies suggest that dual-acting inhibitors of 5-HT and NE reuptake may be more beneficial than selective inhibitors in managing depression. This has given impetus to the search for nontricyclic NSRIs and has lead to a second group of NSRIs, such as venlafaxine and duloxetine.

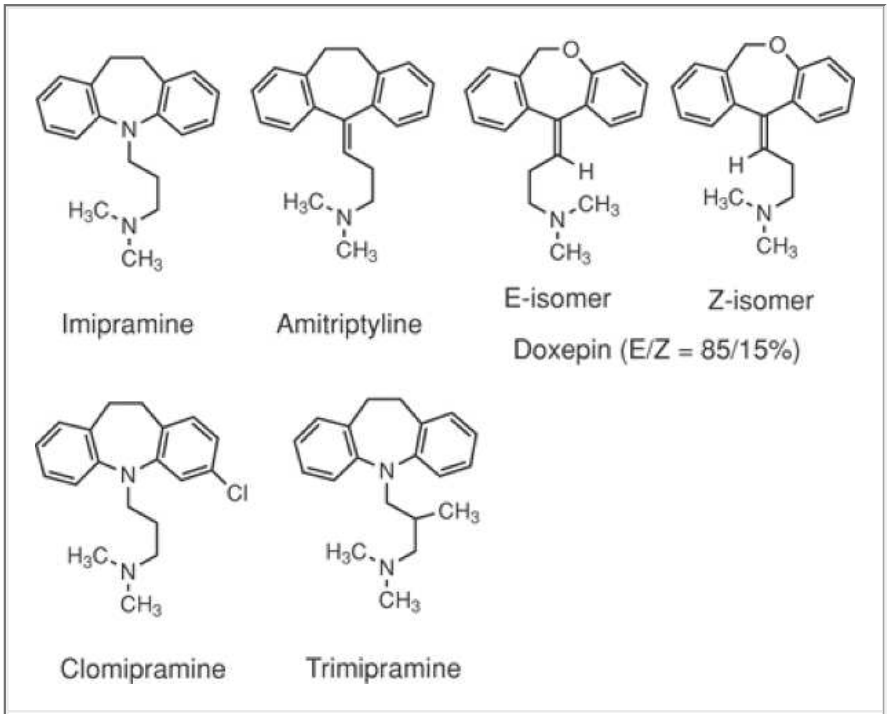

Fig. 21.15. Tricyclic nonselective reuptake inhibitors.

Tricyclic Tertiary Amine Antidepressants

The TCAs in this class belong to the tertiary amine TCAs (Fig. 21.15). The relatively low bioavailability for the tertiary amine TCAs suggests first-pass metabolism (N-demethylation) to their secondary amine active metabolites (nor or desmethyl metabolites) and aromatic ring hydroxylation (Table 21.2). Despite the fact that steady-state serum plasma levels are reached within 1 to 2 days, their onset of antidepressant action typically is at least 2 to 3 weeks or longer. Their volume of distribution is very high, suggesting distribution into the CNS and protein binding. Excretion is primarily as metabolites via renal elimination. Renal and liver function can affect the elimination and metabolism of the parent TCA and its metabolites, leading to increased potential for adverse effects, especially in those patients (i.e., elderly) with renal disease.

Meaningful differences between the tertiary TCAs is largely related to their pharmacokinetics, metabolism to active metabolites, inhibition of CYP isoforms, potential for drug-drug interactions, and half-life of the tertiary TCA.

Mechanisms of action common to the tertiary amine TCAs

The exact mechanism of action for the tertiary TCAs is unclear, but it is known that the parent tertiary amine

SERT. The result is an increase in both NE and 5-HT concentrations in the synaptic cleft. The in vivo antidepressant activity for these TCAs is more complex, however, because of the formation of secondary amine TCA metabolites, which in many cases annuls the 5-HT affinity of the parent TCA, leading to NE transport selectivity. The plasma concentrations for the secondary amine metabolites usually are higher than that of their parent tertiary amine TCA because of rapid N-demethylation metabolism. Note that none of the tertiary amine TCAs have any significant affinity for the DA transporter. During chronic therapy with the tertiary amine TCAs, downregulation of the noradrenergic and serotonergic receptors occurs, which is a result of neurotransmitter hypersensitivity caused by the continued high concentrations of NE and 5-HT at the postsynaptic receptor. The tertiary TCAs are less potent inhibitors than the SSRIs for SERT.

Therapeutic uses common to tricyclic tertiary antidepressants

For the most part, the therapeutic uses for the tertiary amine TCAs are very similar as a group, but these TCAs may be used in different cases of depression because of their variability in their dual mechanism of action as SNRIs and SSRIs. Their efficacy in treating depression suggests that mixed inhibition of NET and SERT influence depression by parallel and independent pathways. The tertiary TCAs may offer an option in the treatment of major depression for patients who have failed treatment with or who do not tolerate SNRIs or SSRIs.

Adverse effects common to tertiary TCAs

Because of their potent and multiple pharmacodynamic effects at histamine H_1, muscarinic, and α_1-adrenergic receptors, the tertiary TCAs exhibit greater anticholinergic, antihistaminic, and α_1-antiadrenergic adverse effects than the secondary TCAs do. Increased cardiotoxicity or frequency of seizures is higher for the tertiary TCAs than for the secondary TCAs, because they are potent inhibitors of sodium channels, leading to changes in nerve conduction. Cardiotoxicity can occur at plasma concentrations approximately 5- to 10 times higher than therapeutic blood levels. These concentrations can occur in individuals who take an overdose of the TCA or who are slow metabolizers and develop higher plasma concentrations on what usually are therapeutic doses.

Drug–drug interactions common to tertiary TCAs

For the most part, drug–drug interactions for the tertiary amine TCAs are very similar to those for the secondary amine TCAs. These reactions, however, may be more pronounced.

The concurrent use of tertiary amine TCAs with SSRIs and other serotonergic drugs may result in 5-HT syndrome (see the discussion of drug interactions of SSRIs). Coadministration of a tertiary amine TCA with an MAOI is potentially hazardous and may result in severe adverse effects associated with 5-HT syndrome.

Because protein binding of the tertiary amine TCAs are high, displacement interactions with other highly protein-bound drugs and drugs with narrow therapeutic indices, although not fully evaluated, may be important. Concurrent use of tertiary amine TCAs with anticholinergic drugs requires close supervision and careful adjustment of the dosage because of potential additive anticholinergic effects (i.e., spastic colon). An additional disadvantage of TCAs is their toxicity from overdosage, especially in those who are being treated for depression having suicidal thoughts.

The plasma concentrations of tertiary amine TCAs usually are lower, and plasma concentrations of their secondary amine metabolites higher, as a result of CYP1A induction.

Patient information common to the tertiary amine TCAs

Common patient information and recommendations are similar to those given to patients who are prescribed secondary TCAs (Table 21.5).

Unique properties of specific tertiary amine TCAs

Amitriptyline

Amitriptyline is a tertiary amine dibenzocycloheptadiene TCA with a propylidene side chain extending from the

central carbocyclic ring (Fig. 21.15). The diarylpropylideneamine moiety for amitriptyline makes it sensitive to photo-oxidation; therefore, its hydrochloride solutions should be protected from light to avoid ketone formation and precipitation.

Pharmacokinetics

Amitriptyline is rapidly absorbed from the GI tract and from parenteral sites. Its pharmacokinetics are shown in Table 21.9. Amitriptyline and its active metabolite, nortriptyline, are distributed into breast milk. Amitriptyline is primarily (65%) metabolized by N-demethylation by CYP2D6 to nortriptyline and hydroxylation to its *E*-10-hydroxy metabolite. Nortriptyline is pharmacologically active as a secondary amine TCA. Amitriptyline shows approximately equal affinity for 5-HT and NE transporters.

Imipramine

Imipramine is a 10,11-dihydrodibenzazepine tertiary amine TCA (Fig. 21.15) that is marketed as hydrochloride and pamoate salts, both of which are administered orally. Although the hydrochloride salt may be administered in divided daily doses, imipramine's long duration of action suggests that the entire oral daily dose may be administered at one time. On the other hand, imipramine pamoate usually is administered as a single daily oral dose. Imipramine preferentially inhibits 5-HT reuptake over NE; however, the formation of its N-desmethyl metabolite removes whatever 5-HT activity imipramine had, with the net result of enhanced noradrenergic activity from inhibition of NE reuptake at the presynaptic neuronal membrane. Imipramine shares the pharmacological and adverse-effect profile of the other tertiary TCAs.

Table 21.9. Pharmacokinetics of the Tricyclic Nonselective Reuptake Inhibit

Parameters	Amitripytline	Clomipramine	Doxepin	Imipramine	Trim
Oral bioavailability (%)	31–61	~50	13–45	29–77	44
Protein binding (%)	95	96–98	ND	89–95	95
Volume of distribution (L/kg)	12–18	17 (9–25)	12–28	23 (15–31)	~3
Elimination half-life (hours)	10–26	32 (19–37)	11–16	11–25	9–
Cytochrome P450 major isoform	2D6	2D6	2D6 and 2C19	2D6 and 2C19	2D
Major active metabolites	Nortriptyline	Desclomipramine (54–77 hours)	Nordoxepin (~30 hours)	Desipramine	De (30
Peak plasma	2–12	2–6 (4.7)	<2	1–2	<2

concentration (hours)					
Excretion (%)	Urine 25–50	Urine 51–60 (14 days)	Renal ~50	Urine ~40 (24 hours)	Fe
	Feces minor	Feces 24–32	Feces minor	Feces minor	Uri
Plasma half-life (hours)	21 (10–46)	34 (22–84)	8–24	18 (9–24)	9
Time to steady-state concentration	—	1–2 weeks	ND	ND	ND

ND = not determind.

The pharmacokinetics for imipramine are shown in Table 21.9. Imipramine is completely absorbed from the GI tract. Imipramine is primarily metabolized by CYP2D6 to its 2- and 10-hydroxylated metabolites and N-demethylated via CYP2C19 and CYP1A2 to desipramine, its N-monodemethylated metabolite, an SNRI.

Therapeutic uses

Besides being used in the clinical treatment of depression, imipramine also has been used for the treatment of functional enuresis in children who are at least 6 years of age (25 mg daily administered 1 hour before bedtime, not to exceed 2.5 mg/kg daily).

Doxepin

Doxepin is a tertiary amine dibenzoxepine derivative with an oxygen replacing one of the ethylene carbons in the bridge. The oxygen introduces asymmetry into the tricyclic ring system, resulting in the formation of two geometric isomers: *E* (*trans*) and *Z* (*cis*) (Fig. 21.15). No commercial attempt was made to separate the isomers; thus, doxepin is administered as a 85:15 mixture of *E*- and *Z*-stereoisomers, with the *Z*-isomer being the more active stereoisomer for inhibiting the reuptake of 5-HT (61). The E-isomer, on the other hand, inhibits the reuptake of NE. Unless otherwise specified, the reported in vitro and in vivo studies with dioxepin were done with the 85:15 geometric mixture.

Mechanism of action

Because doxepin is administered as an 85:15 mixture of geometric isomers, its mechanism of action and antidepressant properties reflects this ratio. Therefore, dioxepin's selectivity for inhibiting presynaptic NE reuptake is most likely caused by the 85% presence of the *E*-isomer in the geometric mixture. Its antidepressant activity is similar to amitriptyline. Data suggest NE reuptake inhibitory potency comparable to imipramine and clomipramine; the fact that doxepin is an 85:15 mixture of *E*- and *Z*-geometric isomers clouds its true efficacy for SERT or NET. The formation of N-desmethyldoxepin results in inhibition of NE reuptake with enhanced noradrenergic activity. As a result of these mixed effects on the 5-HT and NE transporters, doxepin shares the pharmacological and adverse-effect profile of the other TCAs.

The pharmacokinetics for oral doxepin are described in Table 21.9. After oral dosing, no significant difference was found between the bioavailability of the *E*- and *Z*-isomers. The plasma concentrations of the doxepin

isomers remained roughly those of the administered drug, whereas the ratio for the metabolites, *E*-N-desmethyldoxepin and *Z*-N-desmethyldoxepin, were approximately 1:1 (61,62). This similarity in ratios of metabolites is attributed to *E*-doxepine being primarily metabolized in parallel by CYP2D6 and CYP2C19, whereas *Z*-doxepine is primarily metabolized only by CYP2C19 and not at all by CYP2D6 (Table 21.2) (61). Its *Z*-N-demethylated metabolite is pharmacologically more active than its *E*-metabolite as an inhibitor of 5-HT and NE reuptake (61). Both isomers of doxepin showed large volumes of distribution and relatively short half-lives in plasma, suggestive of extensive distribution and/or tissue binding. Renal clearances did not differ for the isomers.

Clomipramine

Clomipramine is considered to be the most powerful antidepressant ever made. This dihydrodibenzazepine TCA, with actions on both the NE and 5-HT transporters, was the last of the major TCAs to come to market. Initially, the U.S. FDA regarded it as another "me-too" drug, and accordingly, they did not license it. Subsequently, however, it was licensed for the treatment of obsessive-compulsive disorders. Clomipramine differs from imipramine only by the addition of a 3-chloro group (Fig. 21.15).

Mechanism of Action

Clomipramine is different from the other TCAs, exhibiting preferential selectivity for inhibiting the reuptake of 5-HT at the presynaptic neuronal membrane. Its antidepressant mechanism of action as an inhibitor of the 5-HT transporter is reduced in vivo, however, because of the formation of its active metabolite, N-desmethylclomipramine, which inhibits the reuptake of NE. As a result of its common structure with the other TCAs, clomipramine shares the pharmacological and adverse-effect profile of the other TCAs.

The efficacy of clomipramine relative to the other TCAs in the treatment of obsessive-compulsive disorder may be related to its potency in blocking 5-HT reuptake at the presynaptic neuronal membrane, suggesting a dysregulation of 5-HT for the pathogenesis of obsessive-compulsive disorder. Clomipramine appears to decrease the turnover of 5-HT in the CNS, probably because of a decrease in the release and/or synthesis of 5-HT.

Although in vitro studies suggest that clomipramine is approximately four times more potent than fluoxetine as a 5-HT reuptake inhibitor, in vivo studies suggest the opposite. This difference has been attributed to the relatively long elimination half-lives for fluoxetine and its principal serotonergic metabolite norfluoxetine. In addition, metabolism of clomipramine to its N-desmethyl secondary amine metabolite decreases the potency and selectivity of 5-HT-reuptake inhibition of clomipramine, but not fluoxetine.

Pharmacokinetics

Clomipramine appears to be well absorbed from the GI tract following oral administration, with an oral bioavailability of approximately 50%, suggesting some first-pass metabolism (Table 21.9). Food does not appear to substantially affect its bioavailability. Clomipramine and its active metabolite, N-desmethylclomipramine, exhibit nonlinear pharmacokinetics at 25 to 150 mg daily. At dosages exceeding 150 mg daily, their elimination half-lives may be considerably prolonged, allowing plasma concentrations of both to accumulate, which may increase the incidence of plasma concentration-dependent adverse effects, particularly seizures. Because of the relatively long elimination half-lives of clomipramine and N-desmethylclomipramine, their steady-state plasma concentrations generally are achieved within approximately 1 to 2 weeks. Plasma concentrations of N-desmethylclomipramine generally are greater than those for chlomipramine at steady-state conditions. Clomipramine crosses the placenta and is distributed into breast milk.

Clomipramine is primarily metabolized by CYP2D6 N-dealkylation to its pharmacologically active metabolite, the 2- and 8-hydroxylated metabolites and their glucuronides, and clomipramine N-oxide (Fig. 21.16). N-dealkylation also involves CYP3A4, CYP2C19, CYP2C9, and CYP1A2. Like all the other secondary amine TCAs, N-desmethylclomipramine is significantly more potent as an inhibitor of NE reuptake than clomipramine is. Although N-desmethylclomipramine is pharmacologically active, its efficacy in obsessive-compulsive disorder is not known. 8-Hydroxyclomipramine and 8-hydroxydesmethylclomipramine also are pharmacologically active, but their clinical importance remains unknown. The hydroxylation and N-demethylation of clomipramine highlight CYP2D6 polymorphism in healthy adults who were phenotyped as

either extensive metabolizers or poor metabolizers of clomipramine. Interindividual variation in plasma concentrations may be caused by genetic differences in the metabolism of the drug. In addition, CYP1A2 ring hydroxylates clomipramine. Less than 1% of an oral dose of clomipramine was excreted unmetabolized into the urine, with 8-hydroxyclomipramine glucuronide as the principal metabolite found in the urine. The effects of renal clearance suggest that clomipramine and desmethylclomipramine should be decreased in patients with renal impairment.

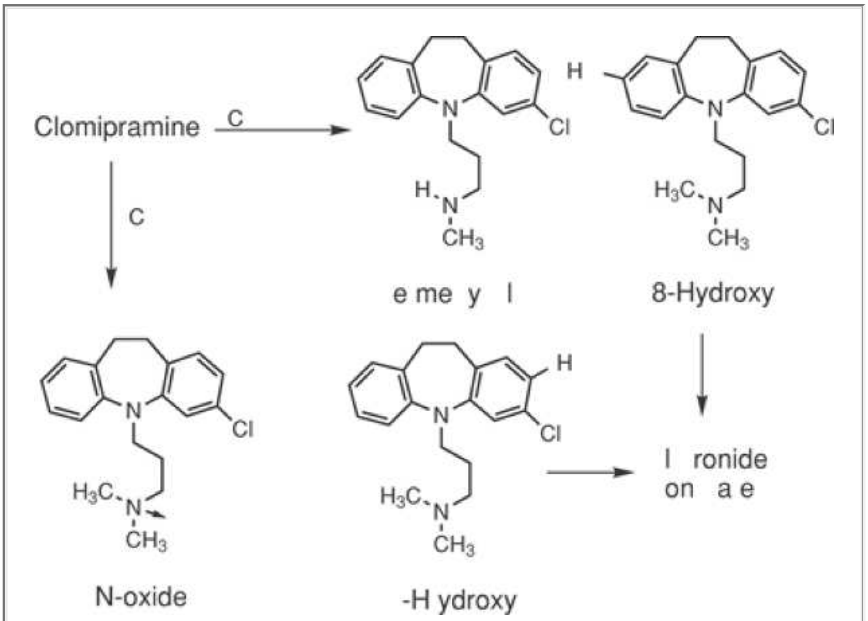

Fig. 21.16. Metabolism of clomipramine.

Pharmacogenetic differences in the metabolism of clomipramine after a single oral dose are apparent as increased plasma clomipramine concentrations in Indian and Pakistani patients compared with Caucasians. In Japanese patients, substantial interindividual variation in demethylation and hydroxylation of clomipramine was observed, although the prevalence of poor demethylators and poor hydroxylators of clomipramine has been estimated to be less than 1%.

If inhibition of SERT is critical to the desired clinical effect for clomipramine, then a patient may fail to respond, because he or she develops higher levels of N-desmethylclomipramine as opposed to the parent drug. On the other hand, if a patient who had responded well and was stabilized to a dose of clomipramine, the drug might lose efficacy if exposed to an environmental agent that is capable of inducing CYP1A or CYP3A4.

Adverse effects

Male patients taking clomipramine should be informed of sexual dysfunction as a side effect associated with antidepressants having significant serotonergic activity. Sexual dysfunction in men appears as ejaculatory incompetence, ejaculatory retardation, decreased

libido, or inability to obtain or maintain an erection. Sexual dysfunction is dose-related and may be treated by simply lowering the drug dose.

Trimipramine

Trimipramine also is a dihydrodibenzazepine TCA that differs structurally from imipramine in that the 5-propyl side chain is branched by a methyl group creating a chiral center (Fig. 21.15). Trimipramine is marketed as a racemic mixture. No data are available regarding the activity of the enantiomers. Apparently, branching the propyl side chain reduces affinity by 100 times for both 5-HT and NE transporters, but the selectivity ratio favors the 5-HT transporter. Although trimipramine has the weakest binding affinity for the monoamine

transporters, it shares the pharmacological and toxicity actions of the other TCAs and is used primarily in the treatment of depression.

The pharmacokinetics for trimipramine are shown in Table 21.9. Trimipramine is rapidly absorbed. Trimipramine demonstrates stereoselectivity in its metabolism to its three major metabolites. (–)-Trimipramine is primarily metabolized via CY2D6 hydroxylation to 2-hydroxytrimipramine, whereas (+)-trimipramine is preferentially metabolized by CYP2C19 N-demethylation to desmethyltrimipramine. Desmethyltrimipramine is further hydroxylated to 2-hydroxydesmethyltrimipramine. (–)-Trimipramine is metabolized by CYP3A4/5 to an unknown metabolite (63,64). Most of the oral dose is excreted in urine in 72 hours, primarily as N-demethylated or hydroxylated and conjugated metabolites. The pharmacokinetics of trimipramine in geriatric individuals (≥65 years of age) do not differ substantially from those in younger adults.

Trimipramine is one of the antidepressants with the most pronounced differences in pharmacokinetics caused by the CYP2D6 genetic polymorphism (63,64). Its bioavailability and systemic clearance depended significantly on the CYP2D6 isoform with a linear dose relationship. Its mean bioavailability was 44% in individuals without CYP2D6 (poor metabolizers) but 16 and 12% in those individuals with two and three active genes of CYP2D6 (fast and ultrafast metabolizers), respectively. Consequently, the mean total clearances of the oral dose were 27, 151, and 253 L/hour in poor, extensive, and ultrarapid metabolizers, respectively. The 44% bioavailability combined with low systemic clearance of trimipramine in poor metabolizers of CYP2D6 substrates results in a very high exposure to trimipramine with the risk of adverse drug reactions. On the other hand, the presystemic elimination may result in subtherapeutic drug concentrations in carriers of CYP2D6 gene duplications with a high risk of poor therapeutic response (63,64).

Other tricyclic NSRIs

Figure 21.17 shows two tricyclic serotonin/NE reuptake inhibitors. One is an analogue of imipramine, and the second is an isostere of doxepin.

Dothiepin

Dothiepin (Dosulepin) is the thio isostere of doxepin and is marketed in Europe as its single E-geometric isomer (Fig. 21.17), in contrast to the active Z-geometric isomer for doxepin. Its antidepressant activity is mediated by inhibition of both the NET and SERT, with preferential affinity for SERT (65). It exhibits greater overall in vitro affinity for NET and SERT than its oxygen isostere doxepin, consistent with its greater potency. Its overall therapeutic efficacy is similar to that of amitriptyline.

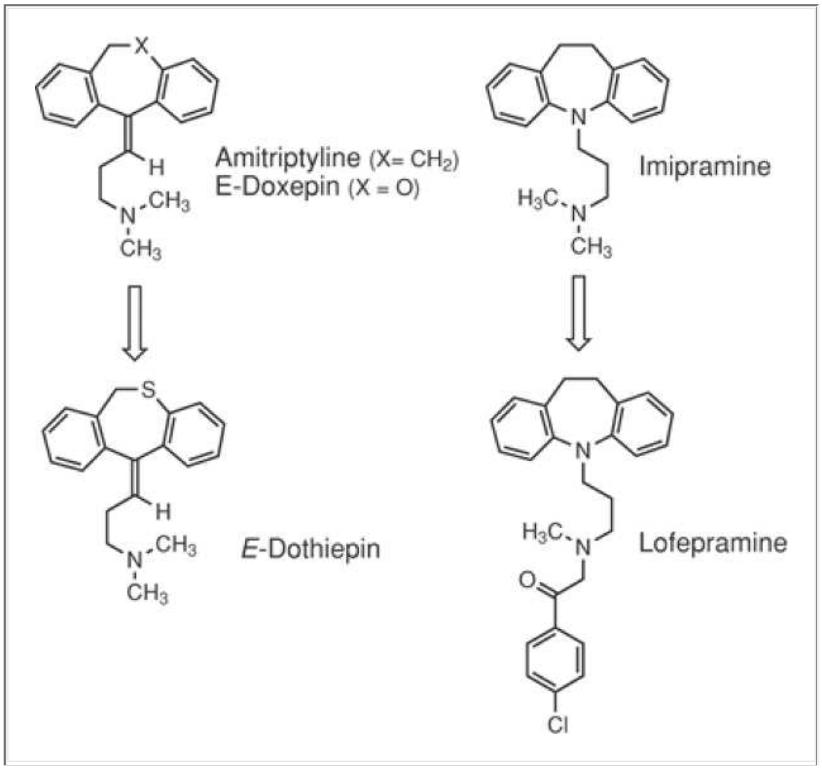

Fig. 21.17. Future tricyclic NSRIs.

Although dothiepin is readily absorbed from the GI tract, it is extensively first-pass metabolized by *S*-oxidation in the liver to its primary active metabolite, dothiepin S-oxide, and by N-demethylation to its minor metabolite, desmethyldothiepin (northiaden) (65). Dothiepin is excreted in the urine, mainly in the form of its metabolites; small amounts of the drug also are excreted in the feces and distributed into breast milk.

The incidence of anticholinergic side effects is less among patients treated with dothiepin than with amitriptyline and without cardiotoxicity at therapeutic doses. The sedative/anxiolytic activity of dothiepin is similar to that of amitriptyline. Dothiepin is an effective treatment for patients with depressive symptoms of varying severity and coexisting anxiety (65).

Lofepramine

Lofepramine differs from imipramine by the attachment of a p-chlorophenacyl moiety to the N-aminopropyl side chain (Fig. 21.17). This change confers enhanced lipophilicity and the potential of more rapid distribution into the CNS with greater in vitro affinity and selectivity for NET. Its mechanism of antidepressant action is attributed to its rapid metabolism to the secondary amine metabolite, desipramine, which selectively inhibits the neuronal uptake of NE (66).

Lofepramine has an oral bioavailability of less than 10% as a result of the extensive first-pass metabolism. Most of a dose of lofepramine is excreted via the urine as metabolites, with a mean elimination half-life of approximately

2 hours. The adverse effects of lofepramine are similar to the secondary TCAs. Lofepramine displays reversible hepatotoxicity (jaundice and hepatitis), usually within 8 weeks of initiation of therapy.

Oral lofepramine is effective in the treatment of various types of depression and is similar in efficacy to imipramine and amitriptyline while inducing fewer adverse effects. This suggests its potential use in patients who are unable to tolerate other antidepressants.

Nontricyclic Serotonin and Norepinephrine Reuptake Inhibitors

Clinical studies suggest that compounds which increase the synaptic availability of both NE and 5-HT have greater efficacy than single-acting drugs in the treatment of major depression. Thus began the efforts to design a drug that combined the properties of SSRIs and SNRIs that only blocked SERTs and NETs and without the unwanted adverse effects of TCAs (67). Currently, the nontricyclic dual inhibitors of 5-HT and NE uptake are venlafaxine, milnacipran, and duloxetine (Fig. 21.18). A structurally related nontricyclic SNRI is atomoxetine. Based on preclinical studies, venlafaxine, milnacipran, and duloxetine inhibit the reuptake of 5-HT and NE both in vitro and in vivo in the following order of decreasing potency: duloxetine> milnacipran> venlafaxine. All the dual reuptake inhibitors exhibit low affinity at neuronal receptors of the other neurotransmitters, suggesting a low side-effect potential. Venlafaxine, milnacipran, and duloxetine have repeatedly shown to be as efficacious as TCA drugs in treating major depressive disorders. These nontricyclic antidepressants reported to produce a faster and greater antidepressant response than an SSRI alone, suggesting that these two mechanisms of action can be synergistic in terms of mediating antidepressant efficacy. Meaningful differences between the nontricyclic NSRIs are largely related to their pharmacokinetics, metabolism to active metabolites, inhibition of CYP isoforms, effect of drug–drug interactions, and the half-life of the nontricyclic NSRI.

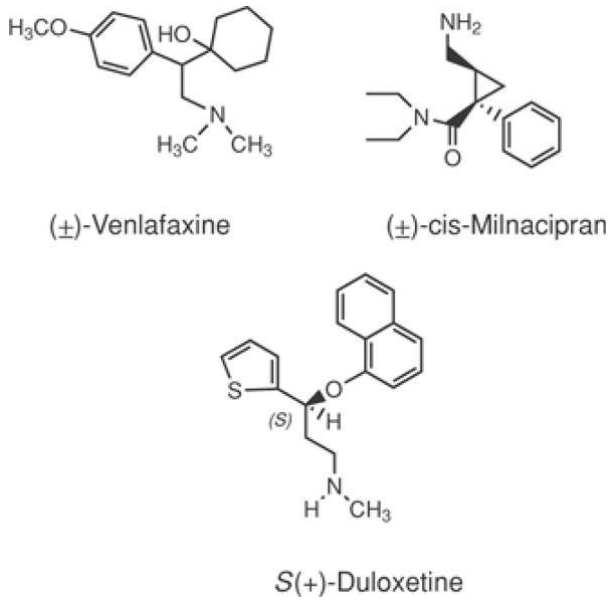

Fig. 21.18. Nontricyclic NSRIs.

Venlafaxine

Venlafaxine is a methoxyphenylethylamine antidepressant that resembles an open TCA with one of the aromatic rings replaced by a cyclohexanol ring and a dimethylaminomethyl group rather than a dimethylaminopropyl chain (Fig. 21.18).

Venlafaxine and its active metabolite, O-desmethylvenlafaxine (ODV), have dual mechanisms of action, with preferential affinity for 5-HT reuptake and weak inhibition of NE and dopamine reuptake. Venlafaxine is approximately 30 times more potent as an inhibitor of SERT than of NET (68). Because of the 30 times difference in transporter affinities, increasing the dose of venlafaxine from 75 to 375 mg/day can sequentially inhibit SERT and NERT. Thus, venlafaxine displays an ascending dose-dependent antidepressant response in contrast to the flat dose–antidepressant response curve observed with the SSRIs. This sequential action for venlafaxine also is consistent with its dose-dependent adverse-effect profile. Its mechanism of action is similar to imipramine.

Venlafaxine is rapidly and well absorbed, but with a bioavailability of 45%, which has been attributed to first-pass metabolism (Table 21.10). Food delays its absorption but does not impair the extent of absorption. Venlafaxine is distributed into breast milk. Venlafaxine is primarily metabolized in the liver by CYP2D6 to its primary metabolite, ODV, which is approximately equivalent in pharmacological activity and potency to

venlafaxine. In vitro studies indicate that CYP3A4 also is involved in the metabolism of venlafaxine to its minor and less active metabolite, N-desmethylvenlafaxine (Fig. 21.19). Protein binding for venlafaxine and ODV is low and is not a problem for drug interactions. In patients with hepatic impairment, elimination half-lives were increased by approximately 30% for venlafaxine and approximately 60% for ODV (Table 21.10). In patients with renal function impairment, elimination half-lives were increased by approximately 40 to 50% for venlafaxine and for ODV. At steady-state doses, venlafaxine and ODV exhibit dose-proportional linear pharmacokinetics over the dose range of 75 to 450 mg/day. Steady-state concentrations of venlafaxine and ODV are attained within 3 days with regular oral dosing. Venlafaxine and its metabolites are excreted primarily in the urine (87%).

Table 21.10. Pharmacokinetics of the Nontricyclic Nonselective Reuptake Inhibitors (NSRIs)

Parameters	Venlafaxine	Milnacipran	Duloxetine
Oral bioavailability (%)	45	90	>70%
Protein binding (%)	25–30	15–30	>90
Volume of distribution (L/kg)	8 (5–19) ODV 5.7	17 (9–25)	1,940
Elimination half-life (hours)	4 (2–7) ODV 11	~8	11–16
Cytochrome P450 major isoform	2D6	None	2D6 and 1A2
Major active metabolites	ODV	None	4-Hydroxy
Peak plasma concentration (hours)	2 ODV 3–4	32–48	6–10
Excretion (%)	Urine 87 (48 hours)	Urine 90	Urine >70
	Feces 2 (35 days)	Feces minor	Feces 15
Plasma half-life (hours)	2	—	6
Time to steady-state concentration (hours)	3	32–48	3–7

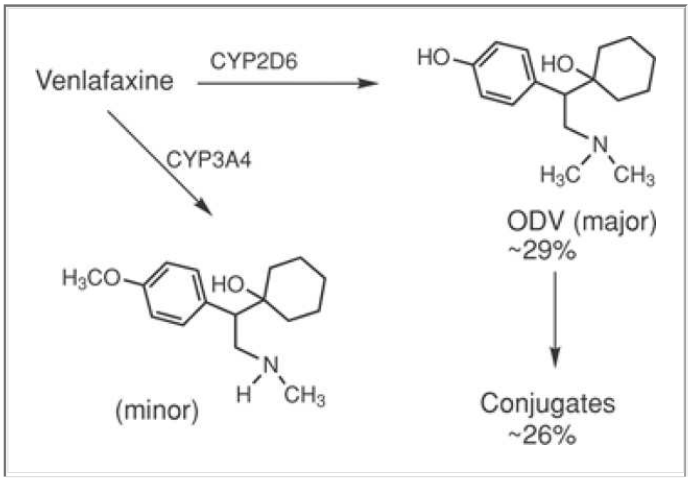

Fig. 21.19. Metabolism of venlafaxine.

The potential for cardiotoxicity with venlafaxine during normal use and for various toxicities in overdose situations are key concerns. Venlafaxine displays minimal in vitro affinity for the other neural neurotransmitter receptors and, thus, a low probability for adverse effects. To minimize GI upset (e.g., nausea), venlafaxine can be taken with food without affecting its GI absorption. Venlafaxine should be administered as a single daily dose with food at approximately the same time each day. The extended-release capsules should be swallowed whole with fluid and should not be divided, crushed, chewed, or placed in water.

Whenever venlafaxine is being discontinued after more than 1 week of therapy, it generally is recommended that the patient be closely monitored and the dosage of the drug be tapered gradually to reduce the risk of withdrawal symptoms.

Although venlafaxine is a weak inhibitor of CYP2D6, variability has been observed in the pharmacokinetic parameters of venlafaxine in patients with hepatic or renal function impairment. As a precaution, elderly patients taking venlafaxine concurrently with a drug that has a narrow therapeutic index and also is metabolized by CYP2D6 should be carefully monitored. Concurrent use of CYP3A4 inhibitors with venlafaxine has been shown to interfere with its metabolism and clearance. Similar to the other antidepressants that block 5-HT reuptake, venlafaxine may interact pharmacodynamically to cause toxic levels of 5-HT to accumulate, leading to the 5-HT syndrome.

Milnacipran

(±)-Milnacipran is the *cis*-aminomethyl derivative of phenylcyclopropanecarboxamide (Fig. 21.18) that acts by inhibiting both NE and 5-HT reuptake. It is structurally different from the other NSRIs and currently is only available in Europe as a racemic mixture, with both enantiomers exhibiting antidepressant activity. Substituting the aminomethyl group of milnacipran with an aminopropyl gives a milnacipran homologue that exhibits antidepressant activity as a potent N-methyl-D-aspartate (NMDA) receptor antagonist. A glutamate hypothesis is being investigated as an alternative mechanism of depression (see the subsection on NMDA antagonists).

Milnacipran selectively inhibits the reuptake of 5-HT (selectivity ratio, 9) at the presynaptic membrane site, thus increasing the concentration of 5-HT in the synaptic cleft (69). Although milnacipran is not a TCA, its mechanism of action is similar to that of imipramine, and its binding and reuptake inhibition profile more closely resembles that of the TCAs. Milnacipran has weak affinity for adrenergic, muscarinic, and H_1 receptors and, therefore, is expected to be devoid of the prominent side effects observed for the TCAs. In clinical studies, milnacipran showed antidepressant efficacy similar to that of TCAs and SSRIs.

In humans, milnacipran distinguishes itself from many other antidepressants by its simple pharmacokinetics. It is rapidly absorbed, with a high oral bioavailability, and it exhibits linear pharmacokinetics over a dose range of 25 to 200 mg/day (Table 21.10) (70). It circulates in the blood and distributes in the body principally as unmetabolized drug. Steady-state plasma levels are reached within 32 to 48 hours after twice-daily oral administration, and its metabolism does not involve the CYP enzyme system. Approximately 50% of the dose is excreted in urine as unmetabolized drug, and another 14% is excreted as its N-glucuronide conjugate. The remaining eliminated drug is composed of conjugated Phase I inactive metabolites. Because the unmetabolized drug is the only compound responsible for the activity of milnacipran, no dosage adjustment is needed in patients presenting liver impairment.

Milnacipran has proven to be a very safe drug, with an adverse-event profile clearly superior to that of TCAs and, to a certain extent, that of SSRIs. Only approximately 10% of patients experience side effects, and only dysuria occurred more frequently (2%) with milnacipran than with TCAs or SSRIs. Milnacipran therefore appears to be an antidepressant with a very favorable benefit:risk ratio, although with a slower onset of action than the TCAs.

Duloxetine

Duloxetine (Fig. 21.18) has been approved for the treatment of depression and diabetic peripheral neuropathic pain. It is another analogue in the line of fluoxetine-based products from Lilly, in which the

phenyl and phenoxy groups of fluoxetine have been respectively replaced with the benzene isostere, thiophene, and a

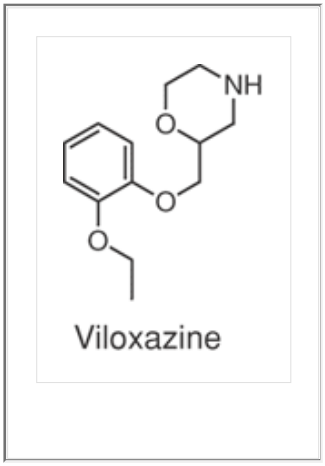
naphthyloxy group (previously described under fluoxetine). Duloxetine exhibits dual inhibition with high affinity for the SERTs and NETs, with a five times preferential inhibition of the SERT (68). Duloxetine appears to be a more potent in vitro blocker of SERTs and NETs than venlafaxine. In humans, duloxetine has a low affinity for the other neuroreceptors, suggesting low incidence of unwanted adverse effects.

Duloxetine appears to be fairly well absorbed after oral doses, with peak plasma levels in 6 to 10 hours and linear pharmacokinetics (Table 21.10) (71). The drug is extensively metabolized in the liver to active metabolites, with 72% of an oral dose primarily excreted in the urine as conjugated metabolites and up to 15% appearing in the feces. Its elimination half-life, time to steady-state blood levels, and mean volume of distribution are shown in Table 21.10.

N-demethylation to an active metabolite (CYP2D6) and hydroxylation of the naphthyl ring (CYP1A2) at either the 4-, 5-, or 6-positions are the main metabolic pathways for duloxetine. Its metabolites are primarily excreted into the urine as glucuronide, sulfate, and O-methylated conjugation products (Fig. 21.20). The major metabolites found in plasma also were found in the urine (71). Preclinical data for 4-hydroxyduloxetine suggests it has a similar pharmacological profile to duloxetine, with selective inhibition of SERT but less activity at the NET.

Viloxazine, originally developed for the treatment of depression and nocturnal enuresis, was withdrawn from consideration for business reasons. It deserves some discussion because of its early relationship with the development of the nonselective reuptake inhibitors.

Research scientists at ICI in England (now Zeneca) recognized that some β-blockers exhibited CNS 5-HT antagonist activity at high doses. To improve the CNS distribution for the β-blockers, the medicinal chemists at ICI constrained the ethanolamine side chain of the β-blockers into a morpholine ring, resulting in the synthesis of viloxazine.



Viloxazine selectively inhibits the presynaptic reuptake of NE reuptake (approximately half as potent as imipramine) and is a weak inhibitor of mouse brain 5-HT reuptake. No appreciable in vivo inhibition of monoamine oxidase activity was observed. It differed from the TCAs in not exhibiting the TCA adverse-effect profile. Viloxazine produces antidepressant activities both similar to and different from the tricyclics desimipramine, imipramine, and amitriptyline. These actions appear to be of relevance with respect to the antidepressant action of this drug.

Presently, viloxazine is classified as an orphan drug, under the trade name of Catatrol, for the treatment of narcolepsy and cataplexy.

Adverse effects have included insomnia, somnolence, headache, nausea, diarrhea, and dry mouth. Mild withdrawal symptoms on abrupt discontinuation have been described in studies with healthy subjects.

Duloxetine is a moderately potent CYP2D6 inhibitor (intermediate between paroxetine and sertraline). Thus, duloxetine should be used with caution when CYP2D6 substrates and inhibitors are coadministered.

Dopamine and Norepinephrine Reuptake Inhibitors

Bupropion

Bupropion (amfebutamone) is a phenylisopropylaminoketone that is structurally related to the phenylisopropylamine CNS stimulant, methamphetamine, and the phenylisopropylaminoketone, cathinone (a constituent in khat), and the anorexiant, diethylpropion (Fig. 21.21). Although structurally similar to the CNS stimulants, bupropion exhibits distinctive different pharmacologic and therapeutic effects. The absence of the tricyclic ring system in bupropion results in a better adverse-effect profile than with the TCAs. The tertiary butyl group in bupropion prevents its N-dealkylation to metabolites that could possess sympathomimetic and/or anorexigenic properties.

Wellbutrin and Zyban (an aid in smoking cessation treatment) are trade name products for bupropion. Therefore, the potential exists for an overdose toxicity in a patient receiving multiple brand name and generic prescriptions containing bupropion for the treatment of depression, smoking cessation, and other off-label uses.

Mechanism of action

Although the mechanism of antidepressant action for bupropion is unclear, in vitro binding studies show bupropion to be a selective inhibitor of dopamine reuptake at the dopamine presynaptic neuronal membrane and minimal inhibition of NE and 5-HT reuptake (Table 21.2). Bupropion does not exhibit clinically significant anticholinergic, antihistaminic, α_1-adrenergic blocking activity, or MAO inhibition.

The mechanism of its antidepressant action is more complex because of bupropion's metabolism to its three principal metabolites (Fig. 21.21), which likely contribute to the mechanism of action for bupropion because their plasma concentrations are as high or higher than those of bupropion, with a longer duration of action (see the discussion of pharmacokinetics below).

Bupropion reduces the discomfort and craving associated with smoking cessation, which suggests that the principal mode of action by bupropion as an aid in smoking cessation is on the withdrawal symptoms following smoking cessation. Its precise mechanism of action, however, remains unclear. The efficacy of bupropion in smoking cessation does not appear to depend on the presence of underlying depression. Bupropion increases extracellular

dopamine concentrations in the CNS, most likely as a result of its inhibition of dopamine and noradrenaline reuptake transporters (Table 21.2). It also has been shown to be an antagonist at the nicotinic receptor at clinically relevant concentrations of bupropion (72). As nicotine concentrations in the CNS drop with smoking cessation, the firing rates of noradrenergic neurons increase, which may be the basis for the withdrawal symptoms. Thus, during withdrawal, bupropion and its active metabolite, hydroxybupropion, reduce the firing rates of these noradrenergic neurons in a dose-dependent manner, attenuating the symptoms of smoking cessation. Furthermore, its ability to antagonize nicotinic receptors also may prevent relapse by attenuating the reinforcing properties of nicotine but probably cannot acutely reduce smoking. Bupropion is extensively metabolized in humans with its major hydroxylated metabolites reaching plasma levels higher than those of bupropion itself. These hydroxylated metabolites share many of the pharmacological properties of bupropion, so they may play a greater role in attenuating the withdrawal and relapse by which bupropion exerts its activity in smoking cessation (73).

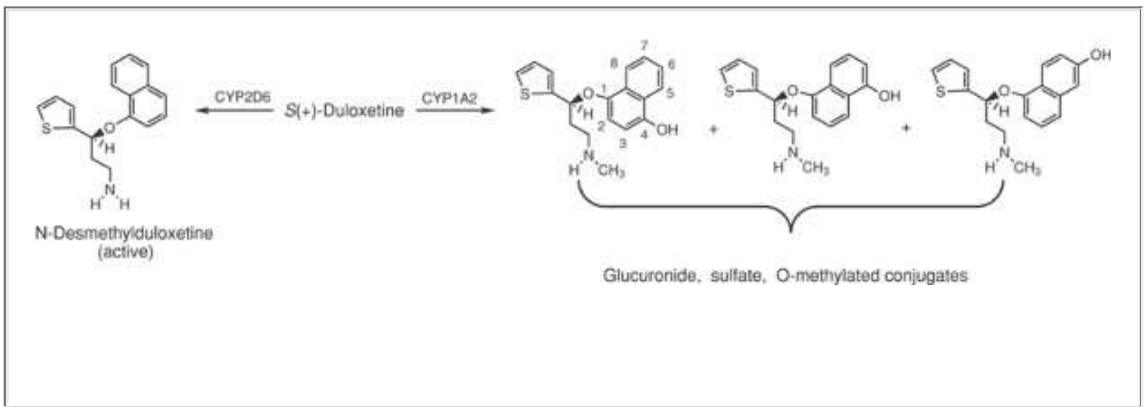


Fig. 21.20. Metabolism of duloxetine.

Pharmacokinetics

Bupropion is absorbed from the GI tract, with a low oral bioavailability as a result of first-pass metabolism. The pharmacokinetic properties of bupropion are shown in Table 21.11. Food does not appear to substantially affect its peak plasma concentration or AUC. Following oral administration, peak plasma concentrations usually are achieved within 2 hours for bupropion and 3 hours for sustained-released bupropion products, followed by a biphasic decline for bupropion. Plasma concentrations are dose-proportional (linear pharmacokinetics) following single doses of 100 to 250 mg/day. The fraction of a dose excreted unmetabolized was less than 1%.

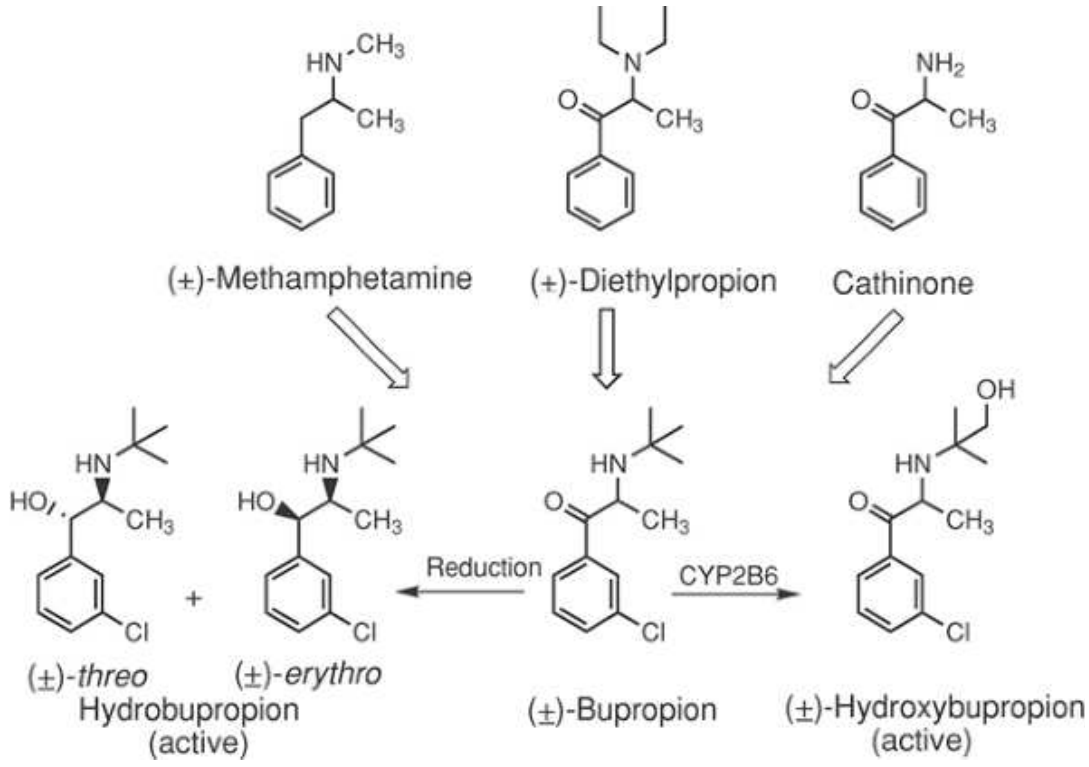

Fig. 21.21. Bupropion, related derivatives, and metabolites.

Bupropion hydroxylation of the tert-butyl group to hydroxypropion is mediated almost exclusively by CYP2B6 and, to a lesser extent, by CYP2E1 (74). Other metabolites include reduction of the aminoketone to amino-alcohol isomers, threo-hydrobupropion and erythro-hydrobupropion (Fig. 21.21). Further oxidation of the bupropion side chain results in the formation of m-chlorobenzoic acid, which is eliminated in the urine as its glycine conjugate. Hydroxybupropion is approximately 50% as potent as bupropion, whereas threo-hydrobupropion and erythro-hydrobupropion have 20% of the potency of bupropion. Peak plasma concentrations for hydroxybupropion are approximately 10 times the peak level of the parent drug at steady state, with an elimination half-life of approximately 20 hours. The times to

peak concentrations for the erythro-hydrobupropion and threo-hydrobupropion metabolites are similar to that of the hydroxybupropion metabolite. The plasma levels of the erythro-hydrobupropion correlate with several side effects, such as insomnia and dry mouth. Their elimination half-lives, however, are longer (~33 and 37

hours, respectively), and steady-state AUCs are 1.5- and 7.0 times that of bupropion, respectively. The hepatic clearance in patients with liver disease was increased from 19 to 29 hours. The median observed t_{max} was 19 hours for hydroxybupropion and 31 hours for threo/erythro-hydrobupropion. The mean half-lives for hydroxybupropion and threo/erythro-hydrobupropion were increased by five- and two times, respectively, in patients with severe hepatic cirrhosis compared with healthy volunteers Bupropion and its metabolites are distributed into breast milk.

Table 21.11. Pharmacokinetics of the Dopamine and Norepinephrine Reuptake Inhibitors (DNRIs) and Serotonin Receptor Modulators (SRMs)

Parameters	Bupropion	Trazodone	Mirtazapine
Oral bioavailability (%)	5–20	65 (60–70)	~50
Protein binding (%)	80	90–95	85
Volume of distribution (L/kg)	19–21	0.84 (0.5–1.2)	107
Elimination half-life (hours)	21 (14–24) ~20 (S,S)-hydroxy	7 (4–9)	16–40
Cytochrome P450 major isoform	2B6	3A4	3A4 and 2D6
Major active metabolites	(S,S)-Hydroxyl	m-chlorophenyl piperazine	None
Peak plasma concentration (hours)	2–3 8 (S,S)-hydroxy	1–2	2
Excretion (%)	Urine 87	Urine 70–75	Urine 75
	Feces 10	Feces 25–30	Feces 15
Plasma half-life (hours)	3–4 20 (S,S)-hydroxy	6 (4–8)	2
Time to steady-state concentration (days)	5 8 (S,S)-hydroxy	3–7	5

In geriatric patients, the apparent half-life of hydroxybupropion averaged approximately 34 hours. Reduction in renal or hepatic function may affect elimination of the major metabolites, because these compounds are moderately polar and are likely to be metabolized further or conjugated in the liver before urinary excretion.

The pharmacokinetic parameters for bupropion and hydroxybupropion did not differ between smokers and nonsmokers, but adolescent females exhibited increased AUCs and volume of distribution (normalized to body weight) and longer elimination half-life than do males for bupropion and its major metabolite, hydroxybupropion. No differences in clearance between males and females, however, were observed.

Drug Interactions

Inhibition studies with the SSRIs and bupropion suggest that bupropion is a potent CYP2D6 inhibitor (74). Bupropion hydroxylation was strongly inhibited by, in the following order, paroxetine> fluvoxamine> sertraline> desmethylsertraline> norfluoxetine> nefazodone> fluoxetine and only weakly inhibited by venlafaxine, ODV, citalopram, and desmethylcitalopram. The inhibition of bupropion hydroxylation in vitro by SSRIs suggests the potential for clinical drug interactions. Therefore, coadministration of drugs that inhibit CYP2D6 warrants careful monitoring. Because of its selective inhibition of DA reuptake, pharmacodynamic interactions with dopamine agonists (e.g., levodopa) and antagonists should be anticipated. Coadministration of bupropion with drugs that lower the seizure threshold should be avoided because of the risk of serious seizures.

Drugs that affect metabolism by CYP2B6 (e.g., orphenadrine and cyclophosphamide) also have the potential to interact with bupropion.

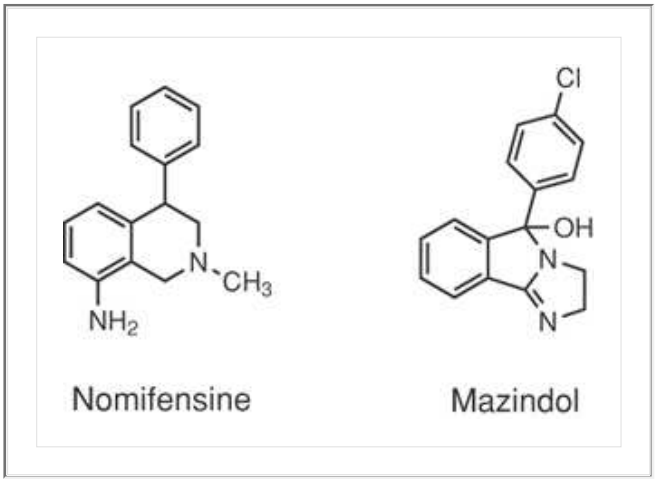
Therapeutic Uses

Besides being used to treat depression, bupropion is a nonnicotine aid in the cessation of smoking. The efficacy of bupropion in smoking cessation is comparable to that of nicotine replacement therapy and should be considered as a second-line treatment in smoking cessation (72,73). It possesses a broad spectrum of infrequent

adverse effects, however, with potential drug metabolism interactions with TCAs, β-adrenergic blocking drugs, and class Ic antiarrhythmics.

Miscellaneous Norepinephrine and Dopamine Reuptake Inhibitors

Nomifensine is a substituted phenylpiperidine (an aminophenyltetrahydroisoquinoline) structurally related to sertraline that was marketed as a stimulatory antidepressant in the mid-1970s but later withdrawn because of a high incidence of hemolytic anemia. Nomifensine inhibits the NE and dopamine reuptake transporters. It displays high affinity for NET (human pK_i = 7.8), moderate affinity for dopamine transporter (pK_i = 6.6), and a low affinity for SERT (5-HT:NE ratio, 65).



Mazindol (Sanorex®) is a phenyl-substituted imidazobenzoisoindole that inhibits both NE and dopamine reuptake transporters. It exhibits high affinity for the NET (rat pK_i = 9.3), good affinity for dopamine transporter (rat pK_i = 7.8), and a 5-HT:NE ratio of 224. Dopamine reuptake inhibitors suppress appetite; thus, mazindol is approved to be marketed as an appetite suppressant.

Serotonin Receptor Modulators

Serotonin Antagonist/Reuptake Inhibitors

General mechanism of action

Serotonin receptor modulators are a class of antidepressants, the function of which is to modulate the concentration of 5-HT in the brain. A neuromodulator functions as a "volume control in the brain and nervous system," regulating the other neurotransmitters through its receptors in the brain in response to external stimuli. As previously described, the serotonergic system modulates a large number of physiological events, such as temperature regulation, sleep, learning and memory, behavior, sexual function, hormonal secretions, and immune activity, and is implicated in stress, anxiety, aggressiveness, and depression disorders. Of the various types of 5-HT receptors (see Chapter 14) mediating serotonergic activity, the 5-HT_{1B} receptors play an important role in modulating the serotonergic system. The 5-HT_{1B} receptors are autoreceptors localized on serotonergic neuron terminals, where they inhibit the release of 5-HT and its biosynthesis; they also are heteroreceptors located on nonserotonergic terminals, where they inhibit the release of other neurotransmitters, such as acetylcholine, γ-aminobutyric acid (GABA), and NE. Excessive amounts of 5-HT in the brain may cause relaxation, sedation, and a decrease in sexual drive; inadequate amounts of 5-HT can lead to psychiatric disorders. Therefore, the 5-HT receptor modulator antidepressants exert their antidepressant effects by mechanisms that enhance noradrenergic or serotonergic transmission by acting as mixed 5-HT_2 antagonists/5-HT reuptake inhibitors (SARI; trazodone), and α_2 adrenergic antagonists/5-HT_2 and 5-HT_3 antagonists (NaSSA; mirtazapine). Chronic antidepressant treatment with SARIs and NaSSAs modulate 5-HT receptor expression and, in turn, 5-HT function.

Trazodone

Trazodone is a phenylpiperazine–triazolopyridine antidepressant that is structurally unrelated to most of the other antidepressant classes (Fig. 21.22).

Mechanism of action

Trazodone acts as an antagonist at 5-HT_{2A} receptors and is a weak inhibitor of 5-HT reuptake at the presynaptic neuronal membrane, potentiating the synaptic effects of 5-HT. Its mechanism of action is complicated by the presence of its metabolite, m-chlorophenylpiperazine (Fig. 21.23), which is a 5-HT_{2C} agonist. At therapeutic dosages, trazodone does not appear to influence the reuptake of dopamine or NE within the CNS. It has little anticholinergic activity and is relatively devoid of toxic cardiovascular effects. The increase in serotonergic activity with long-term administration of trazodone decreases the number of postsynaptic serotonergic (i.e., 5-HT_2) and β-adrenergic binding sites in the brains of animals, decreasing the sensitivity of adenylate (or adenylyl) cyclase to stimulation by β-adrenergic agonists. It has been suggested that postsynaptic serotonergic receptor modification is mainly responsible for the antidepressant action observed during long-term administration of trazodone. Trazodone does not inhibit MAO and, unlike amphetamine-like drugs, does not stimulate the CNS.

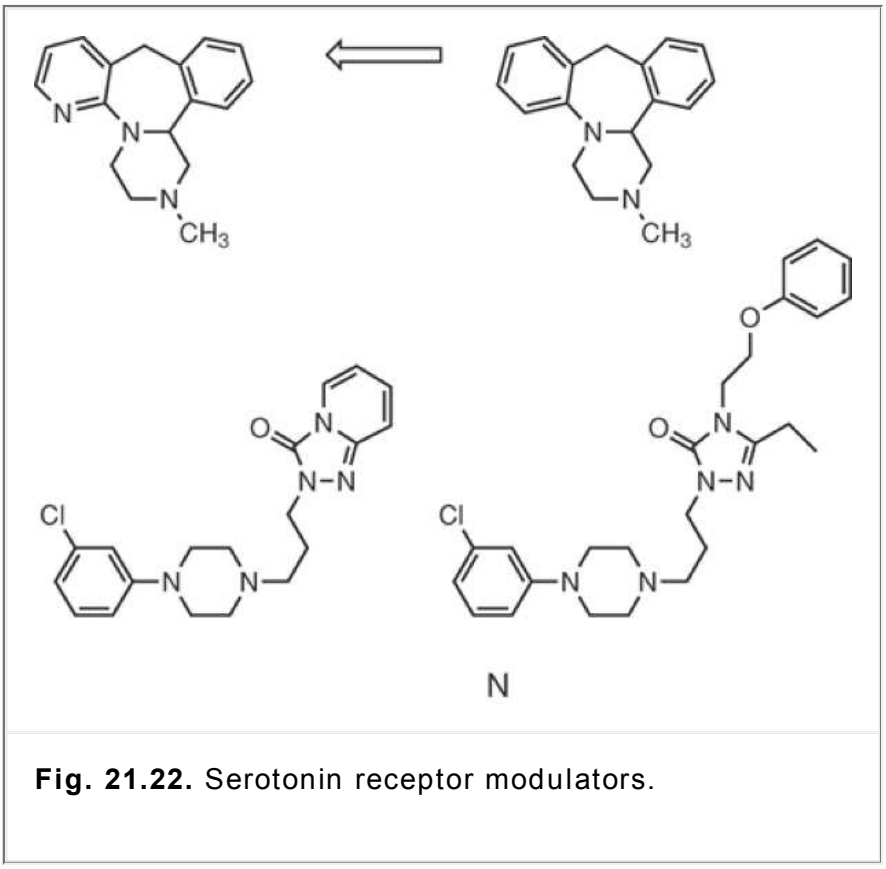


Fig. 21.22. Serotonin receptor modulators.

Trazodone is rapidly and almost completely absorbed from the GI tract following oral administration, with an oral bioavailability of approximately 65% (Table 21.11). Peak plasma concentrations of trazodone occur approximately 1 hour after oral administration when taken on an empty stomach or 2 hours when taken with food. At steady state, its plasma concentrations exhibit wide interpatient variation.

Trazodone is extensively metabolized in the liver by N-dealkylation to its primary active metabolite, m-chlorophenylpiperazine (m-CPP), which subsequently undergoes aromatic hydroxylation to p-hydroxy-m-CPP (Fig. 21.23) (75). In vitro studies indicate that CYP3A4 is the major isoform involved in the production of m-CPP from trazodone (and CYP2D6 to a lesser extent). The p-hydroxy-m-CPP and oxotriazolopyridine-propionic acid (the major metabolite excreted in urine) are conjugated with glucuronic acid. Less than 1% of a dose is excreted unmetabolized.

Trazodone therapy has been associated with several cases of idiosyncratic hepatotoxicity (see Chapter 10). Although the mechanism of hepatotoxicity remains unknown, the generation of an iminoquinone, an epoxide reactive metabolite or both may play a role in the initiation of trazodone-mediated hepatotoxicity (Fig. 21.23)(75). Studies have shown that the bioactivation of trazodone involves, first, aromatic hydroxylation of the 3-chlorophenyl ring, followed by its oxidation to a reactive iminoquinone intermediate, which then reacts with glutathione or, oxidation of the triazolopyridinone ring to an electrophilic epoxide and ring opening by either a Nucleophile (:Nu) or to generate the corresponding hydrated trazodone–Nucleophile conjugate or the stable

diol metabolite, respectively. The pathway involving trazodone bioactivation to the iminoquinone also has been observed with many para-hydroxyanilines (e.g., acetaminophen) (see Chapter 10). including the structurally related antidepressant nefazodone. The reactive intermediates consume the available glutathione, allowing the reactive intermediate to react with hepatic tissue leading to liver damage.

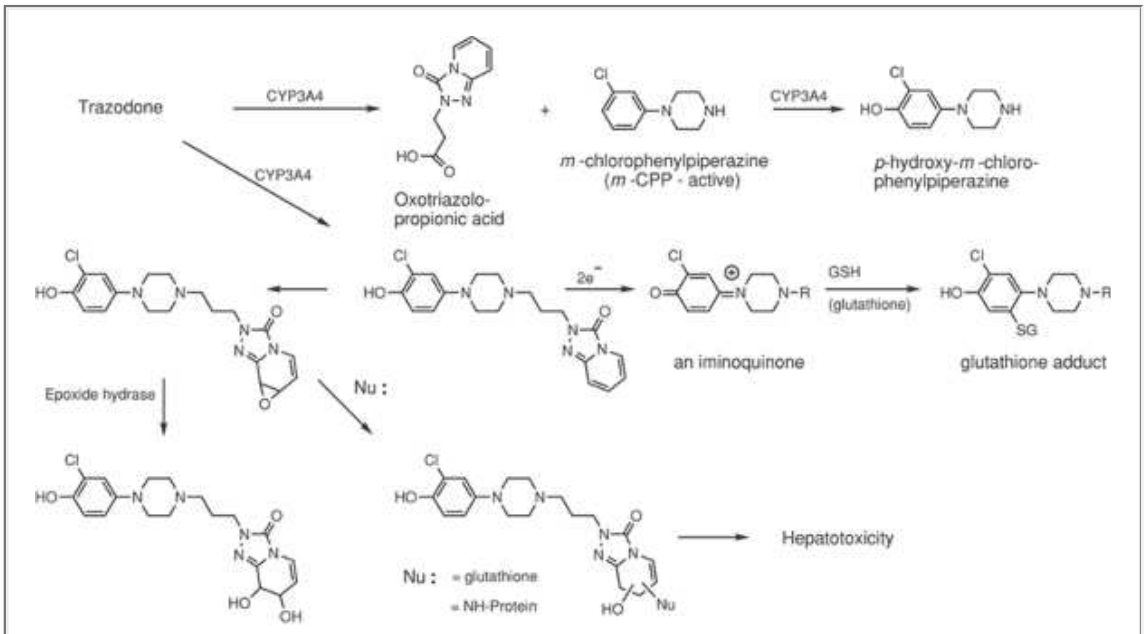

Fig. 21.23. Metabolism of trazodone.

Unlike the TCAs, trazodone does not block the fast sodium channels and, thus, does not have significant arrhythmic activity. Compared with the SSRIs, it has a lesser tendency to cause drug-induced male sexual dysfunction as a side effect. Although trazodone displays α_1-adrenergic blocking activity, hypotension is relatively uncommon. Signs of overdose toxicity include nausea, vomiting, and decreased level of consciousness. Trazodone produces a significant amount of sedation in normal and mentally depressed patients (principally from its central α_1-adrenergic blocking activity and antihistaminic action).

Drug interactions

Trazodone possesses serotonergic activity; therefore, the possibility of developing 5-HT syndrome should be considered in patients who are receiving trazodone and other SSRIs or serotonergic drugs concurrently. When trazodone is used concurrently with drugs metabolized by CYP3A4, caution should be used to avoid excessive sedation. Trazodone can cause hypotension, including orthostatic hypotension and syncope; concomitant administration of antihypertensive therapy may require a reduction in dosage of the antihypertensive agent.

The possibility of drug–drug interactions with trazodone and other substrates, inducers, and/or inhibitors of CYP3A4 exists (75).

Therapeutic uses

Trazodone is used primarily in the treatment of insomnia, mental depression, or depression/anxiety disorders. The drug also has shown some efficacy in the treatment of benzodiazepine or alcohol dependence, diabetic neuropathy, and panic disorders.

Noradrenergic Specific Serotonergic Antidepressants

Mirtazapine

Mirtazapine is a piperazinodibenzoazepine antidepressant that is an isostere of the antidepressant mianserin (Fig. 21.22). A seemingly simple isosteric replacement of an aromatic methine group (CH) in mianserin with a nitrogen to give a pyridine ring (mirtazapine) has profound effects on the physicochemical properties, pharmacokinetics, mechanisms of action, and antidepressant activities (Table 21.12) (31). Profound differences between receptor affinity and transporter affinity, pharmacokinetics, regioselectivity in the

formation of metabolites, and toxicity are observed for mianserin and mirtazapine and their antidepressant mechanisms of action. The pyridine ring increases the polarity of the molecule and decreases the measured partition coefficient and the basicity. Mianserin is a potent inhibitor of NET, whereas mirtazapine has negligible effects on the inhibition of NET (pK_i = 7.1 vs. 5.8 respectively).

Mianserin is currently marketed in Europe as an antidepressant. Mianserin has not been approved for use in the United States because of its serious adverse effects of

agranulocytosis and leukopenia. Mirtazapine has not exhibited this adverse effect

Nefazodone is a phenylpiperazine antidepressant structurally related to trazodone, but it differs pharmacologically from trazodone, the SSRIs, the MAOIs, and the TCAs (Fig. 21.22). When compared with trazodone, nefazodone displays approximately twice the affinity potency for SERT. Nefazodone therapy, however, was associated with life-threatening cases of idiosyncratic hepatotoxicity, and as a result, nefazodone was withdrawn from both the North American and European markets in 2003. The mechanism of hepatotoxicity remains unknown, but nefazodone, being structurally similar to trazodone (Fig. 21.23), is metabolized to p-hydroxynefazodone, m-CPP, and phenoxyethyltriazoledione. In turn, p-hydroxynefazodone is thought to be oxidized to an iminoquinone and/or an epoxide reactive metabolite, which may play a role in the initiation of nefazodone-mediated hepatotoxicity (76).

Mechanism of action

Animal studies indicate that the efficacy of mirtazapine as an antidepressant results from enhancing central noradrenergic and serotonergic activity, possibly through blocking central presynaptic α_2-adrenergic receptors. Blocking these receptors inhibits the negative feedback loop, which increases the release of NE into the synapse. Mirtazapine also is a potent antagonist at 5-HT_2 and 5-HT_3 receptors, and it shows no significant affinity for 5-HT_{1A} or 5-HT_{1B} receptors. Additionally, it displays some anticholinergic properties, and it produces sedative effects (because of potent histamine H_1 receptor antagonism) and orthostatic hypotension (because of moderate antagonism at peripheral α_1-adrenergic receptors). Its antidepressant effect is comparable to the TCAs and may be better than some SSRIs, especially in patients with depression of the melancholic type, but at higher doses, it may cause drowsiness and weight gain. The drug generally is well tolerated, producing no more adverse events (including anticholinergic events) than the SSRIs and fewer adverse events than the TCAs.

The pharmacokinetics for mirtazepine are shown in Table 21.11. Mirtazapine absorption is rapid and complete, with a bioavailability of approximately 50% as a result of first-pass metabolism. The rate and extent of mirtazapine absorption are minimally affected by food. Dose and plasma levels are linearly related over a dose range of 15 to 80 mg. The elimination half-life of the (–)-enantiomer is approximately twice that of the (+)-enantiomer. In females of all ages, the elimination half-life is significantly longer than in males (mean half-life, 37 versus 26 hours).

Table 21.12. Physicochemical and Properties of Mirtazapine and Mianserin

Properties	Mirtazapine	Mianserin
pKa	7.1	7.4

Polarity	2.63 debye	0.82 debye
NERT affinity (pK_i)	5.8	7.1

5-HT release	Yes	No

[a]Partition coefficient (log P) experimental determination.

Following oral administration, mirtazapine undergoes first-pass metabolism by N-demethylation and ring hydroxylation to its 8-hydroxy metabolite, followed by O-glucuronide conjugation (77). In vitro studies indicate that CYP2D6 and CYP1A2 are involved in the formation of the 8-hydroxy metabolite and that CYP3A4 is responsible for the formation of the N-desmethyl and N-oxide metabolites (Fig. 21.24). The 8-hydroxy and N-desmethyl metabolites possess weak pharmacological activity, but their plasma levels are very low and, thus, are unlikely to contribute to the antidepressant action of mirtazapine. Clearance for mirtazapine may decrease in patients with hepatic or renal impairment, increasing its plasma concentrations. Therefore, it should be used with caution in these patients. In vitro studies have shown mirtazapine to be a weak inhibitor of CYP1A2, CYP2D6, and CYP3A4.

Monoamine Oxidase Inhibitors

The discovery of MAOIs resulted from a search for derivatives of isoniazid (isonicotinic acid hydrazide) (Fig. 21.25) with antitubercular activity. During clinical trials with this hydrazine derivative, a rather consistent beneficial effect of mood elevation was noted in depressed patients with tuberculosis. Although no longer used clinically, iproniazid (Fig. 21.25), the first derivative to be synthesized, was found to be hepatotoxic at dosage levels required for antitubercular and antidepressant activity. The antidepressant activity of iproniazid, however, prompted a search for other MAOIs, which resulted in

the synthesis of hydrazine and nonhydrazine MAOIs that were relatively less toxic than iproniazid.

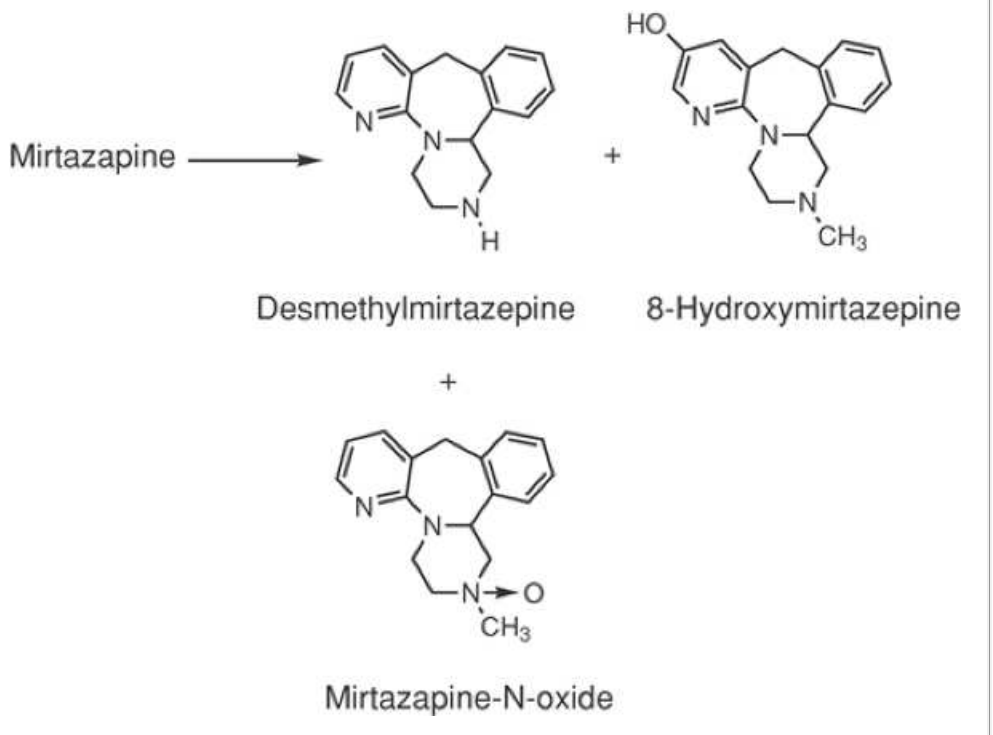

Fig. 21.24. Metabolism of mirtazepine.

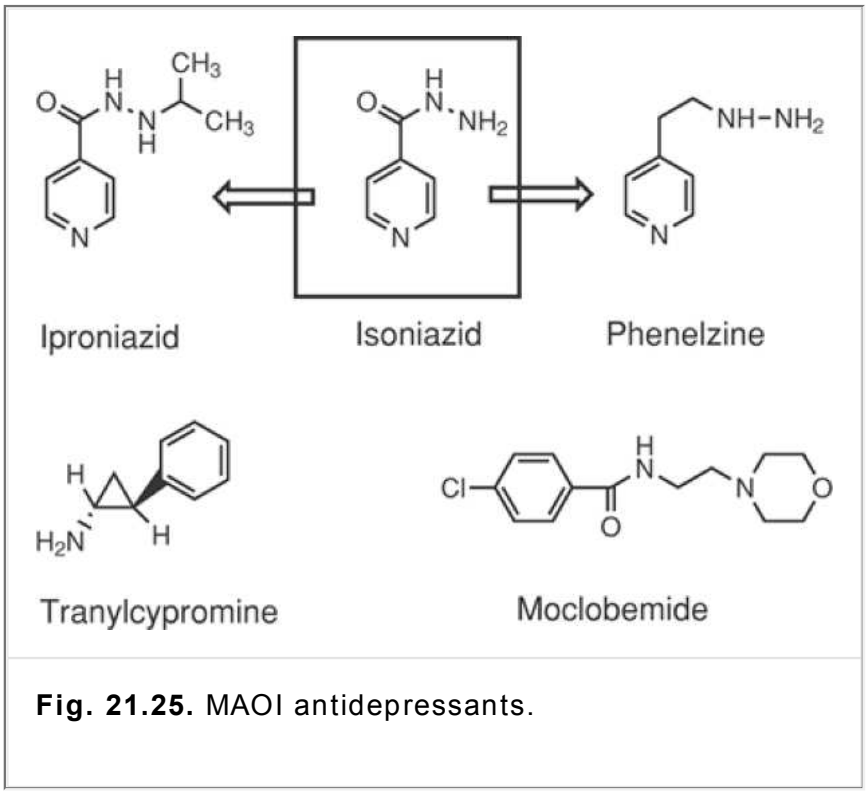

Fig. 21.25. MAOI antidepressants.

The MAOIs can be classified as hydrazines (e.g., phenelzine) and nonhydrazines (e.g., tranylcypromine), which can block the oxidative deamination of naturally occurring monoamines. MAOIs can also be classified according to their ability to selectively or nonselectively inhibit MAO. The currently available MAOI antidepressants (phenelzine and tranylcypromine) (Fig. 21.25) are considered to be irreversible nonselective inhibitors of MAO. The mechanism of antidepressant action of the MAOIs suggests that an increase in free 5-HT and NE and/or alterations in other amine concentrations within the CNS is mainly responsible for their antidepressant effect.

Mechanisms of Action Common to MAOIs

An enzyme found mainly in nerve tissue and in the liver and lungs, MAO catalyzes the oxidative deamination of various amines, including epinephrine, NE, dopamine, and 5-HT. At least two isoforms of MAO exist, MAO-A and MAO-B, with differences in substrate preference, inhibitor specificity, and tissue distribution. The MAO-A substrates include 5-HT, and the MAO-B substrates include phenylethylamine. Tyramine, epinephrine, NE, and dopamine are substrates for both MAO-A and MAO-B. The cloning of MAO-A and MAO-B has demonstrated unequivocally that these enzymes consist of different amino acid sequences and also has provided insight regarding their structure, regulation, and function (51). Both MAO-A and -B knockout mice exhibit distinct differences in neurotransmitter metabolism and behavior (51). The MAO-A knockout mice have elevated brain levels of 5-HT, NE, and dopamine, and they manifest aggressive behavior similar to human males with a deletion of MAO-A. In contrast, MAO-B knockout mice do not exhibit aggression, and only levels of phenylethylamine are increased. Both MAO-A and -B knockout mice show increased reactivity to stress. These knockout mice are valuable models for investigating the role of monoamines in psychoses and in neurodegenerative and stress-related disorders.

The pharmacological effects of MAOIs are cumulative. A latent period of a few days to several months may occur before the onset of the antidepressant action, and effects may persist for up to 3 weeks following discontinuance of therapy.

Adverse Effects Common to MAOIs

Common side effects for the nonselective MAOIs include difficulty getting to sleep and broken sleep, daytime insomnia, agitation, dizziness on standing that results in fainting (orthostatic hypotension), dry mouth, tremor (slight shake of muscles of arms and hands), syncope, palpitations, tachycardia, dizziness, headache, confusion, weakness, overstimulation including increased anxiety, constipation, GI disturbances, edema, dry

mouth, weight gain, and sexual disturbances.

Drug Interactions Common to MAOIs

The most significant drug interaction limiting the efficacy of the nonselective MAOIs is with certain foods that have the potential to cause hypertensive crisis because of the release and potentiation of catecholamines. The severity and consequences of such interactions vary among individuals from only minor increases in blood pressure to substantial and rapid increases in blood pressure within 20 minutes. These patients may experience symptoms associated with brain hemorrhage or cardiac failure.

Hypertensive crises with MAOIs have occurred in some patients following ingestion of foods containing large amounts of tyramine or tryptophan. In general, patients taking MAOIs should avoid protein foods that have undergone protein breakdown by aging, fermentation, pickling, smoking, or bacterial contamination. Some of the common foods to avoid are shown in Table 21.13. Patients should be warned against eating foods

with a high tyramine content, because hypertensive crisis may result. Excessive amounts of caffeine also reportedly may precipitate hypertensive crisis.

Table 21.13. Foods To be Avoided Due to Potential Monoamine Oxidase Inhibitor–Food Interactions

Cheeses
Cheddar
Camembert
Stilton
Processed cheese
Sour cream
Spirits
Chianti

Champagne
Alcohol free/reduced wines
Fish
Pickled herring

Anchovies
Caviar
Miscellaneous
Shrimp paste
Chocolate
Meat tenderizers (papaya)
Meats
Chicken livers
Genoa salami
Hard salami
Pepperoni
Lebanon bologna
Fruit
Figs (overripe/canned)
Raisins
Overripe bananas
Dairy product
Yogurt
Vegetable products

Yeast extract
Pods-broad beans
Bean curd
Soy sauce
Avocado

Table 21.14. Common Information for Patients taking Monoamine Oxidase Inhibitors (MAOIs)

Patient Information	Recommendation
Discontinuance of therapy or dose adjustment	Consult physician
Adding medication (prescription/over-the-counter)	Consult physician
Tyramine containing foods and over- the-counter products	Avoid
Drowsiness, blurred vision	Avoid driving or performing tasks requiring alertness or coordination
Dizziness, weakness, fainting	Arise from sitting position slowly
Alcohol use	Avoid alcohol
Onset of action	Effects may be delayed for a few weeks
Severe headache, palpitation,	Consult physician tachycardia, sense of constriction in throat or chest, sweating, stiff neck, nausea, or vomiting
New physician or dentist	Inform practitioner of MAOI use

The MAOIs interfere with the hepatic metabolism of many prescription and nonprescription (over-the-counter) drugs and may potentiate the actions of their pharmacological effects (i.e., cold decongestants, sympathomimetic amines, general anesthetics, barbiturates, and morphine).

Therapeutic Uses Common to MAOIs

The MAOIs are indicated in patients with atypical (exogenous) depression and in some patients who are unresponsive to other antidepressive therapy. They rarely are a drug of first choice. Unlabeled uses have included bulimia (having characteristics of atypical depression), treatment of cocaine addiction (phenelzine),

night terrors, posttraumatic stress disorder; some migraines resistant to other therapies, seasonal affective disorder (30 mg/day), and treatment of some panic disorders.

A list of information that should be transmitted to the patient concerning use of MAOIs is shown in Table 21.14.

Nonselective MAOI antidepressants

Phenelzine

Phenelzine is a hydrazine MAOI (Fig. 21.25). Its mechanism of action is the prolonged, nonselective, irreversible inhibition of MAO. Phenelzine has been used with some success in the management of bulimia nervosa. The MAOIs, however, are potentially dangerous in patients with binge eating and purging behaviors, and the American Psychiatric Association states that MAOIs should be used with caution in the management of bulimia nervosa.

Table 21.15. Pharmacokinetics of the Monoamine Oxidase Inhibitors (MAOIs)

Parameters	Phenelzine (Nardil)	Tranylcypromine (Parnate)	Meclobemide
Oral bioavailability (%)	NA	~50	50–90
Protein binding (%)	NA	NA	50
Volume of distribution (L/kg)	NA	1.1–5.7	1.2
Elimination half-life (hours)	NA	2.5 (1.5–3.2)	1.5
Peak plasma concentration (hours)	2–3	1.5 (0.7–3.5)	0.82
Excretion route	Urine	Urine	Renal
		Feces	Feces

NA, not available.

Limited information is available regarding MAOI pharmacokinetics of phenelzine (Table 21.15). Phenelzine appears to be well absorbed following oral administration; however, maximal inhibition of MAO occurs within 5 to 10 days. Acetylation of phenelzine to its inactive acetylated metabolite appears to be a minor metabolic pathway (78). Phenelzine is a substrate as well as an inhibitor of MAO, and major identified metabolites of phenelzine include phenylacetic acid and p-hydroxyphenylacetic acid. Phenelzine also elevates brain GABA levels, probably via its β-phenylethylamine metabolite. The clinical effects of phenelzine may continue for up to 2 weeks after discontinuation of therapy. Phenelzine is excreted in the urine mostly as its N-acetyl metabolite. Interindividual variability in plasma concentrations have been observed among patients who are either slow or fast acetylators. Slow acetylators of hydrazine MAOIs may yield exaggerated adverse effects after standard dosing. If adverse neurological reactions occur during phenelzine therapy, phenelzine-induced pyridoxine deficiency should be considered. Pyridoxine supplementation can correct the deficiency while

allowing continuance of phenelzine therapy.

Tranylcypromine

Tranylcypromine is a nonhydrazine, irreversible MAO inhibitor antidepressant agent that was designed as the cyclopropyl analogue of amphetamine (Fig. 21.25). Instead of exhibiting amphetamine-like stimulation, its mechanism of action is nonselective, irreversible inhibition of MAO. Its onset of antidepressant action is more rapid than for phenelzine. Tranylcypromine is well absorbed following oral administration (Table 21.15). Metabolism occurs via aromatic ring hydroxylation and N-acetylation (78). It is a competitive inhibitor of CYP2C19 and CYP2D6 and a noncompetitive inhibitor of CYP 2C9. Most metabolism studies suggest that tranylcypromine is not metabolized to amphetamine contrary to debate. Maximal MAO inhibition, however, occurs within 5 to 10 days. The GI absorption of the tranylcypromine shows interindividual

variation and may be biphasic in some individuals, achieving an initial peak within approximately 1 hour and a secondary peak within 2 to 3 hours. It has been suggested that this apparent biphasic absorption in some individuals may represent different absorption rates. Following discontinuance of tranylcypromine, the drug is excreted within 24 hours. On withdrawal of tranylcypromine, MAO activity is recovered in 3 to 5 days (possibly in up to 10 days). Concentrations of urinary tryptamine, an indicator of MAO-A inhibition return to normal, however, within 72 to 120 hours.

Reversible MAO-A Inhibitor Antidepressants

The major goal for developing new reversible MAO-A inhibitors (RIMAs) is to avoid the severe, life-threatening hypertensive reactions that can occur with irreversible inhibitors. Irreversible inhibition of intestinal and hepatic MAO-A can lead to inhibition of tyramine degradation, thus allowing excessive amounts of naturally occurring tyramine to be absorbed from the food. Because these reversible compounds form unstable complexes with the MAO-A subtype, they can be easily displaced from MAO-A by tyramine. Thus, it becomes possible for ingested tyramine to be metabolized, diminishing the need for the dietary restrictions that plague the use of older irreversible nonselective MAOIs. This new class of selective and reversible inhibitors of MAO-A includes moclobemide (Fig. 21.25).

Moclobemide

Moclobemide is a benzamide derivative containing a morpholine ring with a pK_a of 6.2 and a partition coefficient of 40 in a octanol/pH 7.4 buffer solution. Moclobemide is not currently available commercially in the United States, but is available in the United Kingdom and Australia.

Mechanism of action

Moclobemide is an RIMA that preferentially inhibits MAO-A (~80%) and, to a lesser extent, MAO-B (20–30% inhibition), thereby increasing the concentration of 5-HT, NE, and other catecholamines in the synaptic cleft and in storage sites. During chronic therapy with the MAOIs, adaptive changes at the noradrenergic and serotonergic receptors occur (“downregulation”) as a result of neurotransmitter hypersensitivity because of prolonged concentrations of NE and 5-HT at the postsynaptic receptor (see the discussion of the receptor sensitivity hypothesis for details). This mechanism is likely the basis for its antidepressant activity. Inhibition of MAO-A by moclobemide is short-acting (maximum, 24 hours) and reversible. This is in contrast to phenelzine, which is nonselective, long-acting, and irreversible in its binding to MAO-A and MAO-B.

The pharmacokinetics (Table 21.15) for moclobemide are linear only up to 200 mg; at higher doses, nonlinear pharmacokinetics are observed (79). Although well absorbed from the GI tract, the presence of food reduces the rate but not the extent of absorption of moclobemide. Small quantities of moclobemide are distributed into human breast milk. Moclobemide undergoes a complex metabolism, initially involving morpholine carbon and nitrogen oxidation, deamination, and aromatic hydroxylation. The N-oxide and ring-opened metabolites retain some in vitro MAO-A inhibition. Moclobemide is a weak inhibitor of CYP2D6 in vitro. It is extensively metabolized in the liver by oxidation and is eliminated primarily into the urine as conjugates. Less than 1% of an administered dose of moclobemide is eliminated unmetabolized.

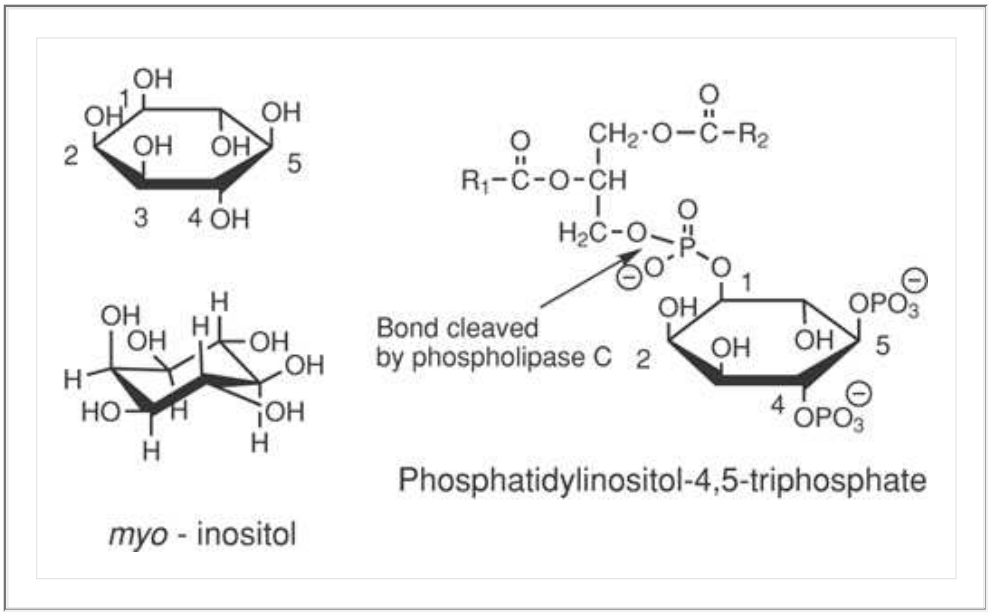
Because moclobemide is partially metabolized by the polymorphic isozymes CYP2C19 and CYP2D6, plasma concentrations of moclobenmide may be affected in patients who are poor metabolizers. In patients who are slow metabolizers, the AUC for moclobemide was 1.5 times greater than the AUC in patients who are

extensive metabolizers and receiving the same dose. This increase is within the normal range of variation (up to twofold) typically seen in patients.

Drug interactions for the RIMAs include interaction with SSRI antidepressants, which can cause the 5-HT syndrome (see the discussion of SSRIs). The effect of stimulant drugs, such as methylphenidate and dextroamphetamine (used to treat ADHD), may be increased. Some over-the-counter cold and hay fever decongestants (i.e., sympathomimetic amines) can have increased stimulant effects. Selegiline, a selective MAO-B used for Parkinson's disease, should not be used concurrently with the RIMAs. Unlike the irreversible MAOIs, no significant interactions with foods occur, because the selective inhibition of MAO-A does not stop the metabolism of tyramine. The RIMAs must not be taken concurrently with a nonreversible MAOI.

Mood Stabilizers

Manic-depression, or bipolar affective disorder, is a prevalent mental disorder with a global impact. Mood stabilizers have acute and long-term effects and, at a minimum, are prophylactic for manic or depressive disorders. Lithium is the classic mood stabilizer and exhibits significant effects on mania and depression but may be augmented or substituted by some antiepileptic drugs. The biochemical basis for mood stabilizer therapies or the molecular origins of bipolar disorder is unknown. Lithium ion directly inhibits two signal transduction pathways. It suppresses inositol trisphosphate signaling through depletion of intracellular inositol and inhibits glycogen synthase kinase-3 (GSK-3), a multifunctional protein kinase. A number of GSK-3 substrates are involved in neuronal function and organization and, therefore, present plausible targets for manic-depression. Despite these intriguing observations, it remains unclear how changes in inositol trisphosphate signaling underlie the origins of bipolar disorder (80,81).



Inositol (myo-inositol), a naturally occurring isomer of glucose, is a key intermediate of the phosphatidylinositol signaling pathway, a second messenger system used by noradrenergic, serotonergic, and cholinergic receptors. The suggestion that lithium might treat mania via its reduction of inositol levels led to experiments showing that oral doses of inositol reverse the behavioral effects of lithium in animals and the side effects of lithium in humans. Cerebrospinal fluid levels of inositol are low in depressed individuals (82). The effectiveness of inositol in treating manic-depression was shown in a double-blind trial that large doses of inositol (12 g) increased inositol concentrations in human cerebrospinal fluid by 70% and led to improvement in depressed patients compared to placebo (82). Valproic acid and carbamazepine are antiepileptic drugs with mood-stabilizing properties that also inhibit inositol trisphosphate signaling through the inositol-depletion mechanism.

Inositol significantly reduced the number of panic attacks per week in patients as compared to fluvoxamine and without the nausea and tiredness that are common with fluvoxamine. Inositol has few known side effects, thus making it attractive for administration to patients with manic-depression who are ambivalent about taking other antidepressant drugs (82).

Lithium

Lithium (from the Greek word *lithos*, meaning “stone”) is a monovalent cation that competes with sodium, potassium, calcium, and magnesium ions at intracellular binding sites; at sugar phosphatases; at protein surfaces; at carrier binding sites; and at transport sites. Lithium readily passes through sodium channels, and high concentrations can block potassium channels. In the 1870s, claims for the healthful effects of lithium fueled the markets for products such as Lithia Beer and Lithia Springs Mineral Water (in 1887, analysis of Lithia Springs Mineral Water proved the water to be rich not only in lithium but also in potassium, calcium, magnesium, fluoride, and other essential trace minerals). In 1890, the Lithia Springs Sanitorium (Georgia) was established using natural lithium water to treat alcoholism, opium addiction, and compulsive behavior, even though manic depression had not been identified as a form of mental illness until the early 1900s.

Lithium's mood-stabilizing properties were revitalized in the 1940s when an Australian physician, John Cade, hypothesized that a toxin in the blood was responsible for bipolar illness. Believing that uric acid would protect individuals from this toxin, he began studying the effects of a mixture of uric acid and lithium in rats. Lithium carbonate was used to dissolve the uric acid. He observed a calming effect of this combination on the rats and subsequently determined that the lithium, rather than the uric acid, was responsible for this calming effect. He then speculated that lithium might be useful in humans as a mood attenuator, subsequently administered lithium to a sample of patients with bipolar disorder, and discovered that lithium not only decreased the symptoms of mania but also prevented the recurrence of both depression and mania when taken regularly by these patients. After a decade of clinical trials, the U.S. FDA approved lithium for treatment of mania in 1970.

Lithium carbonate (Eskalith) is the most commonly used salt of lithium to treat manic depression. Lithium carbonate dosage forms are labeled in mg and mEq/dosage unit, and lithium citrate (Lithobid) is labeled as mg equivalent to lithium carbonate and mEq/dosage unit. Lithium is effectively used to control and prevent manic episodes in 70 to 80% of those with bipolar disorder as well as to treat other forms of depression. Those who respond to lithium for depression often are those who have not responded to TCAs after several weeks of treatment. When giving lithium in addition to their antidepressants, some of these people have shown significant improvement.

Mechanism of action

Lithium therapy for disorders is believed to be effective because of its ability to reduce signal transduction through the phosphatidylinositol signaling pathway (Fig. 21.26) (83,84). In this pathway, the second messengers diacylglycerol and inositol 1,4,5-trisphosphate are produced from the enzymatic hydrolysis of phosphatidylinositol-4,5-bisphosphate (a membrane phospholipid) by the receptor-mediated activation of the membrane-bound, phosphatidylinositol-specific phospholipase C. The second messenger activity for inositol 1,4,5-trisphosphate is terminated by its hydrolysis in three steps by inositol monophosphatases to inactive inositol, thus completing the signaling pathway. To recharge the signaling pathway, inositol must be recycled back to phosphatidylinositol bisphosphate by inositol phospholipid–synthesizing enzymes in the CNS, because inositol is unable to cross the blood-brain barrier into the CNS in sufficient concentrations to maintain the signaling pathway. By uncompetitive inhibition of inositol phosphatases in the signaling pathway, the therapeutic plasma concentrations of lithium ion deplete the pool of inositol available for the resynthesis of phosphatidylinositol-4,5- bisphosphate, ultimately decreasing its cellular levels and, thereby,

reducing the enzymatic formation of the second messengers. Thus, lithium ion restores the balance among aberrant signaling pathways in critical regions of the brain.

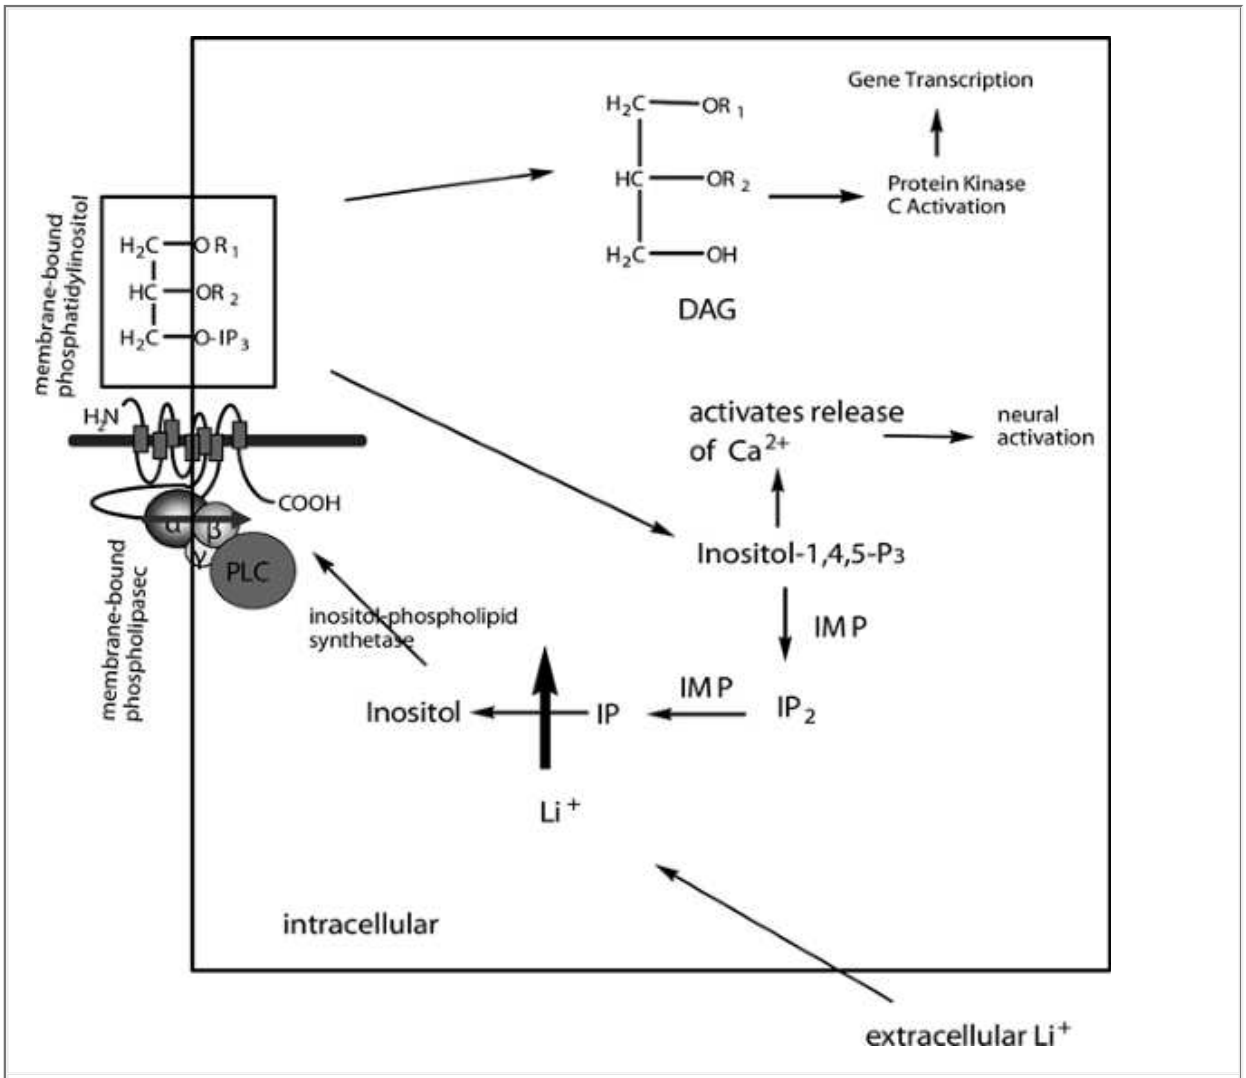


Fig. 21.26. Intracellular phosphatidylinositol signaling pathway and site of action for lithium. Phospholipase (PLC) is a membrane-bound enzyme. IP, inositol monophosphate; DAG, diacylglyceride; IMP, inositol monophosphatase.

The effects of lithium ion on disorders are surprisingly specific because of the inability of inositol to cross the blood-brain barrier and replenish depleted inositol levels. Lithium ion exerts its greatest influence on this signaling pathway when the lithium ion concentration is at saturation conditions.

The clinical efficacy of lithium in the prophylaxis of recurrent affective episodes in bipolar disorder is characterized by a lag in onset and remains for weeks to months after discontinuation. Thus, the long-term therapeutic effect of lithium likely requires reprogramming of gene expression. Protein kinase C and GSK-3 signal transduction pathways are perturbed by chronic lithium at therapeutically relevant concentrations and have been implicated in modulating synaptic function in nerve terminals (84).

Pharmacokinetics

The absorption of lithium is rapid and complete within 6 to 8 hours. The absorption rate of slow-release capsules is slower and the total amount of lithium absorbed lower than with other dosage forms. Lithium is not protein bound. The elimination half-life for elderly patients (39 hours) is longer than that for adult patients (24 hours), which in turn is longer than that for adolescent patients (18 hours). The time to peak serum concentration for lithium carbonate is dependent on the dosage form (tablets, 1–3 hours; extended tab, 4 hours; slow release, 3 hours). Steady-state serum concentrations are reached in 4 days, with the desirable dose targeted to give a maintenance lithium ion plasma concentration range of 0.6 to 1.2 mEq/L, with a level

of 0.5 mEq/L for elderly patients. The risk of bipolar recurrence was approximately threefold greater for patients with lithium dosages that gave plasma concentrations of 0.4 to 0.6 mEq/L. Adverse reactions are frequent at therapeutic doses, and adherence is a big problem. Toxic reactions are rare at serum lithium ion levels of less than 1.5 mEq/L. Mild to moderate toxic reactions may occur at levels from 1.5 to 2.5 mEq/L, and severe reactions may be seen at levels from 2.0 to 2.5 mEq/L, depending on individual response. The onset of therapeutic action for clinical improvement is 1 to 3 weeks. Renal elimination of lithium ion is 95%, with 80% actively reabsorbed in the proximal tubule. The rate of lithium ion urinary excretion decreases with age. Fecal elimination is less than 1%.

Drug interactions

Lithium pharmacokinetics may be influenced by a number of factors, including age. Elderly patients require lower doses of lithium to achieve serum concentrations similar to those observed in younger adults as a result of reduced volume of distribution and

reduced renal clearance. Lithium ion clearance decreases as the glomerular filtration rate decreases with increasing age. Reduced lithium ion clearance is expected in patients with hypertension, congestive heart failure, or renal dysfunction. Larger lithium ion maintenance doses are required in obese compared with nonobese patients. The most clinically significant pharmacokinetic drug interactions associated with lithium involve drugs that are commonly used in the elderly and that can increase serum Li^+ concentrations. People who are taking lithium should consult their physician before taking the following drugs: acetazolamide, antihypertensives, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, calcium channel blockers, carbamazepine, thiazide diuretics, hydroxyzine, muscle relaxants, neuroleptics, table salt, baking powder, tetracycline, TCAs, MAOIs, and caffeine. The tolerability of lithium is lower in elderly patients. Lithium toxicity can occur in the elderly at concentrations considered to be “therapeutic” in the general adult populations. Serum concentrations of lithium ion need to be markedly reduced in the elderly population—and particularly so in the very old and frail.

Adverse effects

Common side effects of lithium include nausea, loss of appetite, and mild diarrhea, which usually taper off within first few weeks. Dizziness and hand tremors also have been reported. Increased production of urine and excessive thirst are two common side effects that usually are not serious problems, but patients with kidney disease should not be given lithium. Taking the day's dosage of lithium at bedtime also seems to help with the problem of increased urination. Other side effects of lithium include weight gain, hypothyroidism, increased white blood cell count, skin rashes, and birth defects.

While on lithium, a patient's blood level must be closely monitored. If the blood level of lithium ion is too low, the patient's symptoms will not be relieved. If the blood level of lithium ion is too high, there is a danger of a toxic reaction.

Therapeutic uses

For many years, lithium has been the treatment of choice for bipolar disorder, because it can be effective in smoothing out the mood swings common to this condition. Its use must be carefully monitored, however, because the range between an effective and a toxic dose is small.

N-Methyl-D-Aspartate Antagonists

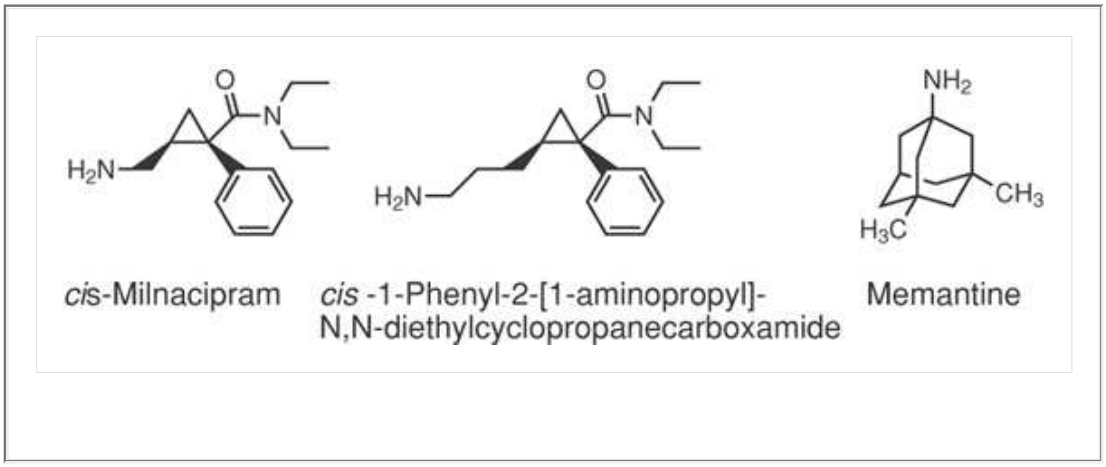
In spite of intensive research, the problem of treating antidepressant-resistant patients has not yet been solved. The past decade has seen a steady accumulation of evidence supporting a role for the excitatory amino acid neurotransmitter, glutamate, and its mGluR1 and mGluR5 receptors in depression and antidepressant activity (85,86). Glutamate plays an essential role as a neurotransmitter in many physiological functions, and an increase in glutamate release can result in activation of NMDA receptors, an underlying cause for depression and anxiety. The NMDA receptor is a ligand-gated ion channel that mediates excitatory synaptic transmission in the CNS. This channel opening and receptor activation are triggered by synaptically released glutamate and require the binding of glycine, which is a coagonist. Studies with NMDA receptor antagonists of mGluR1 and mGluR5 receptors, as well as positive modulators of α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, have antidepressant-like activity in a variety of preclinical models. Furthermore, evidence implicates disturbances in glutamate metabolism, NMDA, and mGluR1/5

receptors in depression and suicidality.

Moreover, antidepressant-like activity can be produced not only by drugs modulating the glutamatergic synapse but also by agents that affect subcellular signaling systems linked to excitatory amino acid neurotransmitter receptors (e.g., nitric oxide synthase). These studies suggest that an intimate relationship exists between regulation of monoaminergic and excitatory amino acid neurotransmission and antidepressant effects.

The concept of NMDA antagonists as antidepressants has generated considerable interest in the NMDA receptor as a target for new antidepressant therapies (85,86,87). Recent data indicate that *cis*-1-phenyl-2-[1-aminopropyl]-N,N-diethylcarboxamide, a NMDA receptor antagonist and homologue of milnacipran, produces sustained relief from depressive symptoms. Several studies have shown that chronic antidepressant treatment can modulate NMDA receptor expression and function. Preclinical studies with this and other NMDA receptor antagonists have demonstrated their potential antidepressant properties.

The combination of traditional antidepressant drugs (e.g., imipramine) and uncompetitive NMDA receptor antagonists (e.g., memantine) may produce enhanced antidepressive effects as a result of synergism. This observation may be of particular importance for the treatment of antidepressant-resistant patients. Most interesting was the observation that fluoxetine, which was inactive in the forced swimming test in rats when given alone, showed a positive effect when combined with memantine (2.5 and 5 mg/kg).



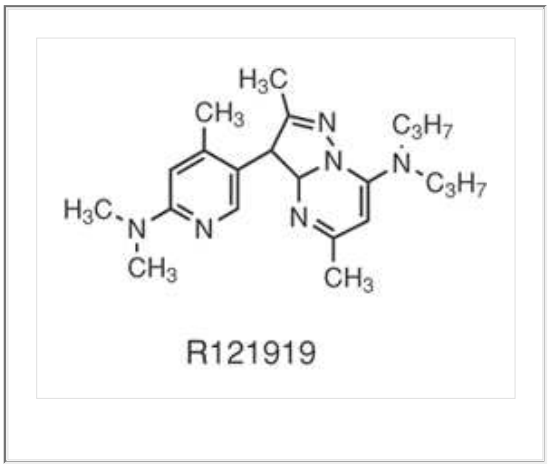
Neuropeptides

The pharmacological treatment of depressive illness has been dominated by drugs that directly target

monoamine neurotransmitter systems. Monoamine transport inhibitors are first-line treatments for depression. Current antidepressants exhibit a delayed onset of therapeutic action, and a significant number of patients are nonresponsive to this treatment regimen (54). Moreover, many patients discontinue treatment because of adverse side effects, including nausea, sexual dysfunction, anorexia, mouth dryness, and cardiotoxicity. A complementary strategy is to identify other treatments that target other neurotransmitter and neuromodulators in the brain. Neuropeptides have been shown to be attractive targets for depression (88,89). Neuropeptides are short-chain amino acid neurotransmitters and neuromodulators often localized in brain regions that mediate emotional behaviors and the response to stress (88,89). The neuropeptides that have been identified in stress include the tachykinins (substance P and neurokinin A), corticotropin-releasing factor, vasopressin, galanin, brain-derived neurotrophic factor (BDNF) and melanocyte- inhibiting factor. Thus, drugs that are antagonists at these neuropeptide receptors might exhibit a lower incidence of adverse effects, because such antagonists would not be expected to bind to the NE and 5-HT neurotransmitter receptors. The expression of BDNF in individuals with MDD is decreased suggesting that BDNF plays a role in the pathophysiology of depression as a regulator of neuronal signaling pathways. Antidepressant drugs increase the BDNF brain levels, and therefore, enhance the mechanism of action of the antidepressant drugs. Drugs that boost the levels of BDNF may lead to the development of novel therapeutic agents for the treatment of MDD and bipolar disorders.

Corticotropin-Releasing Factor

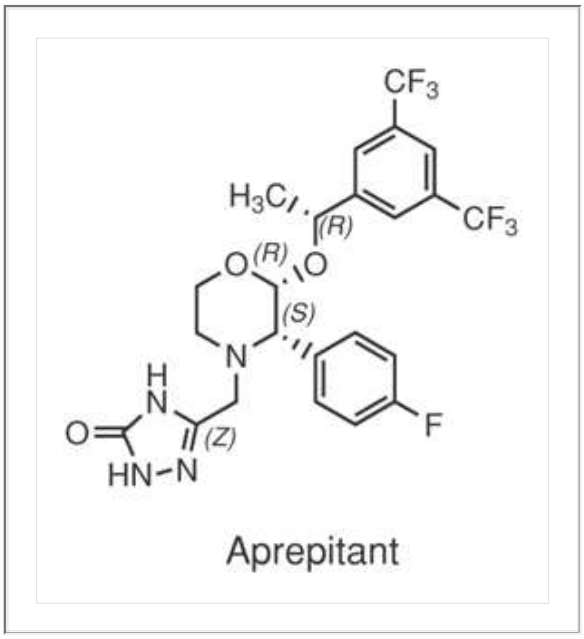
Increasing evidence suggests that the neuroendocrine changes seen in patients suffering from affective disorders may be causally related to the course of depression. The most robustly confirmed neuroendocrine finding among patients with affective disorders is hyperactivity of the hypothalamic-pituitary-adrenocortical (HPA) system, resulting from hyperactive hypothalamic corticotropin-releasing factor (CRF) neurons. Abnormal HPA activity has been implicated in conditions related to stress, including HPA overactivation in depression, eating and substance abuse disorders, irritable bowel syndrome, inflammation, and cardiovascular dysfunction. Preclinical and clinical evidence suggests that both genetic and environmental factors contribute to the development of these HPA system abnormalities. Corticotropin-releasing factor is a 41-amino-acid neuropeptide that initiates and regulates the HPA-axis response to stress, and it has been intensively studied in the pathophysiology and treatment of depression (90). In humans, the CRF system consists of CRF and two G protein–coupled CRF receptors (CRF_1 and CRF_2). The CRF_1 receptors play an important role in mediating the HPA response to stress. Additionally, CRF is capable of reproducing the hormonal changes that are characteristically seen in depressed patients. Postmortem and endocrine studies suggest that both hypothalamic and extrahypothalamic concentrations of CRF are elevated in proportion to antidepressant treatment. High CRF concentrations tend to reestablish the HPA imbalance. The careful manipulation of CRF concentrations with high-affinity CRF_1 antagonists, such as R121919, may hold therapeutic promise for sufferers of depression.



R121919

Substance P

Substance P is an 11-amino-acid neuropeptide belonging to the tachykinin family, mediating its biological actions through activation of G protein–coupled tachykinin (neurokinin-1 [NK_1]) receptors. Its proposed physiological roles include inflammation, pain, GI and respiratory function, stress responses, and emesis. Substance P is uniquely associated with the monoamine neurotransmitters, 5-HT and NE. The 5-HT neurons coexpress substance P, and the firing of NE neurons is modulated by substance P. Preclinical studies have supported a role of the substance P–NK_1 receptor system in stress-related disorders, which has guided the antidepressant development of centrally active NK_1 receptor antagonists, such as aprepitant (91). The NK_1 antagonists are generally well tolerated and exhibit less nausea and sexual dysfunction than some currently used antidepressants.



Vasopressin

The nonapeptide vasopressin is well known for its role on fluid metabolism (see Chapter 7), but it also is a key regulator of the HPA axis. Stress stimulates the release of vasopressin in the pituitary gland, where it strongly potentiates the effects of CRF on adrenocorticotropic

hormone release. These findings suggest that HPA axis dysregulation in depression might be associated with the development of centrally acting vasopressin receptor antagonists for the treatment of depression.

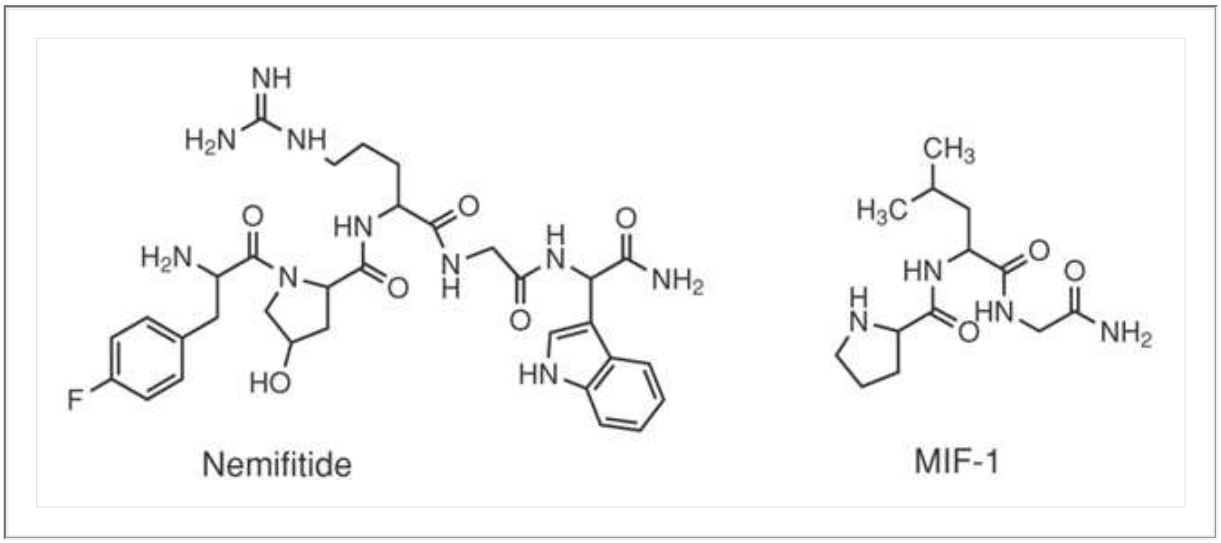
Galanin

Since its discovery in 1983, the neuropeptide galanin has been found to be involved in a wide range of functions, including pain sensation, sexual activity, feeding, and learning and memory (92). Galanin is widely distributed in the central and peripheral nervous systems and in the endocrine system, and it acts as a inhibitory neuromodulator of NE and 5-HT in the brain. The 29- to 30-amino-acid sequence of galanin is conserved (almost 90% among species), indicating the importance of the molecule among species. Galanin is colocalized with acetylcholine, 5-HT, and NE in neurons or in brain regions implicated in cognitive and affective behavior, suggesting a possible role in the regulation of 5-HT and NA neurotransmission in depressive states and during the course of antidepressant therapy. Three galanin receptor subtypes have been cloned and studied, but little is known about their specific contributions to behavioral processes. In the CNS, galanin inhibits acetylcholine release, suggesting a possible role for galanin in cholinergic dysfunction; inhibits neurotransmitter release and neuronal firing rate; and inhibits signal transduction by inhibition of phosphatidyl inositol hydrolysis, leading to symptoms of depression. Thus, blocking the inhibitory effects of galanin on monoamine neurotransmitters with galanin receptor antagonists would be predicted to mimic or augment the action of the other monoamine classes of antidepressants.

Melanocyte-Inhibiting Factor

Nemifitide is a peptide analogue of melanocyte-stimulating hormone release–inhibiting factor currently in clinical development for the potential treatment of moderate to severely depressed patients (93). It is rapidly absorbed, with a peak plasma concentration of 10 min and an elimination half-life of 15 to 30 minutes in most subjects. The pharmacokinetic results indicate that the dose is proportional in the dose range investigated. No evidence indicated systemic accumulation of drug following five daily doses. No serious adverse events or clinically significant systemic adverse events occurred at any of the doses investigated in the more than 100 subjects dosed in these studies. Drug-related adverse events were limited to local and transient skin reactions (pain and/or erythema) at the injection site, especially at the high doses administered. Melanocyte-stimulating hormone release–inhibiting factor-1 (MIF-1) has been shown to have antidepressant activity when administered subcutaneously (10 mg for 5 consecutive days) in a double-blind study to 20 depressed patients

who all met the DSM-IIIR criteria for major depression. After the 5-day treatment with MIF-1, these patients all exhibited substantial improvement in their symptoms of depression (94). Moreover, the potential clinical efficacy of combining MIF-1 (0.01 mg/kg IP) with small doses of the TCAs amitriptyline (5 mg/kg IP) or desipramine (1.25 mg/kg IP) may be of benefit in the therapy of depressed patients.



Herbal Therapy

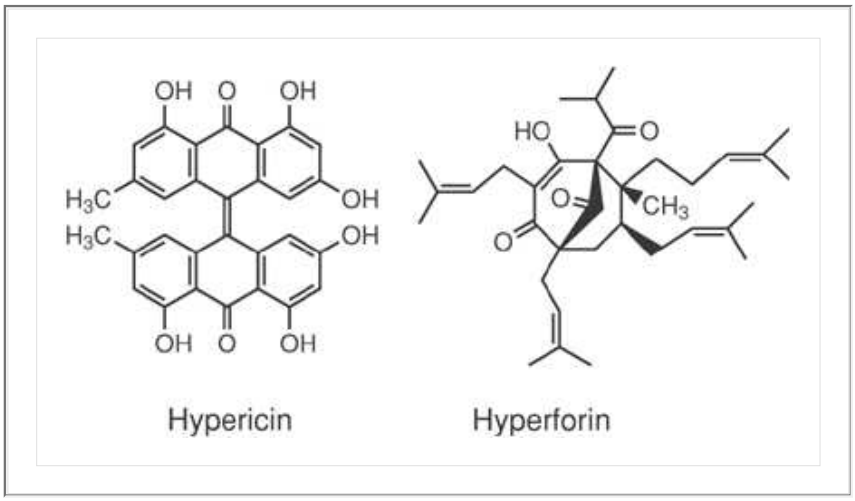
In the past few years, much interest has been generated regarding the use of herbs in the treatment of both depression and anxiety (95). Recent studies, however, have revealed potentially fatal interactions between herbal remedies and traditional drugs.

St. John's wort (*Hypericum perforatum*), an herb used extensively in the treatment of mild to moderate depression in Europe, has aroused interest in the United States. A bushy, low-growing plant covered with yellow flowers in summer, St. John's wort has been used for centuries in many folk and herbal remedies. In Germany, hypericum is used in the treatment of depression more than any other antidepressant. The scientific studies that have been conducted regarding its use have been short-term, however, and have used several different doses. St. John's Wort works like the SSRIs, in that it not only increases the availability of 5-HT in synaptic clefts by blocking its reuptake but also increases the availability of NE, which increases energy and alertness, and dopamine, which increases the feeling of well-being.

Ingestion of St John's wort increases the expression (i.e., upregulation) of intestinal P-glycoprotein and of CYP3A4 in the liver and intestine, which impairs the absorption and stimulates the metabolism of other CYP3A4 substrates (e.g., the protease inhibitors indinavir and nevirapine, oral contraceptives, and TCAs [e.g., amitriptyline]), resulting in their subtherapeutic plasma levels. Hyperforin, the principal component in St. John's wort (2–4% in the fresh herb) contributes to the induction of CYP3A4. Furthermore, it not only inhibits the neuronal reuptake of 5-HT, NE, and dopamine, like many other antidepressants, but also inhibits GABA and L-glutamate uptake. This broad-spectrum effect is obtained by an elevation of the intracellular sodium ion concentration, probably resulting from activation of sodium conductive pathways not yet

finally identified but most likely to be ionic channels. This makes hyperforin the first member of a new class of compounds with a preclinical antidepressant profile because of a completely novel mechanism of action (95,96). Hypericin, the other component in St. John's wort, also may exhibit inhibitor action on key neuroreceptors and may be responsible for the phototoxicity/photosensitivity of St. John's wort.

The National Institutes of Health conducted a double-blind, 3-year study in patients with major depression of moderate severity using St. John's wort and sertraline. This study did not support the use of St. John's wort in the treatment of major depression, but a possible role for St. John's wort in the treatment of milder forms of depression was suggested. Health care providers should alert their patients about potential drug interactions with St. John's Wort. Some other frequently used herbal supplements that have not been evaluated in large-scale clinical trials are ephedra, gingko biloba, echinacea, and ginseng. Any herbal supplement should be taken only after consultation with the physician or other health care provider.



Electroconvulsive Therapy

Electroconvulsive therapy (ECT) has been in use since the late 1930s to treat a variety of severe mental illnesses, most notably major depression. Use of ECT is beneficial particularly for individuals whose depression is severe or life threatening or who cannot take antidepressant medication. Often, ECT is effective in cases where antidepressant drugs do not provide sufficient relief of symptoms.

Electroconvulsive therapy remains the “gold standard” for the treatment of major depression and a variety of other psychiatric and neurologic disorders (97). Because of the effectiveness and resurgence of ECT, more patients are considered to be good candidates for this treatment option. Overall, these patients are medication refractory and elderly and, thus, are more sensitive to polypharmacy. Additionally, these patients tend to have more coexisting medical problems.

In recent years, ECT has been much improved. A muscle relaxant is given before treatment, which is done under brief anesthesia. Electrodes are placed at precise locations on the head to deliver electrical impulses. The stimulation causes a brief (~30 seconds) seizure within the brain. The person receiving ECT does not consciously experience the electrical stimulus. For full therapeutic benefit, at least several sessions of ECT, typically given at the rate of three per week, are required. Electroconvulsive therapy appears to increase the sensitivity of postsynaptic 5-HT receptors and upregulation of 5-HT_{1A} postsynaptic receptors.

Side effects may result from the anesthesia, the ECT treatment, or both. Common side effects include temporary short-term memory loss, nausea, muscle aches, and headache. Some people may have longer-lasting problems with memory after ECT. Sometimes, a person's blood pressure or heart rhythm changes. If these changes occur, they are carefully watched during the ECT treatments and are immediately treated.

Case Study

Victoria F. Roche

S. William Zito

NL is an 84-year-old female who had to move to a retirement community after losing her husband to a prolonged battle with cancer. She desperately misses her home and the life they shared there, and the move was made all the more devastating because of the need to find good homes for their beloved cats. NL has experienced symptoms of depression regularly during her adult life but never sought medical assistance until her husband fell ill. She has been taking escitalopram (Lexapro, 10 mg q.d.) for 3 years, although it has not totally controlled the despair and anxiety that she experiences, especially at night. After being off cigarettes for 20 years, she has started smoking again, which is adding to her distress. She is embarrassed by her need for antidepressant medication and finds it hard to talk with her physician about her feelings. Recently, she has become restless and agitated, both at bedtime and during the day, and is considering self-medicating with St. John's wort, which has been highly recommended by a member of the bridge club she has joined. She is in your pharmacy now, carrying a bottle of Kaopectate and trying to select a St. John's wort product.

NL has osteoporosis that is being managed with sodium alendronate (Fosamax), and fortunately, the

recent falls she experienced after losing her balance on standing did not result in any broken bones. In addition to thyroid hormone replacement therapy, her other current medications include metoprolol for high blood pressure and clonazepam for restless leg syndrome. Turn your attention to the antidepressant choices shown below, and prepare to make a recommendation to NL and her physician.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient specific factors and desired therapeutic outcomes and make a therapeutic decision.
5. Counsel your patient.

Chapter 22

Psychotherapeutic Drugs: Antipsychotic and Anxiolytic Agents

Raymond G. Booth

Drugs covered in this chapter:

- Phenothiazine class
- Thioxanthines class
- Benzamide class
- Benzazepines
  - Clozapine
  - Loxapine
  - Olanzapine
  - Quetiapine
- Benzisoxazole and benzisothiazoles
  - Risperidone
  - Ziprasidone
- Miscellaneous antipsychotic agents
  - Aripiprazole
  - Molindone
  - Sertindole
- Benzodiazepines
  - Chlordiazepoxide
  - Diazepam
  - Flurazepam
  - Oxazepam
- Miscellaneous anxiolytic agents
  - Eszopiclone
  - Zalpidem
  - Zolpidem

Overview of Mental Illnesses

Mental illnesses that can be treated with psychotropic drugs are broadly categorized as psychoses, neuroses, and mood (depression, bipolar) disorders. Different classes of psychotropic agents differ in their ability to modify symptoms of these mental illnesses; thus, an appropriate diagnosis is critical to selecting an efficacious psychotropic drug. This chapter is focused on the medicinal chemistry of drugs that are used to treat psychosis and anxiety disorders. The definitive diagnostic criteria for psychiatric disorders in the United States are well described in the *Diagnostic and Statistical Manual of Mental Disorders of the American Psychiatric Association* (DSM-IV-TR) (1). The psychoses (e.g., schizophrenia) are among the most severe mental illnesses and commonly include symptoms of delusions and sensory hallucinations. In anxiety disorders (neuroses), the ability to comprehend reality is retained, but mood changes (anxiety, panic, dysphoria) and thought (obsessions, irrational fears) and behavioral (rituals, compulsions, avoidance) dysfunction can be disabling. Mood and panic disorders usually include dysfunction of the autonomic nervous system (e.g., altered patterns of sleep and appetite) in addition to psychic abnormalities. Depression can lead to self-harm and suicide. In general, antipsychotic agents, which can have severe neurological side effects, should be used to treat only the most severe mental illnesses (i.e., psychoses such as schizophrenia).

Schizophrenia

Definition

An historical definition of schizophrenia may begin approximately 100 years ago, with the German psychiatrist Emil Kraepelin's description of a type of dementia that was characterized as a severe, chronic mental disorder without known external causation wherein functional deterioration progresses with the symptoms of hallucinations, delusions, thought disorder, incoherence, blunted affect, negativism, stereotyped behavior, and lack of insight (2). The deterioration progresses to catatonia and hebephrenia (illogical, incoherent, and senseless thought processes and actions, delusions, and hallucinations). Meanwhile, the Swiss psychiatrist Eugen Bleuler coined the term “schizophrenia” to take into account the perceived “schism” or splitting in mental functioning (3).

A modern definition of schizophrenia comes from DMS-IV (1). The diagnostic criteria for schizophrenia require two or more of the following characteristic symptoms to be present for a significant proportion of time during a 1-month period: delusions, hallucinations, disorganized speech, or grossly disorganized or catatonic behavior. There is, however, flexibility in the diagnostic criteria that leaves room for professional psychiatric judgment. For example, it is enough if hallucinations consist of a voice maintaining a running commentary on the patient's behavior or there are two or more voices that converse with each other. Also, for a significant proportion of time, one or more areas of social functioning, such as work, interpersonal relationships, or self-care, are markedly below the level achieved before the onset of symptoms. Continuous symptoms must persist for 6 months. Finally, before a diagnosis of schizophrenia is made, affective disorders as well as, drug/alcohol abuse or other medical conditions must be ruled out.

Etiology of Schizophrenia

A neurobiological basis for schizophrenia and related psychotic syndromes remains elusive. Compelling evidence linking genetic factors to the etiology of schizophrenia is not apparent despite enormous progress in

the field of molecular genetics and numerous investigations of hereditary factors associated with psychotic illnesses. Current epidemiological evidence suggests that individual variation in susceptibility to schizophrenia involves alleles of moderate to small effect in multiple genes. Investigations of environmental causative factors have focused on prenatal and perinatal risk factors for brain damage. For example, studies have examined the incidence of schizophrenics who were born under conditions of obstetrical complications, influenza epidemics, food shortages, and Rh factor incompatibility. Neuroanatomical hypotheses include increased ventricular volume; however, neuropathological changes associated with schizophrenic brains are not obvious as in, for example, Parkinson's disease. In contrast, neurochemical abnormalities are well documented. Alterations of brain dopaminergic neurotransmission in psychoses have been studied for more than 30 years, and this field of psychobiological research generally revolves around the “dopamine hypothesis” of schizophrenia.

Clinical Significance

There is probably no greater contribution to morbidity in life than those disorders that affect the mind. The burden of depression, psychosis, anxiety, and other related disorders take a significant toll on individuals and society as a whole. The ability to effectively address these maladies in clinical practice relies on an understanding of neuropharmacology and the chemical characteristics of psychotropic agents used to treat patients. Although certain agents may be effective, they also may convey significant adverse effects. Case in point, 25 years ago we had effective agents to treat psychosis. Their effectiveness came at a high price, however, because in many patients, these agents produced severe extrapyramidal symptoms. As the understanding of neuropharmacology and structure–activity relationship evolved, the introduction of atypical antipsychotics to the treatment armamentarium came about. The ability of these agents to influence serotonergic and dopaminergic activity is thought by many to convey additional effectiveness while limiting extrapyramidal symptoms. Consequently, these agents have revolutionized the treatment of psychosis and related disorders. As a class, the atypical antipsychotics are fairly heterogeneous, and clinicians may choose certain agents based on their activities at various receptors. As you read this chapter, pay particular attention to the receptor affinity of all the psychotropic agents and how it is thought to translate into effectiveness and/or toxicity. This will help you in your practice to make rational treatment decisions based on inherent characteristics of these agents, their performance in clinical trials, and your clinical understanding of the patient.

David Hayes Pharm.D.
Clinical Assistant Professor, Department of Clinical Sciences & Administration, University of Houston College of Pharmacy

The connection between dopaminergic neurotransmission and schizophrenia is an example of a “pharmacocentric” approach to characterizing the etiology and neuropathology of mental illnesses (4,5,6). The dopamine hypothesis of schizophrenia arose from observations that the first relatively safe and effective antipsychotic drugs, the phenothiazines, such as chlorpromazine, used in the early 1950s affected brain dopamine metabolism (7). Simply put, the dopamine hypothesis of schizophrenia suggests that schizophrenia results from increased dopaminergic neurotransmission and that approaches which decrease dopaminergic neurotransmission will alleviate psychotic symptoms (8). Most antipsychotic agents have activity to limit dopaminergic neurotransmission, providing some indirect evidence to support the dopamine hypothesis of schizophrenia. In a seminal study by Seeman et al. (9), the average daily dose of antipsychotic was found to correlate well with affinity for dopamine D_2-type receptors. Moreover, extrapyramidal side effects of antipsychotic drugs certainly correlates with their dopamine D_2 antagonism effect. It should be noted, however, that functional interaction of antipsychotic drugs with the D_2 receptor is complex, involving antagonism, inverse agonism, and partial agonism. For example, recent studies show that essentially all clinically used antipsychotic drugs are D_2 inverse agonists (10), suggesting that biochemical as well as clinical effects may not be explained by simple blockade of agonist (dopamine) access to the D_2 receptor.

The dopamine hypothesis of schizophrenia and pharmacotherapy involving antagonism of dopamine receptors (especially the D_2-type) has dominated research directions, but it should be noted that the entire argument is somewhat circular. Consideration of potential new drugs as antipsychotic agents usually is limited to compounds that have demonstrated behavioral or biochemical evidence of antidopaminergic actions. Of course, this somewhat conservative and exclusive approach is practical considering the lack of proven alternative neuropharmacological explanations of antipsychotic drug activity. Nevertheless, in light of the nearly 50 years of research focusing on brain dopaminergic systems, uncontested evidence linking the etiology of psychotic illnesses to the neurobiology of dopaminergic systems has remained elusive. Alternative explanations, especially those involving adrenergic and serotonergic receptor systems, probably will gain popularity as more

atypical antipsychotic drugs (e.g., clozapine) are introduced and also found to have actions at these receptor systems, perpetuating and expanding the pharmacocentric approach to antipsychotic drug design and development.

Role of Dopamine Receptors in Schizophrenia

Modern molecular biological methods involving recombinant DNA techniques have led to cloning and characterization of five different dopamine receptors: D_1 (446 amino acids), $D_{2\ short}$ (414 amino acids) and $D_{2\ long}$ (443 amino acids), D_3 (400 amino acids), D_4 (387 amino acids), and D_5 (477 amino acids) [for a review, see Hartman and Civelli (11)]. The amino acid sequence, as deduced from their established nucleotide sequence,

shows that dopamine receptors are a member of the G protein–coupled receptor (GPCR) superfamily that is structurally characterized by a 7-transmembrane-spanning region. Currently, no medicinal chemical probes with high selectivity to distinguish between the five subtypes are available; thus, dopamine receptors often are classified as two major types, according to the functional effect on adenylyl cyclase (12): The D_1-types that stimulate adenylyl cyclase are D_1 and D_5; the D_2-types that inhibit adenylyl cyclase are $D_{2\ short}$, $D_{2\ long}$, D_3, and D_4.

Several chemical probes are available that can distinguish between the general D_1-type and D_2-type receptor families (Fig. 22.1). The R-(+)-isomer of the benzazepine derivative, SKF 38393, is used for research as a selective D_1-type partial agonist. Meanwhile, the structurally related benzazepine derivative, R-(+)-SCH 23390, is used as a selective D_1-type receptor antagonist. Although not very selective for D_1-type over D_2-type receptors, the rigid benzophenanthridine derivative (–)-dihydrexidine is a useful research tool, because it is a D_1-type full efficacy agonist (produces stimulation of adenylyl cyclase equivalent to dopamine itself) (13,14). Selective D_2-type full agonists, such as the pyrazole derivative (–)-quinpirole, and D_2-type antagonists, such as (–)-sulpiride, also are available to researchers. Currently, the dopamine D_3 receptor subtype is of particular neuropharmacological interest because of its preferential distribution in certain limbic regions of mammalian brain, notably in the nucleus accumbens of the basal forebrain. It is proposed that highly D_3-selective drugs might be developed as antipsychotic agents with preferential limbic antidopaminergic actions while sparing the extrapyramidal basal ganglia, presumably decreasing the neurological movement disorder side effects associated with antipsychotic drug therapy (vide infra). The tetrahydronaphthalene, (+)-7-hydroxy-N,N-di-n-propyl-2-aminotetralin (7-OH-DPAT), and some of its congeners are particularly promising D_3-selective lead agents. The benzazepine clozapine, which is proposed to have a superior antipsychotic clinical profile with a low incidence of extrapyramidal side effects, shows relatively greater affinity for the D_4 dopamine receptor subtype in addition to its relatively high affinity for serotonin 5-HT_2, adrenergic a_1 and α_2, muscarinic M_1, and histamine H_1 receptors (15).

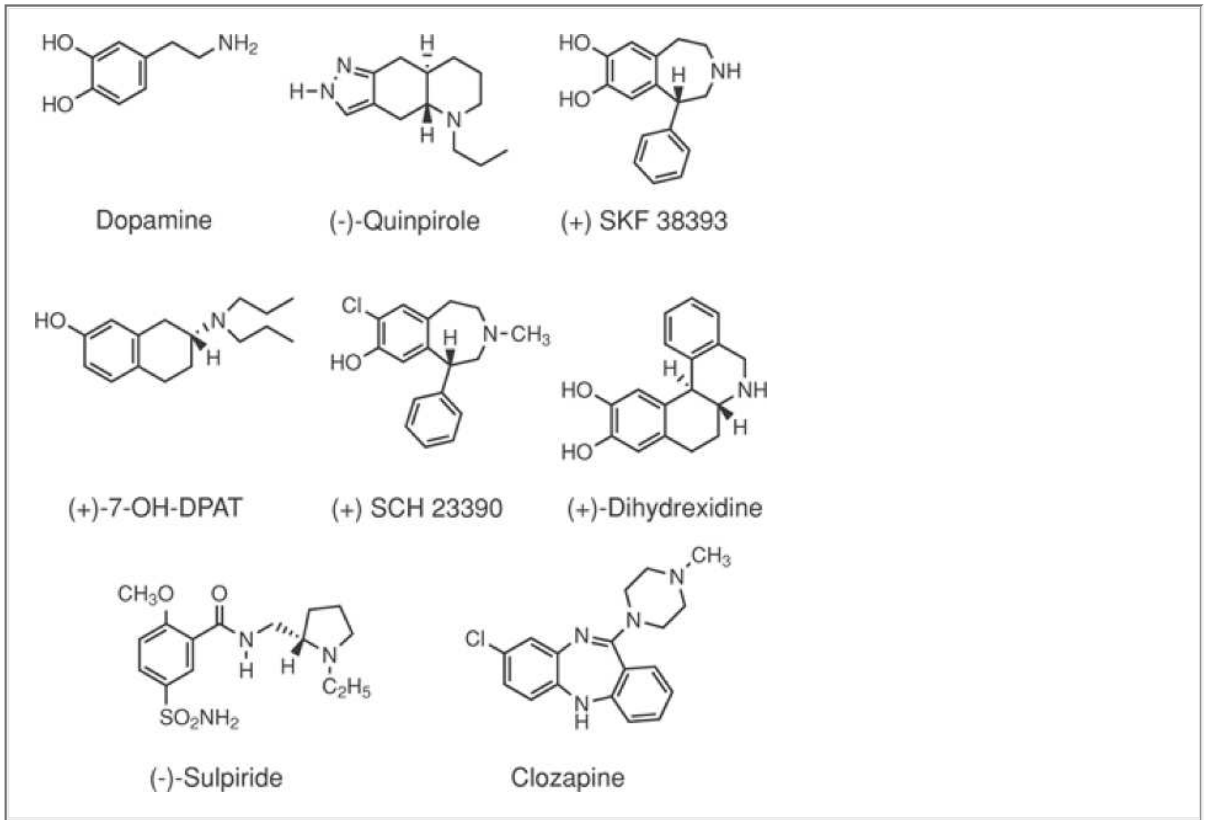

Fig. 22.1. Structures of compounds useful for characterizing dopamine receptors.

Dopamine Receptors and Functional Selectivity

It is now realized that the same GPCR can couple to different G*a* proteins to result in "multifunctional" signaling (16). Molecular mechanisms to account for GPCR multifunctional signaling involve the concept of "GPCR permissiveness," which assumes a high degree of flexibility in the interactions between a ligand, receptor, and G protein (17). These interactions occur mainly between the G proteins and the second and third intracellular loops

and carboxy-terminal tail of the receptor. Some factors that influence this interaction include receptor:G protein ratios and amounts, alternative GPCR splicing, and conformational changes in the G protein and/or receptor. A critical assumption of GPCR multifunctional signaling theory is that a heterogeneity of active receptor conformations exists and that agonist ligands differ in their ability to induce, stabilize, or select among receptor conformations, as described in the "stimulus trafficking" hypothesis (18). Of particular relevance to the medicinal chemist, it follows that on binding, agonist ligand chemical structural parameters are among the most important determinants of GPCR conformation that influences type of G*a* protein and signaling pathway activated. Thus, ligand stereochemistry or other more subtle structural parameters may influence GPCR conformation to affect the type of G protein and intracellular signaling pathway activated, resulting in ligand-specific functional outcomes (19,20). Ligands that show such "functional selectivity" (21,22,23) can be exploited for drug design purposes. A

clinically relevant example is the antipsychotic drug aripiprazole, which interacts with the dopamine D_2 receptor to produce antagonist, inverse agonist, or agonist functional effects, depending on the D_2 receptor cellular milieu (e.g., G-protein complement and concentration) and particular location (e.g., presynaptic vs. postsynaptic and extrapyramidal vs. limbic brain regions).

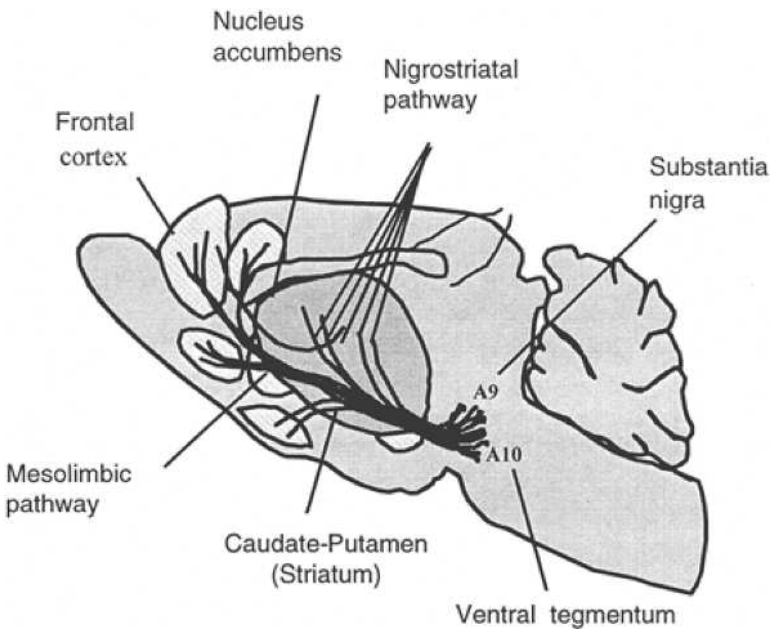

Fig. 22.2. Some dopamine pathways in mammalian brain.

The dopamine D_1-type and D_2-type receptor families are differentially distributed in mammalian forebrain dopaminergic pathways. The extrapyramidal nigrostriatal pathway, which plays a key role in locomotor coordination, consists of neurons with cell bodies in the A9 pars compacta of the substantia nigra in the midbrain. These neurons project to the basal ganglia structures caudate nucleus and putamen (collectively referred to as striatum) in the forebrain (Fig. 22.2). Degeneration of neurons in the nigrostriatal pathway is the hallmark pathological feature of Parkinson's disease, clinically manifested as bradykinesia, muscular rigidity, resting tremor, and impairment of postural balance. Blockade of dopamine receptors on cholinergic neurons in striatum is associated with the sometimes severe extrapyramidal, parkinsonian-like side effects (muscular rigidity, bradykinesia, akathisia) that frequently occur with antipsychotic drug treatment.

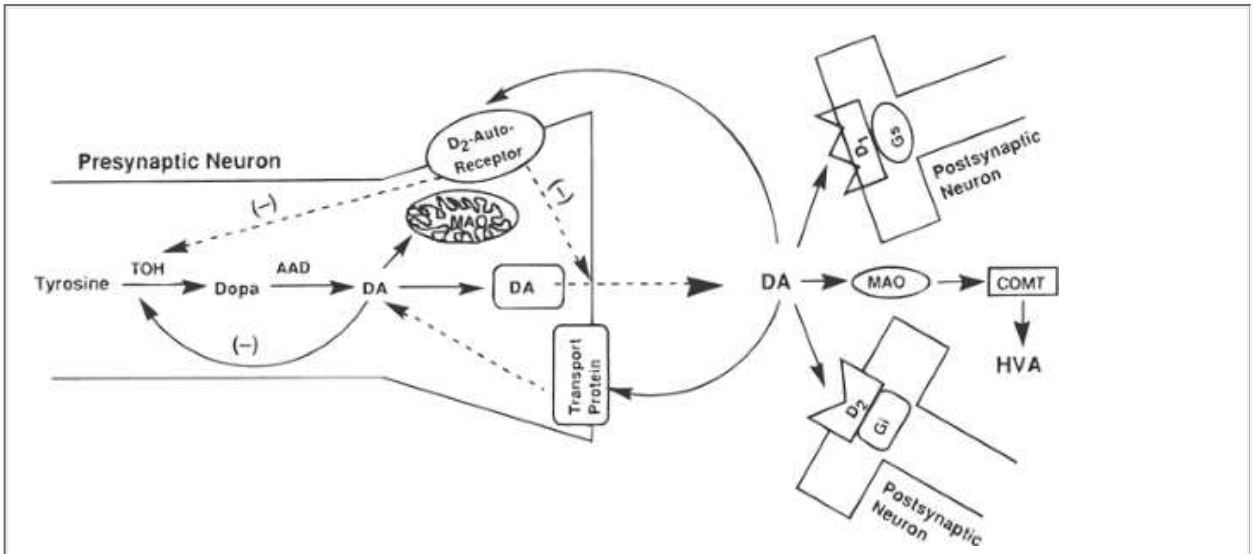

Fig. 22.3. Tyrosine is hydroxylated in a rate-limiting step by tyrosine hydroxylase (TOH) to form dihydroxylphenylalanine (DOPA), which is decarboxylated by L-aromatic amino acid decarboxylase (AAD) to form dopamine (DA). Newly synthesized DA is stored in vesicles, from which release occurs into the synaptic cleft by depolarization of the presynaptc neuron in the presence of Ca^{2+}. The DA released into the synaptic cleft may go on to stimulate postsynaptic D_1- and D_2-type autoreceptors that negatively modulate DA synthesis (via inhibition of TOH) and release. The action of synaptic DA is inactivated largely via reaccumulation into the presynaptic neuron by high-affinity DA neurotransport proteins located on the nerve terminal membrane. Free cytoplasmic DA negatively modulates DA synthesis via end-product (feedback) inhibition of TOH by competition with biopterin cofactor. Cytoplasmic pools of DA may undergo metabolic deamination by monoamine oxidase (MAO), an enzyme bound to the outer membrane of mitochondria, to form dihydroxyphenylacetaldehyde, which oxides to didydroxyphenylacetate (DOPAC). The DA or DOPAC may undergo methylation by catechol-O-methyltransferase (COMT), ultimately forming homovanillic acid (HVA), a metabolite excreted in urine.

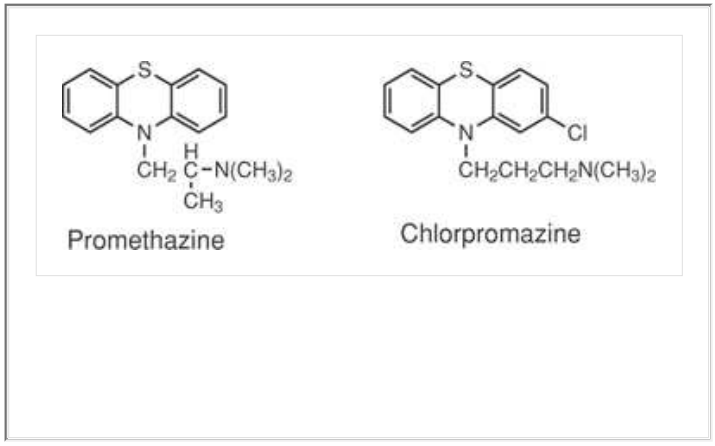
The mesolimbic and mesocortical pathway, involved in integration of emotions, behaviors, and higher thought processes, consists of neurons with cell bodies in the A10 ventral tegmentum. These neurons project to limbic forebrain structures, including the nucleus accumbens and amygdala, and to higher levels of cerebral function, such as the frontal cortex (Fig. 22.2). According to the dopamine hypothesis, increased dopaminergic neurotransmission in limbic pathways contributes to the "positive" symptoms (e.g., hallucinations and excited delusional behavior that can be reduced with typical antipsychotic drugs) but not necessarily to the "negative" symptoms (e.g., catatonia) observed in the clinical manifestation of schizophrenia.

Typical antipsychotic drugs act in both extrapyramidal and limbic brain regions at D_2-type dopamine receptors that can be located postsynaptically (on cell bodies, dendrites, and nerve terminals of other neurons) as well as presynaptically on dopamine neurons. Dopamine receptors located presynaptically on dopamine cell bodies and nerve terminals are called autoreceptors and act to negatively modulate neuronal firing and dopamine synthesis and release (Fig. 22.3) (24). Low concentrations of certain

dopamine agonists can stereospecifically activate dopamine D_2-type autoreceptors to decrease dopamine synthesis (25,26) and release (27), thus reducing dopaminergic neurotransmission. Therefore, consistent with the dopamine hypothesis of schizophrenia, selective dopamine autoreceptor agonists could, theoretically, be pharmacotherapeutic agents in schizophrenia and related mental illnesses. In fact, activation of dopamine autoreceptors may form an integral part of the therapeutic action of the most recently developed antipsychotic drugs, such as the D_2 receptor partial agonist aripiprazole (28).

In addition to postsynaptic dopamine receptors and presynaptic dopamine D_2-type autoreceptors, heteroreceptors,

such as adenosine (A_2) (29), histamine (H_1) (30,31), and serotonin (5-HT_{1A}) (32), located on or near presynaptic dopaminergic nerve terminals in the striatum (extrapyramidal) or nucleus accumbens (limbic) regions of brain can modulate dopamine synthesis (and release) by altering the activity of tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. Similarly, activation of adrenergic (α_2) autoreceptors in the limbic structure hippocampus negatively modulates the release of the neurotransmitter norepinephrine (33). It is proposed that atypical antipsychotic drugs, such as clozapine, may interact with these other neurotransmitter receptor systems (i.e., histamine, serotonin, and adrenergic) instead of (or in addition to) dopamine receptor systems. Preceding the introduction of the first clinically successful phenothiazine-type neuroleptic, chlorpromazine, the first phenothiazine to be used to treat psychiatric patients in the 1940s (unsuccessfully) was promethazine, an "antihistamine" H_1 antagonist.



Treatment of Schizophrenia and Related Psychoses

The most widely used class of drugs in the treatment of psychotic disorders are the so-called neuroleptics. This term suggests that such medicines "take hold" (*lepsis*) of the central nervous system (CNS) to suppress movement as well as behavior. Although the connotation has been stretched to include biochemical and clinical antagonism of dopamine D_2 receptors, debilitating extrapyramidal movement side effects are implicit in the clinical definition of neuroleptic antipsychotic drugs. Indeed, the term "neuroleptic" is so synonymous with neurologic side effects that newer antipsychotic drugs, without substantial risk of extrapyramidal effects, are referred to as atypical neuroleptic drugs. Also implied in the term "atypical" is a mechanism of antipsychotic action other than (or in addition to) postsynaptic D_2 receptor blockade.

In general, neuroleptic therapy benefits patients with schizophrenia or other psychiatric illnesses marked by agitation, aggressive and impulsive behavior, and impaired reasoning. Positive symptoms respond to treatment with typical neuroleptics, whereas negative symptoms are not appreciably affected. In general, neuroleptics provide calming, mood-stabilizing, and antihallucinatory effects, and their beneficial impact on psychiatric medicine is unquestioned in spite of their sometimes severe extrapyramidal side effects. Chemical classes of neuroleptics include the phenothiazines, thioxanthenes, and butyrophenones. The dibenzodiazepines and benzisoxazoles are examples of atypical neuroleptics that have less potential for extrapyramidal side effects and have activity at brain serotonin 5-HT_2, adrenergic α_1/α_2, and/or histamine H_1 receptors, in addition to dopamine receptors.

Mechanism of Action of Antipsychotic Drugs

Given that the pathogenesis of schizophrenia and related psychiatric disorders is unknown, it is perhaps naïve to suggest how drugs act at the molecular level to relieve the symptoms of these disorders. Nevertheless, it generally is agreed that the antipsychotic mechanism of action of neuroleptics involves modulation of dopamine neurotransmission in the mesolimbic–mesocortical pathways. This may be achieved via direct interaction with D_2-type receptors and include the functional spectrum of antagonism, inverse agonism, and/or partial agonism. Antipsychotic drug clinical efficacy, however, is not solely accounted for by D_2-type receptor interactions; other CNS receptor systems (acetylcholine, histamine, norepinephrine, and serotonin) appear to be involved, especially for the atypical drugs described below.

Side Effects of Neuroleptics

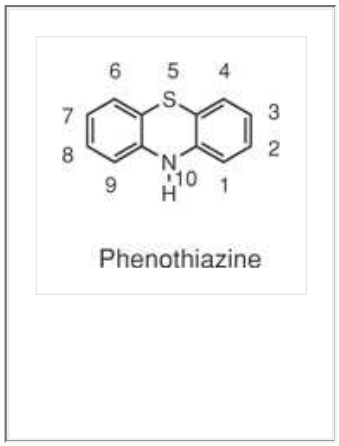
Many of the side effects associated with antipsychotic agents can be attributed to their antagonist activity at a variety of CNS receptors, which include histamine H_1, adrenergic α_1/α_2, cholinergic M_1 receptors, serotonin 5-HT_2, and dopamine D_2 receptors in the brain. For example, antipsychotic drug side effects such as sedation,

hypotension, sexual dysfunction, and other autonomic effects reflect blockade of adrenergic and histamine receptors. Meanwhile, the anticholinergic actions of neuroleptics in cardiac, ophthalmic, gastrointestinal, bladder, and genital tissue result from antagonism of muscarinic acetylcholine receptors. Such anticholinergic actions also are characteristic of atypical antipsychotics such as clozapine, and it has been proposed that anticholinergic activity may be beneficial in controlling negative symptoms in schizophrenics. The parkinsonian-like movement side effects of neuroleptics clearly result from antagonism of dopamine D_2 receptors in the nigrostriatal pathway, and the severity of these extrapyramidal side effects increases with the ratio of their antidopaminergic to anticholinergic potency. Extrapyramidal side effects occur in 30 to 50% of patients receiving standard doses of typical neuroleptics and tend to occur during the first to eighth week of therapy. Extrapyramidal side effects include acute dystonias (e.g., facial grimacing, torticollis,

and oculogyric crisis), akathisia (motor restlessness), and parkinsonian-type symptoms, such as bradykinesia, cogwheel rigidity, tremor, masked face, and shuffling gait. The higher the D_2 potency of the neuroleptic, the worse the side effects, some of which can be reversed using anticholinergic drugs. Tardive dyskinesia occurs in 15 to 25% of patients after prolonged treatment with typical neuroleptics and is characterized by stereotyped, involuntary, repetitive, choreiform movements of the face, eyelids, mouth (grimaces), tongue, extremities, and trunk. There also are metabolic and endocrine side effects of neuroleptics, such as weight gain, hyperprolactinemia, and gynecomastia. Relatively common dermatologic reactions (e.g., urticaria and photosensitivity) also are observed especially with the phenothiazines. Interestingly, anticholinergic and dopaminergic agents worsen tardive dyskinesia, whereas antidopaminergic agents tend to suppress the symptoms. The pathophysiology of tardive dyskinesia is not known, and the disorder essentially is irreversible.

Meanwhile, antagonism of dopamine D_2-type receptors in the chemoreceptor trigger zone in the brainstem is responsible for beneficial antiemetic effects produced by neuroleptics. Several phenothiazines (e.g., promethazine and prochlorperazine) are marketed to exploit this pharmacological effect.

Development of Phenothiazine and Related Neuroleptics



Although the phenothiazine nucleus was synthesized in 1883, and although it was used as an anthelmintic for many years, it has no antipsychotic activity. The basic structural type from which the phenothiazine antipsychotic drugs trace their origins is the antihistamines of the benzodioxane type I (Fig. 22.4). In 1937, Bovet (34) hypothesized that specific substances antagonizing histamine ought to exist, tried various compounds known to act on the autonomic nervous system, and was the first to recognize antihistaminic activity. With the benzodioxanes as a starting point, many molecular modifications were carried out in various laboratories in a search for other types of antihistamines. The benzodioxanes led to ethers of ethanolamine of type II, which after further modifications led to the benzhydryl ethers (type III), which are characterized by the clinically useful antihistamine diphenhydramine, or to ethylenediamine (type IV), which led to antihistamine drugs, such as tripelennamine (type V). Further modification of the ethylenediamine type of antihistamine resulted in the incorporation of one of the nitrogen atoms into a phenothiazine ring system, which produced phenothiazine (type VI), a compound that was found to have antihistaminic properties and, similar to many other antihistaminic drugs, a strong sedative effect. Diethazine (type VI) is more useful in the treatment of Parkinson's disease (because of its potent antimuscarinic action) than in allergies, whereas promethazine (type VII) is clinically used as an antihistaminic. After the ability of promethazine to prolong barbiturate-induced sleep in rodents was discovered, the drug was introduced into clinical anesthesia as a potentiating agent.

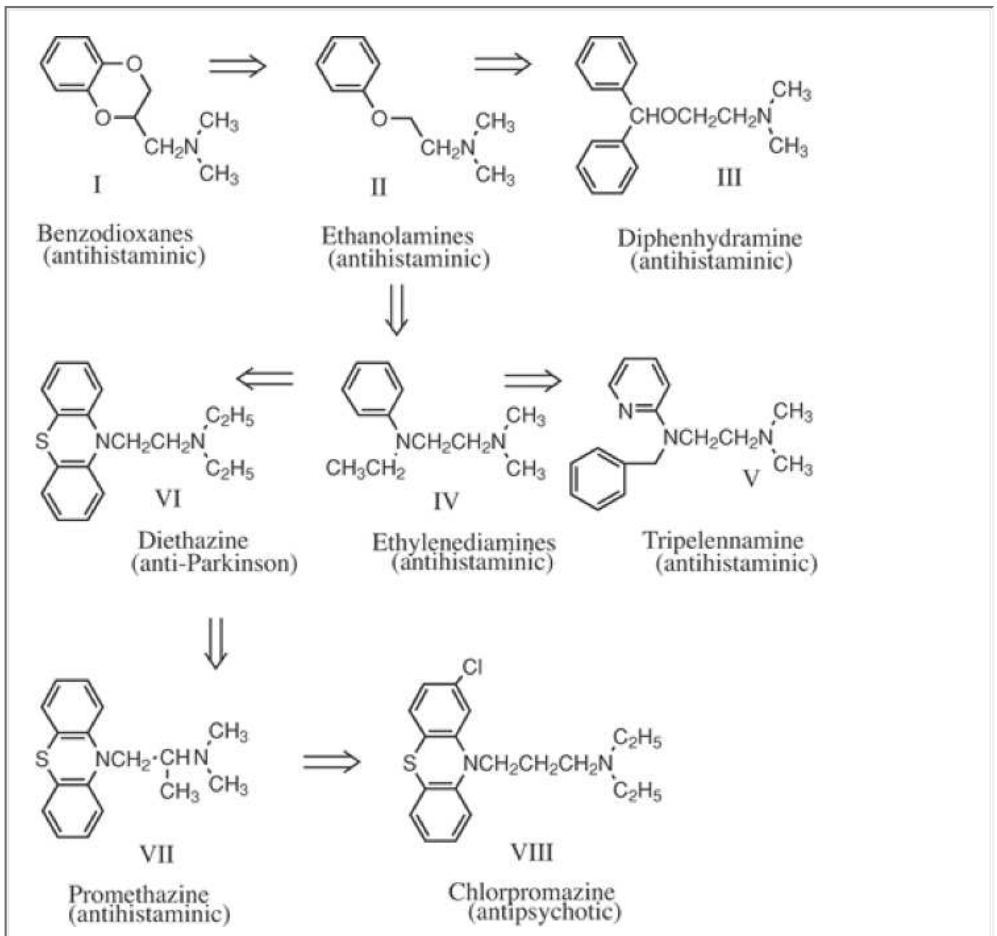


Fig. 22.4. Development of phenothiazine-type antipsychotic drugs.

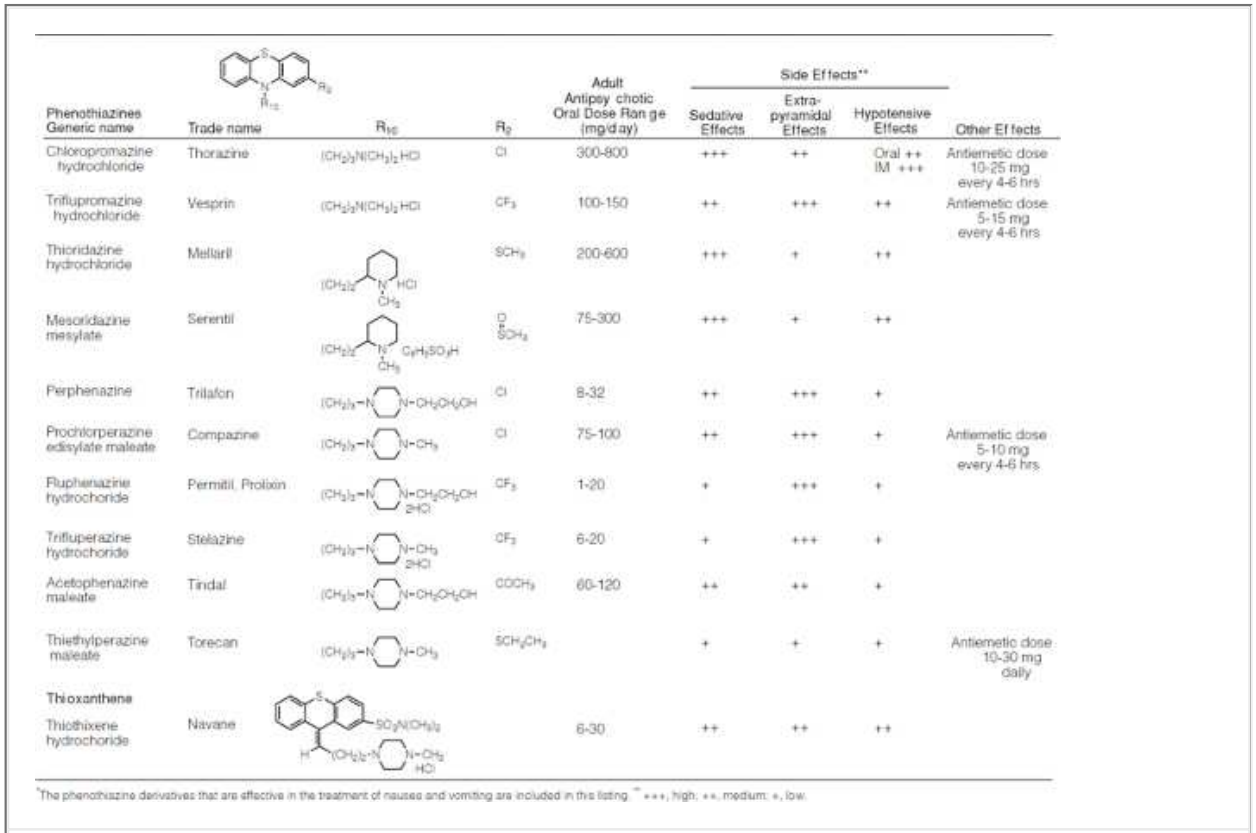
To enhance the sedative effects of such phenothiazines, Charpentier and Courvoisier synthesized and evaluated many modifications of promethazine. This research effort eventually led to the synthesis of chlorpromazine (type VIII) in 1950 at the Rhône-Poulenc Laboratories (35). Soon thereafter, the French surgeon Laborit and his coworkers described the ability of this compound to potentiate anesthetics and produce artificial hibernation (36). They noted that chlorpromazine, by itself, did not cause a loss of consciousness but did produce only a tendency to sleep and a marked disinterest in the surroundings. The first attempts to treat mental illness with chlorpromazine alone were made in Paris in 1951 and early 1952 by Paraire and Sigwald. In 1952, Delay and Deniker began their important work with chlorpromazine (37). They were convinced that chlorpromazine achieved more than symptomatic relief of agitation or anxiety and that this drug had an ameliorative effect on psychosis. Thus, what initially involved minor molecular modifications of an antihistamine that produced

sedative side effects resulted in the development of a major class of drugs that initiated a new era in the drug therapy for the mentally ill. More than anything else in the history of psychiatry, the phenothiazines and related drugs have positively influenced the lives of schizophrenic patients, enabling them to assume a greatly improved role in society.



Phenothiazines Generic name	Trade name	R_{10}	R_2	Adult Antipsychotic Oral Dose Range (mg/day)	Side Effects** Sedative Effects	Extrapyramidal Effects	Hypotensive Effects	Other Effects
Chloropromazine hydrochloride	Thorazine	$(CH_2)_3N(CH_3)_2HCl$	Cl	300-800	+++	++	Oral ++ IM +++	Antiemetic dose 10-25 mg every 4-6 hrs
Triflupromazine hydrochloride	Vesprin	$(CH_2)_3N(CH_3)_2HCl$	CF_3	100-150	++	+++	++	Antiemetic dose 5-15 mg every 4-6 hrs
Thioridazine hydrochloride	Mellaril		SCH_3	200-600	+++	+	++	
Mesoridazine mesylate	Serentil		O SCH_3	75-300	+++	+	++	
Perphenazine	Trilafon		Cl	8-32	++	+++	+	
Prochlorperazine edisylate maleate	Compazine		Cl	75-100	++	+++	+	Antiemetic dose 5-10 mg every 4-6 hrs
Fluphenazine hydrochloride	Permitil, Prolixin		CF_3	1-20	+	+++	+	
Trifluperazine hydrochloride	Stelazine		CF_3	6-20	+	+++	+	
Acetophenazine maleate	Tindal		$COCH_3$	60-120	++	++	+	
Thiethylperazine maleate	Torecan		SCH_2CH_3		+	+	+	Antiemetic dose 10-30 mg daily
Thioxanthene								
Thiothixene hydrochoride	Navane			6-30	++	++	++	

*The phenothiazine derivatives that are effective in the treatment of nausea and vomiting are included in this listing. **+++, high; ++, medium; +, low.

Table 22.1. Phenothiazine and the Thioxanthene Derivatives Used as Neuroleptics*

More than 24 phenothiazine and the related thioxanthene derivatives are used in medicine, most of them for psychiatric conditions. The structures, generic and trade names, dose, and side effects of phenothiazines and thioxanthenes currently used as neuroleptics are listed in Table 22.1.

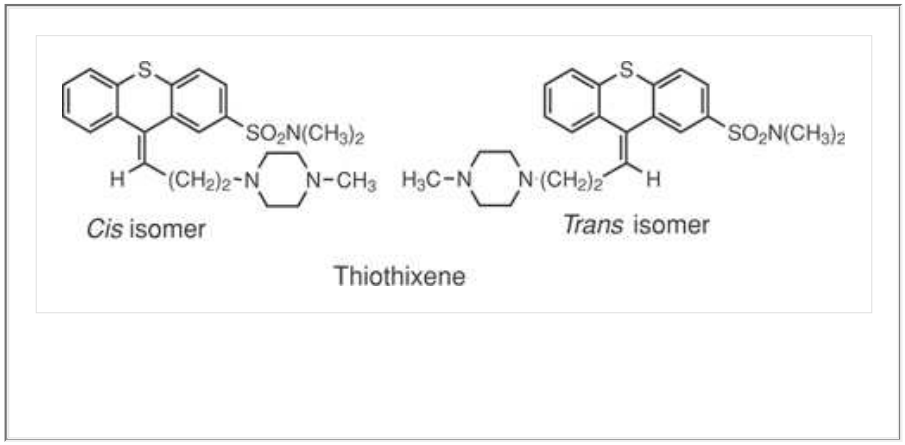
Structure–activity relationships of phenothiazine and thioxanthene neuroleptics

It is presumed that phenothiazine and thioxanthene neuroleptics mediate their pharmacological effects mainly through interactions at D_2-type dopamine receptors. Examination of the x-ray structures of dopamine (in the preferred *trans a*-rotamer conformation) and chlorpromazine shows that these two structures can be partly superimposed (Fig. 22.5) (38). In the preferred conformation of chlorpromazine, its side chain tilts away from the midline toward the chlorine-substituted ring.

The electronegative chlorine atom on ring "a" is responsible for imparting asymmetry to this molecule, and the attraction of the amine side chain (protonated at physiologic pH) toward the ring containing the chlorine atom indicates an important structural feature of such molecules. Phenothiazine and related compounds lacking a chlorine atom in this position are, in most cases, inactive as neuroleptic drugs. In addition to the ring "a" substituent, another major requirement for therapeutic efficacy of phenothiazines is that the side-chain amine contain three carbons separating the two nitrogen atoms (Fig. 22.5). Phenothiazines with two carbon atoms separating the two nitrogen atoms lack antipsychotic efficacy. Compounds such as promethazine (Fig. 22.4, VII) are primarily antihistaminic and are less likely to assume the preferred conformation.

When thioxanthene derivatives that contain an olefinic double bond between the tricyclic ring and the side chain

are examined, it can be seen that such structures can exist in either the *cis* or *trans* isomeric configuration. The *cis* isomer of the neuroleptic thiothixene is several-fold more active than both the *trans* isomer and the compound obtained from saturation of the double bond. Structure D in Figure 22.5 shows that the active structure of dopamine does not superimpose with a *trans*-like conformer of chlorpromazine that would be predicted to be inactive.



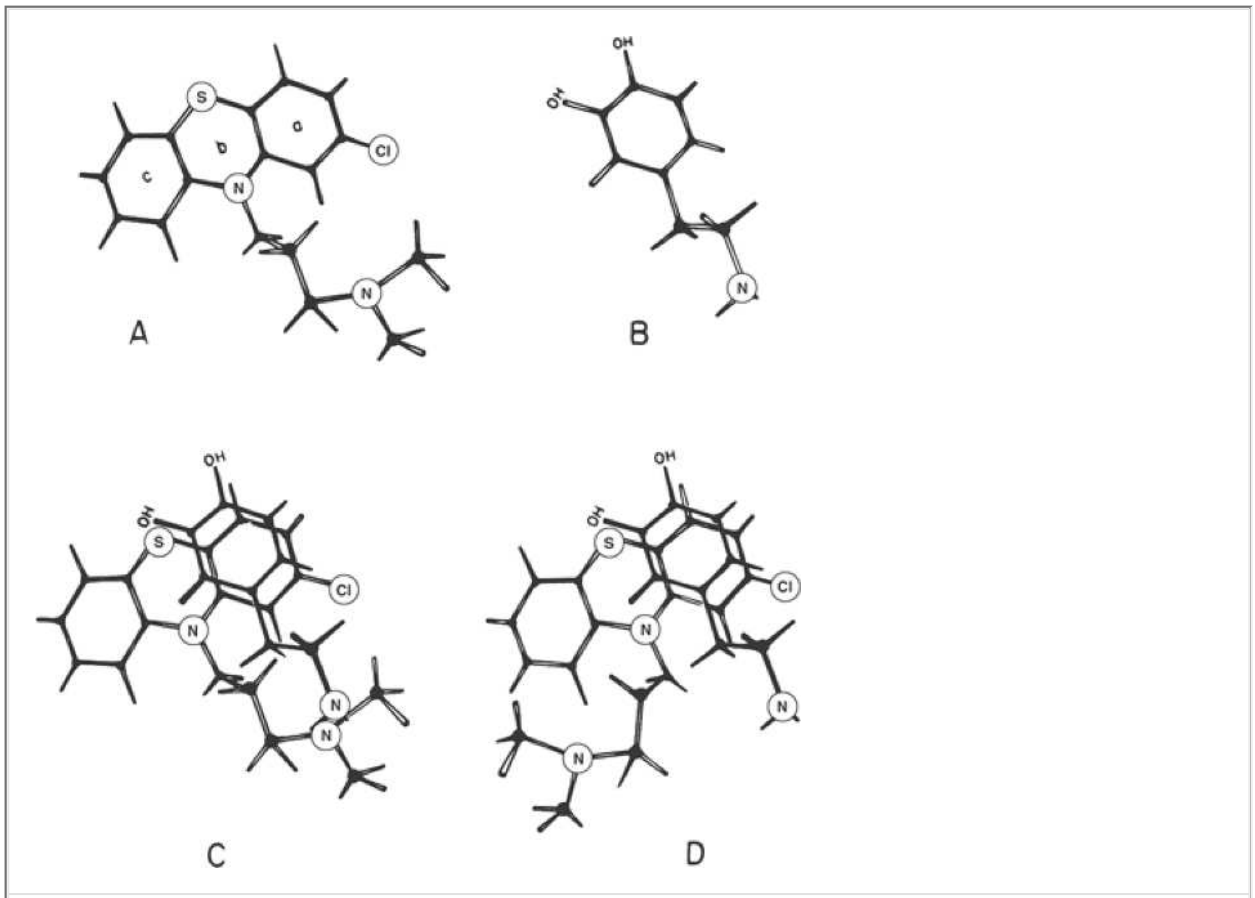


Fig. 22.5. Conformations of chlorpromazine (A), dopamine (B), and their superposition (C) as determined by x-ray crystallographic analysis. The a, b, and c in (A) designate rings. Also shown (D) is another conformation in which the alkyl side chain of chlorpromazine is in the trans conformation (ring a and amino side chain), which is not superimposable on to dopamine. (Adapted from Horn AS, Snyder SH. Chlorpromazine and dopamine: Conformational similarities that correlate with the antischizophrenic activity of phenothiazine drugs. Proc Natl Acad Sci U S A 1971;68:2325–2328; with permission.)

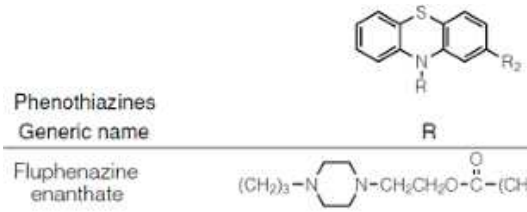

Phenothiazines Generic name	R	R_2	Dosage Range (mg)	Typical Duration of Action (weeks)
Fluphenazine enanthate		CF_3	25-100	1-2
Fluphenazine decanoate		CF_3	25-200	2-3
Perphenazine enanthate		Cl	25-100	1-2
Thioxanthene				
Flupenthixol decanoate			100-200	1-2

Table 22.2. Long-acting Neuroleptics for IM Depot Injection

Long-acting neuroleptics

The duration of action of many of the neuroleptics with a free hydroxyl (OH) moiety can be considerably prolonged by the preparation of long-chain fatty acid esters (Table 22.2). Thus, fluphenazine decanoate and fluphenazine enanthate were the first of these esters to appear in clinical use and are longer acting, with fewer side effects, than the unesterified precursor. The ability to treat patients with a single intramuscular injection every 1 to 2 weeks with the enanthate or every 2 to 3 weeks with the decanoate ester means that problems associated with patient compliance to the drug regimens and with drug

malabsorption can be reduced. Table 22.2 lists long-acting forms of phenothiazine and thioxanthene, which are derivatives available in the United States and other countries.

Metabolism of phenothiazines and thioxanthenes

Increasing evidence suggests that the metabolism of neuroleptic drugs is of major significance in the effects of these drugs. Although considerable information about the metabolism of the extensively studied chlorpromazine is available, information about many of the other drugs administered for prolonged periods is scant. Generally, however, the liver microsomal cytochrome P450–catalyzed metabolic pathways for neuroleptics are similar to those for many other drugs. Some metabolic pathways for chlorpromazine are shown in Figure 22.6. It should be kept in mind that during metabolism, several processes can and do occur for the same molecule. For example, chlorpromazine can be demethylated, sulfoxidized, hydroxylated, and glucuronidated to yield 7-O-glu-nor-CPZ-SO. The combination of such processes leads to more than 100 identified metabolites. Evidence indicates that the 7-hydroxylated derivatives and, possibly, other hydroxylated derivatives as well as the mono- and didesmethylated products (nor_1-CPZ, nor_2-CPZ) are active in vivo and at dopamine D_2 receptors, whereas the sulfoxide (CPZ-SO) is inactive. Although the thioxanthenes are closely related to the phenothiazines in their pharmacological effects, there seems to be at least one major difference in metabolism: Most of the thioxanthenes do not form ring-hydroxylated derivatives. Metabolic pathways for phenothiazines and thioxanthenes are significantly altered, both quantitatively and qualitatively, by a number of factors, including species, age, gender, interaction with other drugs, and route of administration.

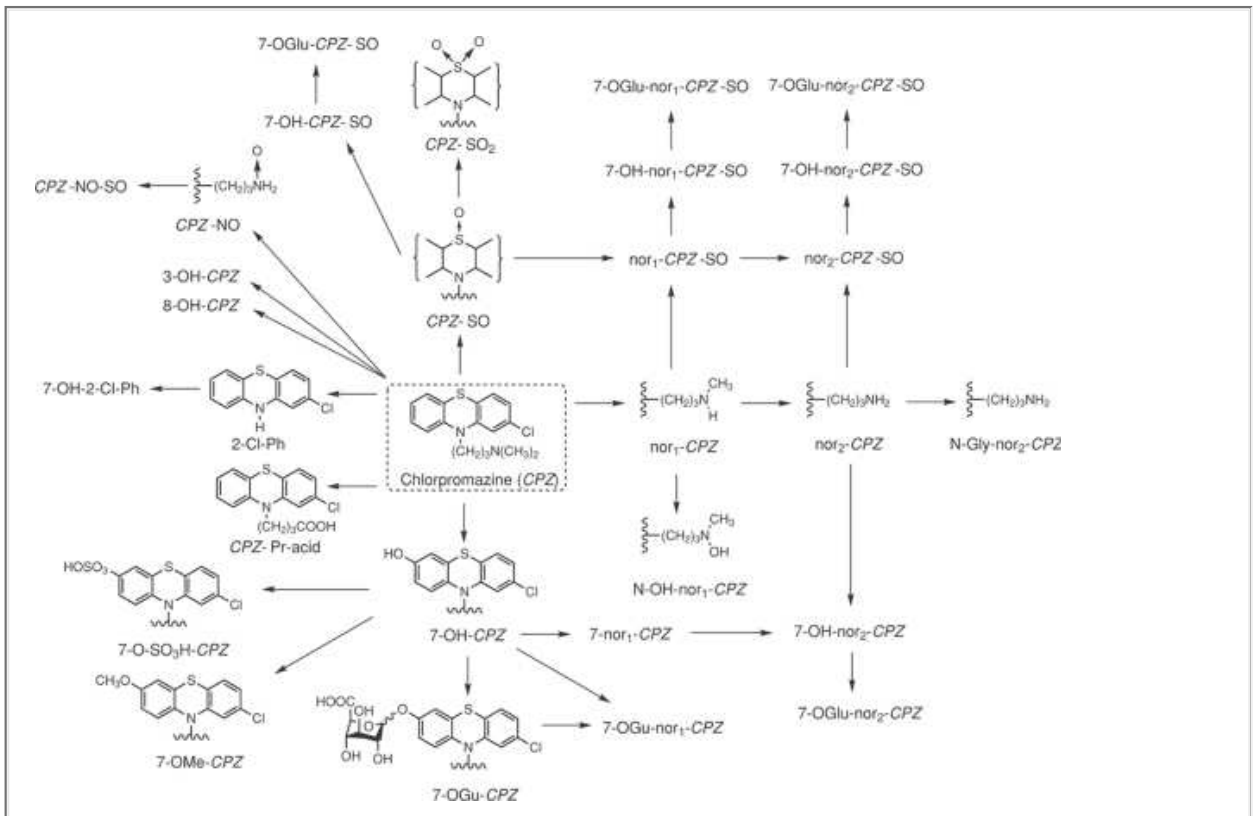

Fig. 22.6. Metabolism of chlorpromazine. CPZ, chlorpromazine; NO, N-oxide; SO, sulfoxide; SO_2, sulfone; O-Glu, O-glucuronide; Ph, phenothiazine; Pr-acid, propionic acid; $O\text{-}SO_3H$, sulfate.

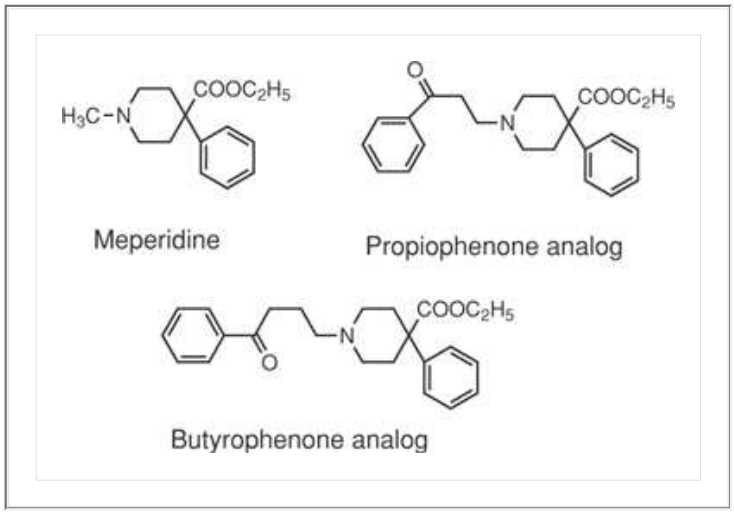
Development of Butyrophenone Neuroleptics

In the late 1950s, Janssen and coworkers synthesized the propiophenone and butyrophenone analogues of meperidine in an effort to increase its analgesic potency (39). The propiophenone analogue had 200-fold the

P.610

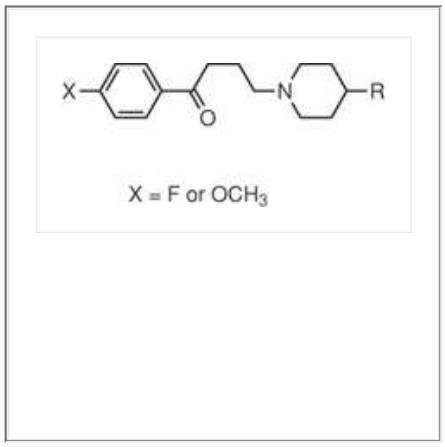
analgesic potency of meperidine, but the butyrophenone analogue also displayed activity resembling that of chlorpromazine. Janssen and coworkers found that it was possible to eliminate the morphine type of analgesic activity and, simultaneously, to accentuate the chlorpromazine type of neuroleptic activity in the butyrophenone series, provided that certain structural changes are made.



Structure–activity relationships

Haloperidol binds with equally high affinity to dopamine D_2, and serotonin 5-HT_2 receptors in mammalian brain tissue, and both of these receptor systems may be involved in mediating the antipsychotic activity of the butyrophenones. In most respects, the pharmacological effects of haloperidol and other butyrophenones differ in degree, but not in kind, from those of the piperazine phenothiazines. Haloperidol produces a high incidence of extrapyramidal reactions, but its sedative effect in moderate doses is less than that observed with chlorpromazine. Haloperidol has less prominent autonomic effects than the other antipsychotic drugs do, and only mild hypotension occurs with the use of haloperidol, even in high doses.

All butyrophenone derivatives displaying high neuroleptic potency have the following general structure:



The attachment of a tertiary amino group to the fourth carbon of the butyrophenone skeleton is essential for neuroleptic activity; lengthening, shortening, or branching of the three-carbon propyl chain decreases neuroleptic potency. Replacement of the keto moiety (e.g., with the thioketone group as in the butyrothienones, with olefinic or phenoxy groups, or reduction of the carbonyl group) decreases neuroleptic potency. In addition, most potent butyrophenone compounds have a fluorine substituent in the para position of the benzene ring. Variations are possible in the tertiary amino group without loss of neuroleptic potency; for example, the basic nitrogen usually is incorporated into a 6-membered ring (piperidine, tetrahydropyridine, or piperazine) that is substituted in the para position.

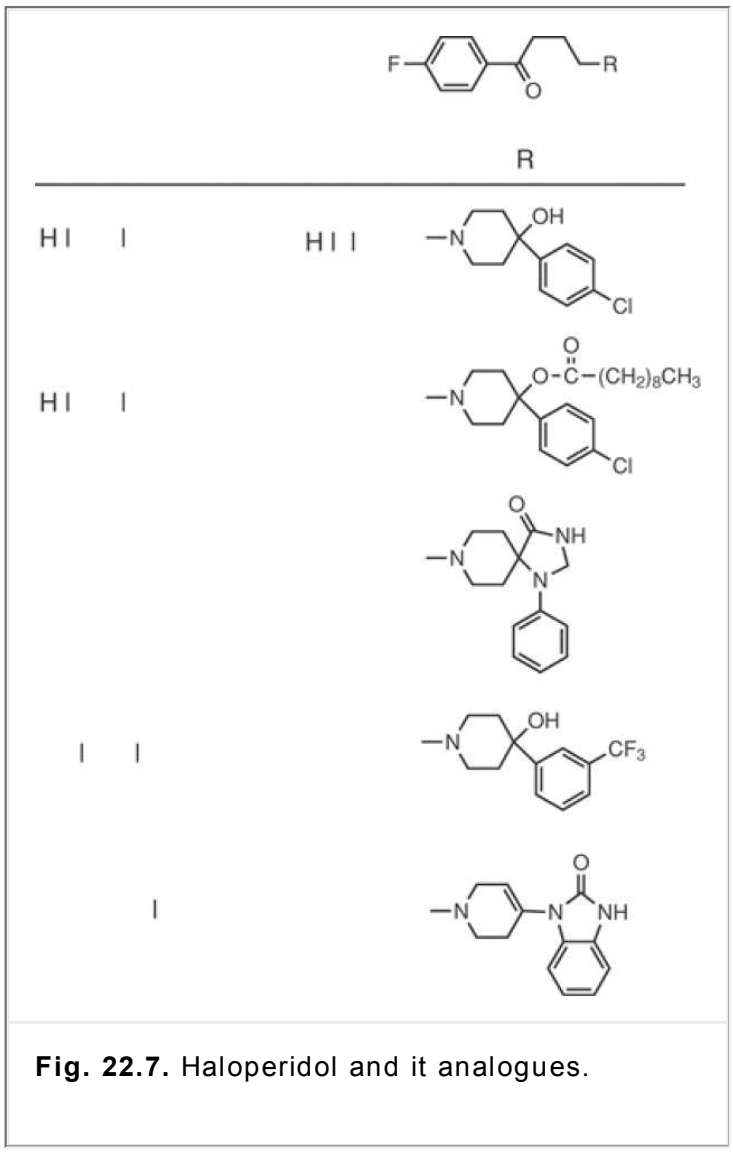


Fig. 22.7. Haloperidol and it analogues.

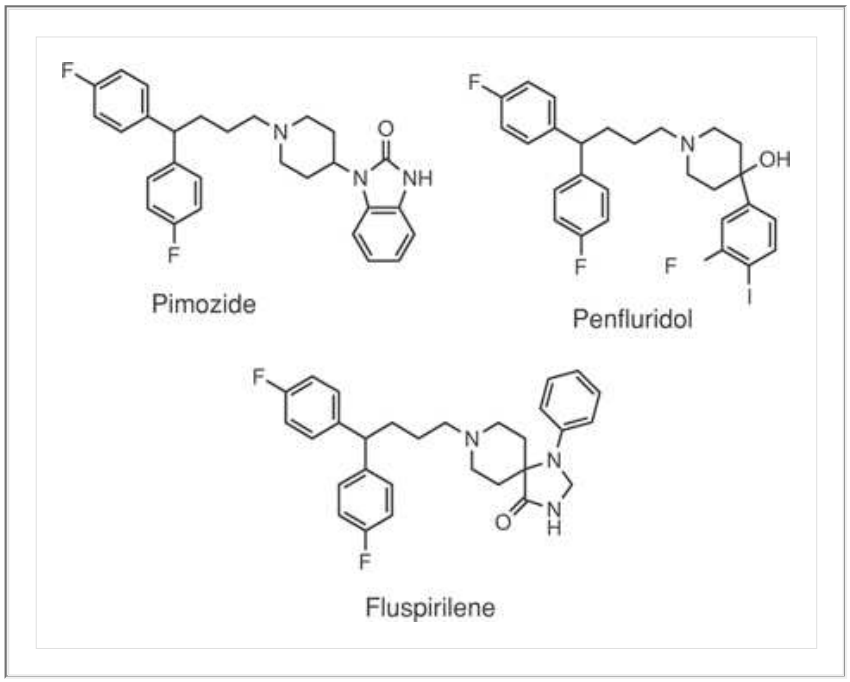
Haloperidol was introduced for the treatment of psychoses in Europe in 1958 and in the United States in 1967 (Fig. 22.7). It is an effective alternative to more familiar antipsychotic phenothiazine drugs and also is used for the manic phase of bipolar (manic-depressive) disorder. Haloperidol decanoate has been introduced as depot maintenance therapy. When injected every 4 to 6 weeks, the drug appears to be as effective as daily orally administered haloperidol. Other currently available (mostly in Europe) butyrophenones include the very potent spiperone (spiroperidol) as well as trifluperidol and droperidol. Droperidol, a short-acting, sedating butyrophenone, is used in anesthesia for its sedating and antiemetic effects and, sometimes, in psychiatric emergencies as a sedative-neuroleptic. Droperidol often is administered in combination with the potent narcotic analgesic fentanyl for preanesthetic sedation and anesthesia.

Modification of the haloperidol butyrophenone side chain by replacement of the keto function with a di-4-flurophenylmethane moiety results in diphenylbutyl piperidine neuroleptics, such as pimozide, penfluridol, and fluspirilene. The diphenylbutyl piperidines neuroleptics have a longer duration of action than the butyrophenone analogues. All are effective in the control of

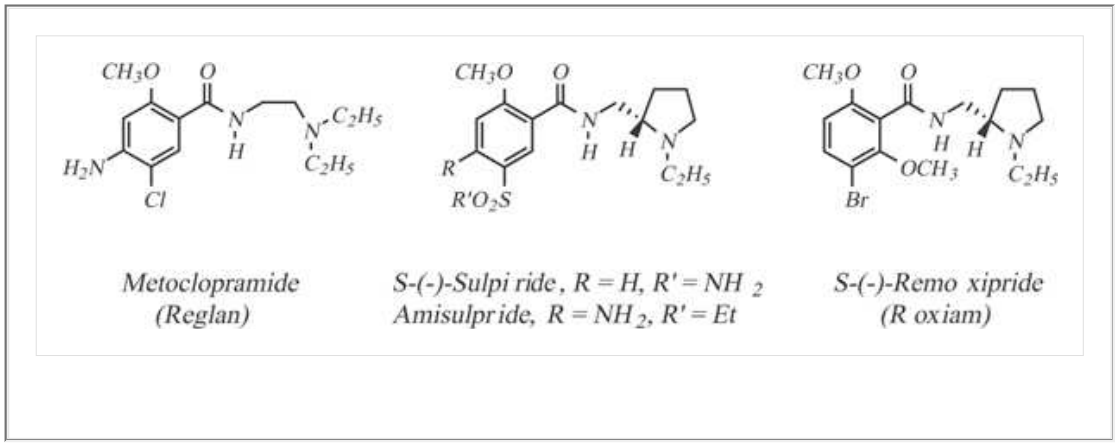
schizophrenia, and pimozide in particular has been shown to be useful in treating acute exacerbation of schizophrenia and in reducing the rate of relapse in chronic schizophrenic patients (40). Pimozide also is used for treatment of Tourette's syndrome, a movement disorder that is characterized by facial tics, grimaces, strange and uncontrollable sounds, and sometimes, involuntary shouting of obscenities. This disorder may be misdiagnosed by clinicians as schizophrenia. Typically, the onset of Tourette's syndrome occurs at age 10, and standard treatment for Tourette's syndrome in the past has been the neuroleptics, such as haloperidol. Chronic treatment of Tourette's syndrome with haloperidol as well as with pimozide carries the risk of producing potentially irreversible tardive dyskinesia. Penfluridol and fluspiriline, although not currently available in the United States, are other examples of

long-acting neuroleptics in this structure class.



Metabolism

Haloperidol is readily absorbed from the gastrointestinal tract. Peak plasma levels occur 2 to 6 hours after ingestion. The drug is concentrated in the liver and CNS. Approximately 15% of a given dose is excreted in the bile, and approximately 40% is eliminated through the kidney. Figure 22.8 shows the typical oxidative metabolic pathway of butyrophenones as exemplified by haloperidol (41).



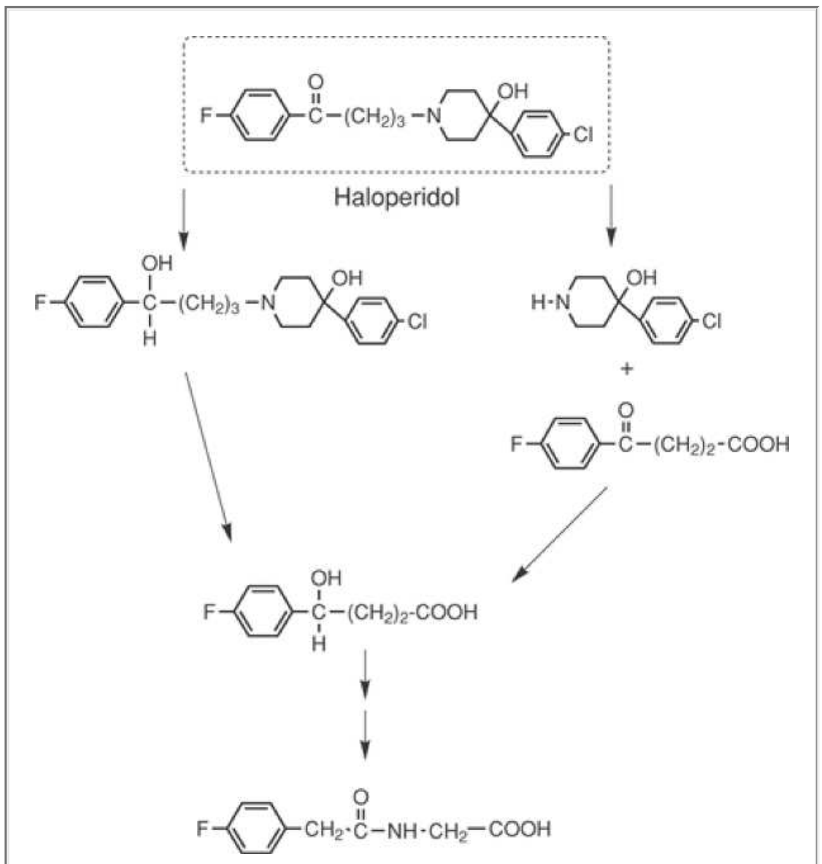


Fig. 22.8. Metabolism of haloperidol.

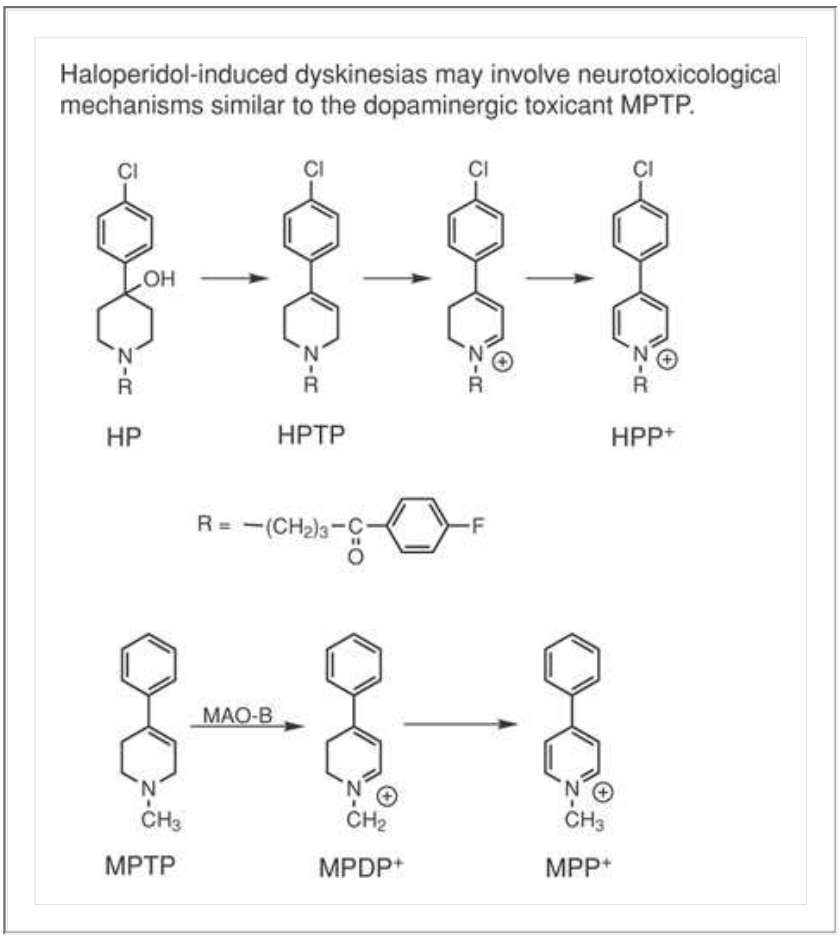
Additional Classes of Antipsychotic Agents

Benzamide derivatives

Certain benzamide derivatives have both local anesthetic and antiemetic properties (47). The benzamide metoclopramide has limited local anesthetic activity but is an efficacious antiemetic drug that modifies gastric motility. Similar to the phenothiazine antiemetics (e.g., promethazine), metoclopramide was found to antagonize dopamine D_2-type receptors in the chemoreceptor trigger zone of the brainstem and, subsequently, was shown to be neuroleptic (48). Metoclopramide has relatively low affinity and selectivity for several receptors in addition to D_2/D_3 antagonism. It blocks muscarinic M_3 and serotonin 5-HT_{1A} GPCRs as well as the 5-HT_3 ligand-operated ion channel. Moreover, numerous studies have documented its anticholinesterase activity. The weak affinity and lack of selectivity of metoclopramide likely is explained by the large number of permissible conformers arising from the flexible 2-(diethylamino)ethyl moiety.

Toxicology

As described in the text (see the discussion regarding side effects of neuroleptics), extrapyramidal side effects occur in 30 to 50% of patients receiving standard doses of typical neuroleptics. Extrapyramidal side effects include acute dystonias, akathisia, and parkinsonian-type symptoms, such as bradykinesia, cogwheel rigidity, tremor, masked face, and shuffling gait. Tardive dyskinesia is a severe extrapyramidal side effect that occurs in 15 to 25% of patients after prolonged treatment with typical neuroleptics. Tardive dyskinesia is characterized by stereotyped, involuntary, repetitive, choreiform movements of the face, eyelids, mouth, tongue, extremities, and trunk. The pathophysiology of tardive dyskinesia is not known, and the disorder essentially is irreversible.



Haloperidol (Fig. 22.7) is a potent neuroleptic associated with a high incidence of tardive dyskinesia. Microsomal-catalyzed dehydration of haloperidol yields the corresponding 1,2,3,6-tetrahydropyridine derivative, HPTP, which is a close analogue of the parkinsonian-inducing neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Long-term (58-week) administration of HPTP to nonhuman primates alters both presynaptic and postsynaptic dopaminergic neuronal function, which may contribute to the neurotoxicologic effects of haloperidol (42). In baboons treated chronically with HPTP, animals developed orofacial dyskinesia, and histopathological studies revealed volume loss in the basal forebrain and hypothalamus, along with other neuronal cell loss that may be relevant to the pathophysiology of tardive dyskinesia (43). In humans and baboons, HPTP is oxidized in vivo to the corresponding pyridinium species, HPP^+, similar to the oxidation of MPTP to its ultimate neurotoxic species MPP^+. HPP^+ is neurotoxic to dopaminergic and, especially, serotonergic neurons in vivo in rats (44), and HPP^1 has been identified in the urine of humans treated with haloperidol (45). Furthermore, in a recent study involving psychiatric patients who were treated chronically with haloperidol, the severity of tardive dyskinesia and parkinsonism was associated with an increased serum concentration ratio of HPP^1 to haloperidol (46), providing compelling clinical evidence for the neurotoxicity of HPP^+. Investigations continue to determine if neuroleptic-induced pathology of the extrapyramidal motor system, such as that associated with tardive dyskinesia, may be related to production of MPP^+/HPP^+-type species in humans.

See Chapter 25 for a related discussion of Parkinson's disease caused by MPTP.

Several analogues of metaclopramide in which the side chain is incorporated into a pyrrolidine ring include S-(–)-sulpiride and S-(–)-remoxipride. Both drugs display neuroleptic properties. Sulpiride produces a relatively low incidence of extrapyramidal side effects, putatively because of a preferential effect on limbic versus extrapyramidal (striatum) tissue. The hydrophilic properties of sulpiride may account for its poor oral absorption, limited penetration into the CNS, and resulting low potency. The racemic para-amino congener of sulpride, amisulpride, is used as an antipsychotic agent outside the United States. Remoxipride was a promising neuroleptic that is comparable to haloperidol in potency and efficacy and has less incidence of extrapyramidal and autonomic side effects. Life-threatening aplastic anemia, however, was reported with remoxipride use, which prompted its withdrawal from the market.

Benzazepine derivatives

Clozapine, olanzapine, loxapine, and quetiapine are benzazepine-type derivatives with antipsychotic activity and atypically low risk of extrapyramidal side effects (Fig. 22.9).

Mechanism of action

Currently, it generally is agreed that the mechanism of benzazepine-type and other recently introduced atypical antipsychotic drugs (e.g., risperidone, ziprasidone, and aripiprazole) involves occupancy of both D_2 and 5-HT_{2A} receptors. Meanwhile, activity at other dopamine and serotonin receptor subtypes as well as at adrenergic, histamine, and muscarinic receptors may contribute to psychotherapeutic effects, such as modulation of negative symptoms, and certainly may cause autonomic (cardiovascular, sedative, sexual) and other peripheral antimuscarinic side effects

(gastrointestinal, urinary, ophthalmic). Short-term weight gain for both typical and atypical antipsychotic drugs likely correlates to high H_1 receptor affinity (49). The high 5-HT_{2A} receptor affinity of atypical antipsychotic agents (e.g., clozapine and olanzapine) led to the proposal that 5-HT_{2A} antagonism accounts for the lower propensity of these drugs to cause extrapyramidal side effects, but reduced affinity for D_2 receptors also likely plays a role. Nevertheless, antagonism of presynaptic 5-HT_{2A} receptors that inhibit dopamine release from striatal dopaminergic nerve terminals could increase dopaminergic neurotransmission in the striatum to modulate postsynaptic D_2 blockade and reduce extrapyramidal symptoms.

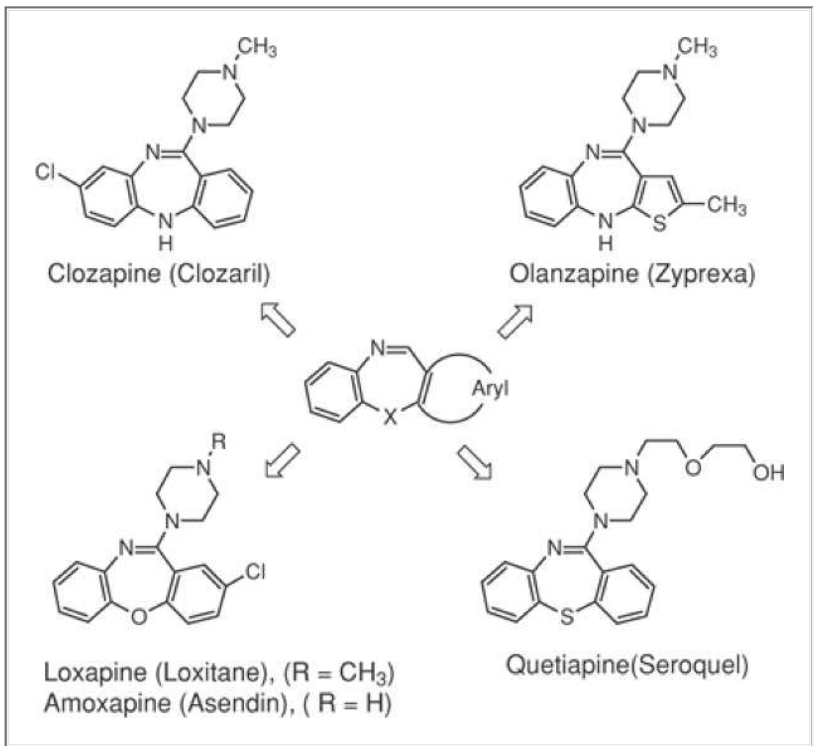


Fig. 22.9. Benzazepine derivatives.

Specific drugs Clozapine

The dibenzazepine clozapine is representative of the new generation of antipsychotic drugs that have greatly reduced or minimal extrapyramidal side effects and do not produce tardive dyskinesia with long-term use. Clozapine also appears to effectively alleviate the negative symptoms of schizophrenia and has proven to be beneficial in treating patients who do not respond adequately to classical neuroleptic agents, such as the phenothiazines or butyrophenones. A serious drawback to the use of clozapine, however, is the potentially fatal agranulocytosis that is reported to occur in 1 to 2% of unmonitored patients (50), necessitating weekly white blood cell counts for at least the first 6 months of pharmacotherapy. Clozapine is orally active and metabolized mainly by CYP3A4 to inactive desmethyl, hydroxyl, and N-oxide derivatives, with a half-life of approximately 12 hours. Clozapine has

relatively low affinity for brain dopamine D_1 and D_2 receptors (moderate affinity for D_4) in comparison to its affinity at adrenergic α_1 and α_2, histamine H_1, muscarinic M_1 and serotonin 5-HT_{2A} receptors (15,51).

Olanzapine

The thienobenzodiazepine olanzapine is an effective atypical antipsychotic agent that is close in structure to clozapine but has a somewhat different neuropharmacological profile, in that it is a more potent antagonist at dopamine D_2 and, especially, serotonin 5-HT_{2A} receptors (15). Olanzapine is well absorbed after oral administration and is metabolized mainly by CYP1A2 to inactive metabolites, with a variable half-life of approximately 20 to 50 hours.

Loxampine

The dibenzo-oxazepine loxapine is another antipsychotic in this structural class that has a more typical neuroleptic biochemical profile with mainly antidopaminergic activity at D_2-type receptors. Loxapine undergoes Phase I aromatic hydroxylation to yield several phenolic metabolites that have higher affinity for D_2 receptors than the parent. Loxapine also undergoes N-demethylation to form amoxapine, which is used clinically as an antidepressant. Amoxapine binds to D_2 receptors and inhibits the norepinephrine neurotransporter to block neuronal norepinephrine reuptake, a correlate of antidepressant activity.

Quetiapine

Quetiapine is a dibenzothiazepine with a brain receptor–binding profile similar to that of clozapine. Quetiapine binds most effectively to histaminergic H_1, adrenergic a_1 and a_2, and serotonergic 5-HT_{2A} receptors in the brain and has even lower affinity than clozapine for dopaminergic D_2 receptors. Unlike clozapine, however, quetiapine also has very low affinity for muscarinic receptors. Quetiapine is 100% bioavailable, but first-pass metabolism yields at least 20 metabolites via CYP3A4, with a half-life of approximately 6 hours. Quetiapine is about as effective as haloperidol in treating the positive symptoms of schizophrenia, but it also manages negative symptoms and induces a lower incidence of extrapyramidal side effects.

Benzisoxazole and benzisothiazole derivatives

Neuroanatomical and neurophysiologic interactions between dopaminergic and serotonergic systems, together with evidence that several benzazepine-type antipsychotic agents (e.g., clozapine and olanzapine) have high affinity for 5-HT_{2A} receptors, led to the proposal that combination D_2/5-HT_{2A} antagonists may produce atypical antipsychotic effects (52,53). Combining the chemical features present in the potent benzamide D_2 antagonists (e.g., remoxipride) with those of the benzothiazolyl piperazine 5-HT_{2A} antagonists (e.g., tiospirone) led to the development of the 3-(4-piperidinyl)-1,2-benzisoxazole nucleus present in the 5-HT_{2A}/D_2 antagonist risperidone and ziprasidone, which also have relatively high affinity at histamine H_1 and adrenergic α_1/α_2 receptors (Fig. 22.10).

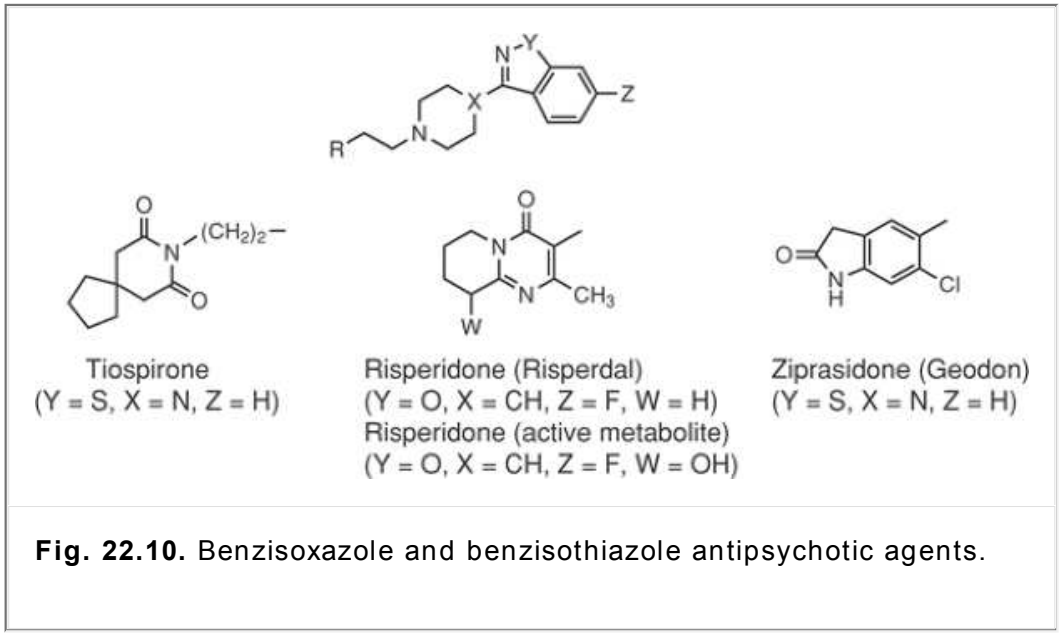

Fig. 22.10. Benzisoxazole and benzisothiazole antipsychotic agents.

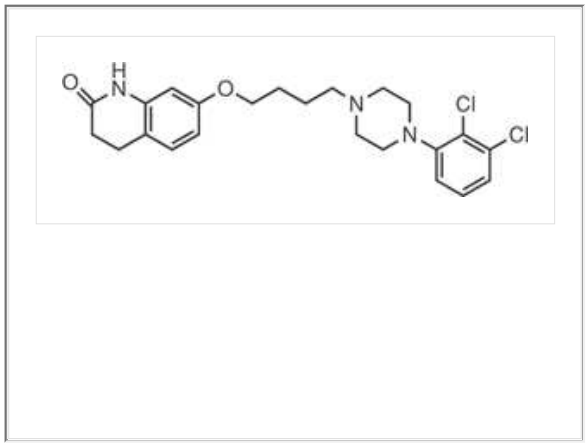
Specific drugs Risperidone

Risperidone has antiserotonergic effects similar to the benzazepine-type antipsychotic drugs. It is proposed that the 5-HT_{2A} antagonist activity of risperidone uninhibits dopaminergic neurotransmission in the striatum and cortex, reducing the severity of D_2 antagonist-induced extrapyramidal side effects and alleviating negative symptoms of schizophrenia while maintaining a blockade of limbic system D_2 receptors (54). Risperidone is well absorbed orally and undergoes hepatic CYP2D6-catalyzed 9-hydroxylation (active metabolite) and N-dealkylation (Fig. 21.10). The half-life of risperidone (as well as of hydroxyrisperidone) is approximately 22 hours.

Ziprasidone

Ziprasidone is chemically similar to risperidone but with a substitution of piperzinyl and benzisothiazole for piperidinyl and benzisoxazole and with minor aromatic modification. Like risperidone, ziprasidone is a high-affinity antagonist at 5-$HT_{2A/C}$ and D_2 receptors as well as at adrenergic α_1/α_2 and histamine H_1 receptors. Moreover, ziprasidone can activate 5-HT_{1A} receptors (55) that regulate dopaminergic neurotransmission in brain regions involved in critical cognitive functions. Thus, in addition to D_2 partial agonism (see below), 5-HT_{1A} agonism is now thought to be an important pharmacological property for atypical antipsychotic drug efficacy (56). Ziprasidone (half-life, 6 hours) has an oral bioavailability of approximately 60%, which can be enhanced in the presence of fatty foods. It is extensively metabolized (<5% excreted unchanged) by aldehyde oxidase, which results in reductive cleavage of the S–N bond, and then by S-methylation. Ziprasidone also can undergo CYP3A4-catalyzed N-dealkylation and S-oxidation (Fig. 22.11) (57).

Miscellaneous derivatives Aripiprazole



Aripiprazole is an arylpiperazine quinolinone derivative that has complex functional activity at several aminergic receptors currently thought to be important in the pathophysiology and pharmacotherapy of schizophrenia, including dopamine D_2 and serotonin 5-HT_{1A} and 5-$HT_{2A/C}$ receptors. The affinity of aripiprazole for D_2 receptors is relatively high; however, it has a low propensity to cause untoward extrapyramidal symptoms and hyperprolactinemia (58). This may be explained by the ability of aripiprazole to show partial agonist activity at some D_2 receptors, depending on the cell type expression—that is, it is a functionally selective drug (59). Aripiprazole also is a high-affinity partial agonist at 5-HT_{2A} receptors and a low-affinity agonist at 5-HT_{2C} receptors, and it has moderate affinity for α_1-adrenergic and histamine H_1 receptors. As with other atypical antipsychotic drugs, such as the benzazepines, molecular mechanisms related to efficacy are presumed to include a balanced

occupancy of 5-HT_{2A} receptors and D_2 receptors. Interestingly, the incidence of clinically significant weight gain is relatively low for aripiprazole as well as for risperidone (58), likely because of the relatively moderate histamine H_1 receptor affinity of these agents. In addition, the agonist properties of aripiprazole at 5-HT_{2C} receptors may reduce its potential for weight gain, because 5-HT_{2C} activity is associated with satiety (60). Aripiprazole (half-life, 75 hours) is orally bioavailable (90%) and undergoes hepatic CYP3A4- and CYP2D6-catalyzed N-dealkylation and hydroxylation as well as dehydrogenation to dehydroaripiprazole (half-life, 90 hours), which is an active metabolite (Fig. 22.12) (61).

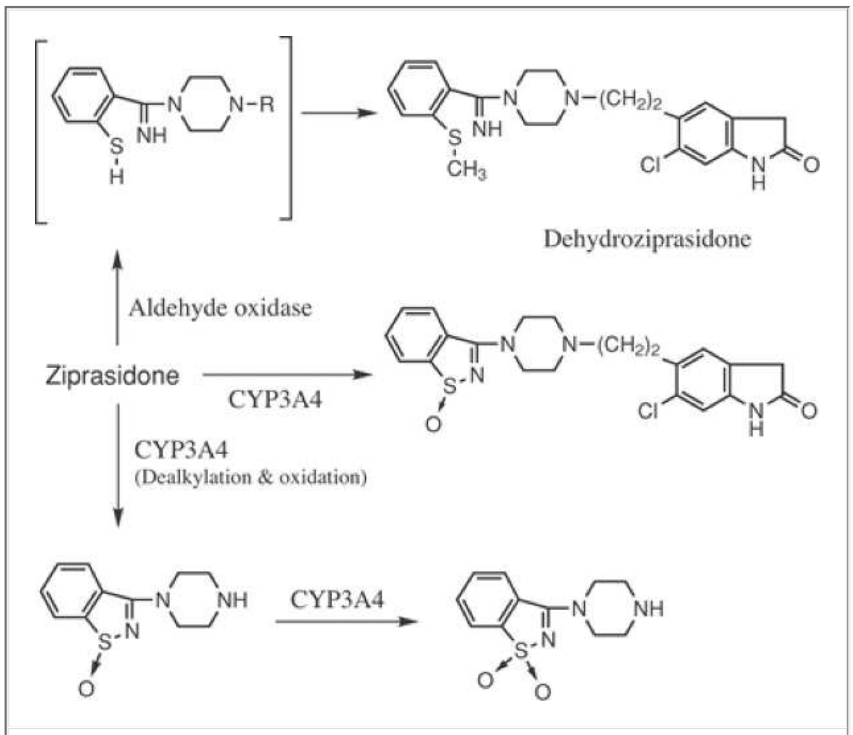


Fig. 22.11. Metabolism of ziprasidone.

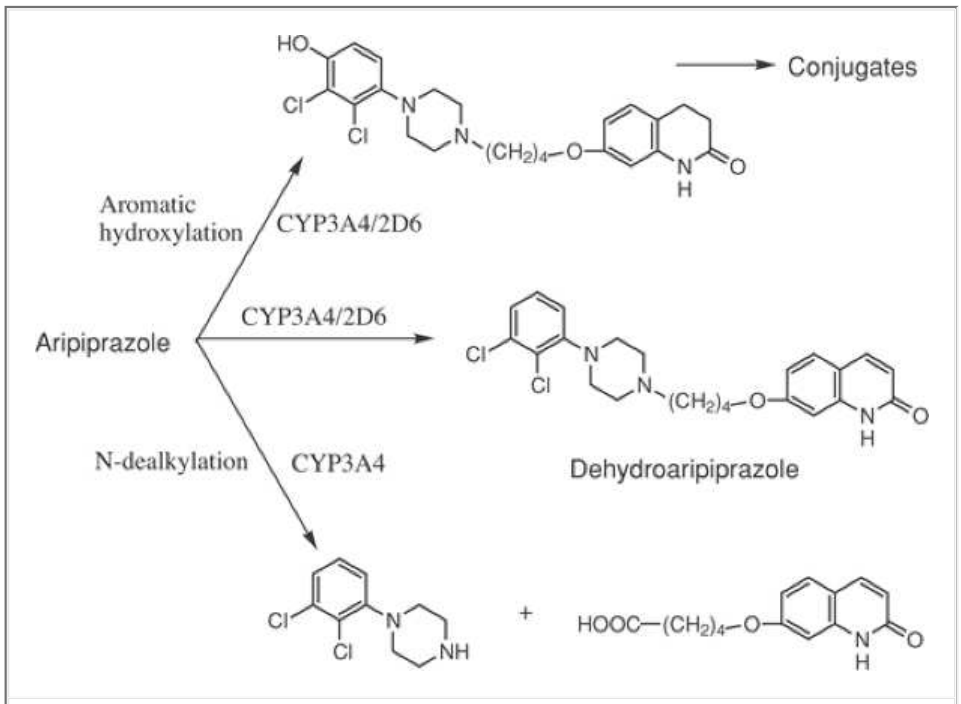

Fig. 22.12. Metabolism of aripiprazole.

Molindone

Molindone hydrochloride, a tetrahydro-indolone derivative, is a neuroleptic agent that is structurally unrelated to any of the other marketed neuroleptics. Molindone is less potent than haloperidol at blocking D_2 receptors; however, it nonetheless can produce extrapyramidal side effects. Metabolism studies in humans show molindone to be rapidly absorbed and metabolized when given orally. There are 36 recognized metabolites, with less than 2 to 3% unmetabolized molindone being excreted in urine and feces. Clinical studies show that the antipsychotic effects of molindone last more than 24 hours, suggesting that one or more metabolites may contribute to its activity in vivo (62).

Sertindole

Sertindole is an indole-containing compound that behaves as a high-affinity serotonin 5-HT_2 receptor antagonist, with weak affinity for adrenergic α_1 receptors and almost no affinity for dopaminergic D_2 receptors. It is about as effective as haloperidol in the treatment of acute and chronic schizophrenia, but with much lower incidence of extrapyramidal side effects. Sertindole is relatively nonsedating, and its effects are long lasting (several days) (63).

Anxiety and Anxiety Disorders

Definitions

Anxiety can be defined as a sense of apprehensive expectation. In reasonable amounts and at appropriate times, anxiety is helpful (e.g., anxiety before an examination may cause a student to initiate an appropriate study plan). Too much anxiety, however, can be deleterious. Anxiety can be considered pathological when it is either completely inappropriate to the situation or is in excess of what the situation normally should call for. An example of the former is nocturnal panic attacks—episodes of extreme anxiety that arise out of one of the most physiologically quiet times of the day, stage III/IV sleep (64). An example of the latter is specific phobias—for example, an irrational fear to venture outside of one's home.

According to the DMS-IV (1), abnormal anxiety is that level of anxiety that interferes with normal social or

occupational functioning. This definition is helpful to distinguish between normal and pathologic levels of anxiety. To meet general DSM-IV criteria, anxiety symptoms must not be caused by an exogenous factor (e.g., caffeine) or a medical condition (e.g., hyperthyroidism). Examples of anxiety disorders include specific phobias, generalized anxiety disorder (chronic abnormally high level of worry), social phobia (e.g., fear of public speaking), obsessive-compulsive disorder, panic disorder with or without agoraphobia (avoidance of situations believed by the patient to precipitate panic attacks), and posttraumatic stress disorder.

Etiology of Anxiety Disorders

Studies of patients with anxiety disorders have not revealed a general gross neuroanatomical lesion. In vivo functional imaging studies, however, show altered blood flow or utilization of glucose in certain brain areas in patients with anxiety conditions, including obsessive-compulsive disorder (65,66), panic disorder (67,68), specific phobia (69), generalized anxiety disorder (70), and posttraumatic stress disorder (71), mostly implicating the prefrontal cortex and hippocampus (and other limbic areas) as being involved in the anatomy of pathologic anxiety. It is important to note that there is significant comorbidity for anxiety and major depressive disorders, and it is not clear if one illness has primacy or is part of the other (72). Likewise, although there may be genetic predisposition to general distress that can lead to anxiety and/or depression, no clear genetic evidence suggests specific symptoms of either disorder.

A variety of neurotransmitters, neuromodulators (e.g., adenosine), and neuropeptides (e.g., cholecystokinin, corticotropin-releasing factor, and neuropeptide Y) are suggested to be involved in the pathophysiology of anxiety. Currently, abundant evidence exists to document the involvement of the neurotransmitters γ-aminobutyric acid (GABA), norepinephrine, and serotonin in anxiety, and research increasingly is revealing that these neurotransmitter systems have complex anatomical and functional interrelationships. For example, stimulation of the locus ceruleus, which contains the highest concentration of norepinephrine cell bodies in the CNS, generates a state of agitation and fear behaviors in laboratory animals (73). Meanwhile, data suggest that benzodiazepines influence norepinephrine release by stimulating inhibitory GABA receptors located on noradrenergic neurons (74).

GABA Receptors

The major inhibitory neurotransmitter in the mammalian CNS, GABA is widespread, with approximately one-third of all synapses in the CNS utilizing this neurochemical for intercellular communication (75). The two major classes of GABA receptors are inotropic $GABA_A$ and metabotropic $GABA_B$ receptors. There also exist $GABA_C$ inotropic receptors that activate chloride channels, similar to $GABA_A$. The $GABA_C$ receptors may play a role in cognitive and memory functions (76); however, there currently are no drugs that target these receptors.

$GABA_A$ Receptor

The $GABA_A$ receptor is a member of the gene superfamily of ligand-gated ion channels that is known as the "cys-loop" family because of the presence of a cysteine loop in their N-terminal domain (77,78,79). These receptors exist as heteropentameric subunits arranged around a central ion channel (Fig. 22.13). The five polypeptide subunits are composed of an extracellular region, four membrane-spanning α-helical cylinders, and a large intracellular cytoplasmic loop. The $GABA_A$ ion channel conducts chloride and is defined by the second of the

four membrane-spanning α-helical cylinders. The first $GABA_A$ polypeptide subunit was sequenced in 1987 (80), and so far, 19 different subunits have been isolated. These polypeptides are denoted as α_{1-6}, β_{1-3}, γ_{1-3}, δ, ε, π, θ, and θ_{1-3}. The subunits can combine in varied proportions (81) and alternatively spliced variants are common. Thus, many possible receptor subtypes may exist. The major (60%) $GABA_A$ receptor isoform in the adult mammalian (rat) brain consists of α_1, β_2, and γ_2 subunits ($GABA_{A1a}$) (82).

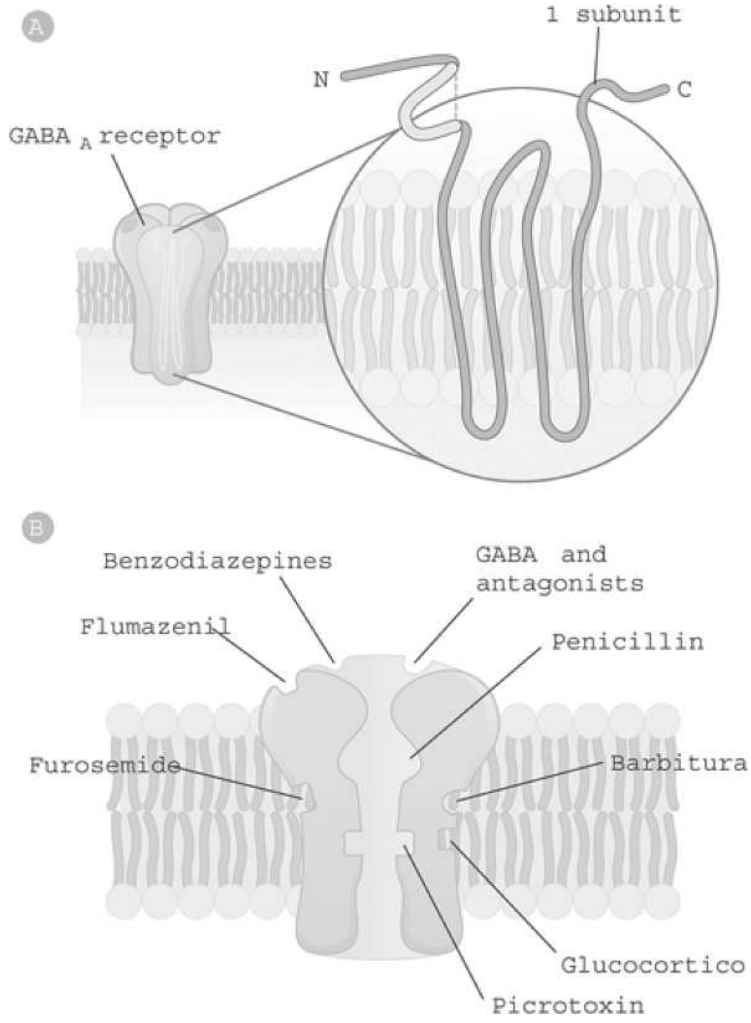

Fig. 22.13. Schematic representation of the γ-aminobutyric acid$_A$ (GABA$_A$) receptor. The GABA$_A$ receptors have a pentameric structure composed predominantly of α, β, and γ subunits arranged, in various proportions, around a central ion channel that conducts chloride. Each subunit has four membrane-spanning regions and a cysteine loop in the extracellular N-terminal domain (dashed line). The type and proportion of α and γ subunit composition affects affinity, pharmacological activity, and efficacy of ligands. (Chou J. Strichartz GR, Lo EA. Pharmacology of Excitatory and Inhibitory Neurotransmission. In: Golan DE, ed. Principles of Pharmacology. Philadelphia: Lippincott Williams & Wilkins, 2005:142; with permission.)

The GABA$_A$ extracellular N-terminal region contains a number of distinct binding sites for neuroactive drugs (e.g., barbiturates, benzodiazepines, β-carolines, and neurosteroids). The benzodiazepines, among the most commonly prescribed anxiolytic agents, bind to the benzodiazepine receptor (BZR), which is defined mostly by the α and γ subunits. The α and γ subunit composition can dramatically affect affinity and efficacy of BZR ligands (83,84). Early research on the BZR gave rise to the pharmacological concept of inverse agonism in addition to the better known concepts of agonism and antagonism. Inverse agonist compounds bind to the BZR on the GABA$_A$ receptor complex and negatively modulate GABA binding and neurophysiological activity (i.e., agonists decrease chloride conductance), producing physiological effects opposite that of GABA (e.g., anxiogenesis and pro-convulsant action). The BZR agonist ligands potentiate GABA binding and activity to increase chloride conductance, enhancing physiological effects of GABA (e.g., sedation and anticonvulsant activity). The BZR antagonists occupy the receptor but have no intrinsic activity to modulate GABA binding and function. A clinical example of a BZR antagonist is the compound flumazenil, which is used to reverse benzodiazepine-induced sedation in overdose. There also have been developed agents that are partial agonists and inverse partial agonists at the BZR/GABA$_A$ receptor complex. The

existence of a $GABA_A$ receptor complex that recognizes benzodiazepines has implications for our understanding of both normal and pathologic anxiety states and suggests the existence of endogenous $GABA_A$ receptor ligands. Thus, anxiety could conceivably be either a lack of an endogenous $GABA_A$ receptor agonist or a relative excess of a $GABA_A$ receptor antagonist or inverse agonist.

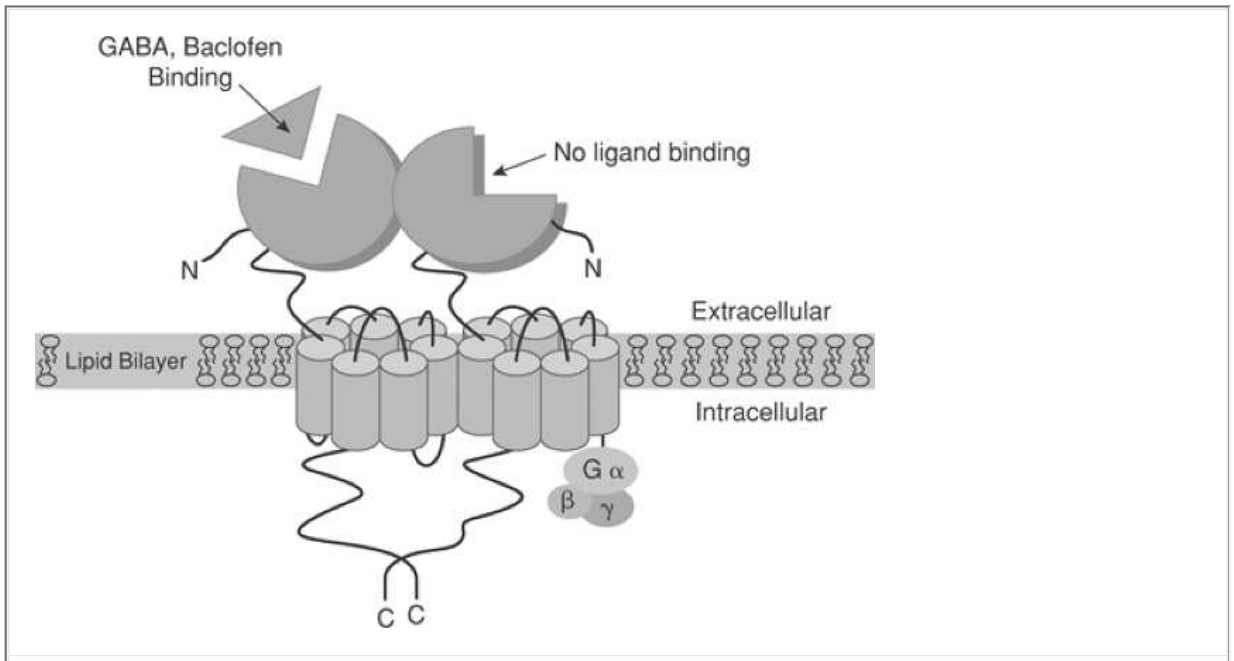

Fig. 22.14. Schematic representation of the γ-aminobutyric $acid_B$ ($GABA_B$) receptor.

$GABA_B$ Receptors

The $GABA_B$ receptors are GPCRs that exist as two major subtypes, $GABA_{B(1)}$ and $GABA_{B(2)}$. The $GABA_{B(1)}$ subtype can be expressed as $GABA_{B(1a)}$ and $GABA_{B(1b)}$ isoforms that differ in their extracellular NH_2-terminal domains but are derived from the same gene (85). Interestingly, it was discovered early on that compared to native $GABA_B$ receptors, recombinant $GABA_{B(1a)}$ and $GABA_{B(1b)}$ receptors expressed in heterologous cells display 100- to 150-fold lower affinity for agonist ligands. Likewise, recombinant $GABA_{B(1a)}$ and $GABA_{B(1b)}$ receptors were shown to couple inefficiently to their effector systems (predominantly via $G\alpha_i$ and $G\alpha_o$). These surprising pharmacological findings were explained by the discovery that recombinant $GABA_{B(1a)}$ and $GABA_{B(1b)}$ receptors expressed in heterologous cells are retained in the endoplasmic reticulum (84). In fact, it turned out that $GABA_{B(1)}$ receptors do not traffic to the cell membrane surface in the absence of $GABA_{B(2)}$ receptors. This remarkable discovery that the $GABA_{B(2)}$ receptor coexpresses on the cell surface with the $GABA_{B(1a)}$ or $GABA_{B(1b)}$ receptor to form a functional heterodimeric GPCR was reported simultaneously by three industry research groups in 1998 (85,86,87,88). The $GABA_B$ receptors were the first GPCR shown to function not as a single protein but, rather, as two distinct subunits, neither of which is functional by itself (Fig. 22.14). Homo- and/or heterodimerization (and oligomerization) now is documented for many GPCRs and may account for the diverse signaling functionality for this protein family.

The structure of functional heterodimeric $GABA_{B(1)}/GABA_{B(2)}$ GPCRs (Fig. 22.14) is assumed to be very different and considerably more complex in comparison to other aminergic GPCRs that are able to function as monomers. Functional $GABA_B$ receptors are proposed to contain a binding pocket that consists of two globular lobes separated by a hinge region. According to the Venus flytrap model, the two lobes close on ligand binding; however, it is thought that ligands bind in only one of the lobes (89,90,91). The individual $GABA_{B(1)}$ and $GABA_{B(2)}$ subunits can affect a number of other membrane and cytoplasmic proteins to result in complex signaling and a diverse array of pharmacological and physiological effects. For example, $GABA_B$ receptors modulate activity of calcium channels, potassium channels, adenylyl cyclase, and phospholipase C via $G\alpha_i$, $G\alpha_o$, and $G_{\beta\gamma}$ proteins. Meanwhile, preclinical data suggests that drugs which affect $GABA_B$ receptor function may produce, for example, anxiolytic, anticonvulsant, and antidepressant effects as well as muscle relaxant and analgesic effects (90,91).

R(-)-Baclofen

The only drug currently in clinical use that selectively interacts with the $GABA_B$ receptor is baclofen (β-p-chlorophenyl-GABA). Baclofen was first synthesized in 1962 and was shown to have potent muscle relaxant and analgesic activity. In 1972, the racemate was marketed to treat spasticity disorders (92). In 1980, the R-(–)-enantiomer of baclofen was shown to stereoselectively interact (as an agonist) with what is now known as the $GABA_B$ receptor (93). The role of $GABA_B$ receptors in anxiety, however, is not clear, and baclofen (racemate) is approved only for use as a spasmolytic agent (see Chapter 25).

Drugs Used in the Treatment of Anxiety

Benzodiazepines

The benzodiazepines are the prototypic antianxiety agents. They target the $GABA_A$ receptor, and although other molecular targets (e.g., serotonin neuroreceptors) now are exploited for anxiolytic pharmacotherapy, none of the alternative approaches has been shown to match either the efficacy or the rapid onset of the benzodiazepines (84). Chlordiazepoxide was the first benzodiazepine to be marketed for clinical use in 1960. Its effectiveness and wide margin of safety were major advances over compounds, such as barbiturates, used previously. A variety of new benzodiazepines followed, each with some minor differences from the competition. The major factors considered when selecting an agent include rate and extent of absorption, presence or absence of active metabolites, and degree of lipophilicity. These factors help to determine how a benzodiazepine is marketed and used; for example, an agent that is rapidly absorbed, highly lipid soluble, and without active metabolites would be useful as a hypnotic but less useful for treatment of a chronic anxiety state. On the other hand, a compound with slower absorption, active metabolites, and low lipophilicity would be a more effective antianxiety agent but less helpful as a soporific.

Despite their efficacy in a variety of pathologic anxiety syndromes, the benzodiazepines are not perfect anxiolytics. Such a hypothetical agent would selectively ameliorate anxiety without inducing other behavioral effects. Future efforts to enhance the efficacy of benzodiazepine anxiolytics may depend on a greater understanding of the heterogeneity of the $GABA_A$ receptor—for example, which specific clinical actions (anxiolytic, muscle relaxation, sleep facilitation) reside with which specific subunit composition.

Development of benzodiazepine anxiolytics

In the 1950s, the medicinal chemist Sternbach noted that “basic groups frequently impart biological activity,” and in accordance with this observation, he synthesized a series of compounds by treating various chloromethylquinazoline N-oxides with amines to produce what he hoped would be products with “tranquilizer” activity at the New Jersey laboratories of Hoffman LaRoche (94,95). Sternbach's studies included the reaction of 6-chloro-2-chloromethyl-4-phenylquinazoline-3-oxide with methylamine, which yielded the unexpected rearrangement product 7-chloro-2-(N-methylamino)-5-phenyl-3H-1,4,-benzodiazepin-4-oxide (Fig. 22.15). This product was given the code name RO 50690 and screened for pharmacological activity in 1957. Subsequently, Randall et al. (96,97) reported that RO 50690 was hypnotic and sedative and had antistrychnine properties similar to the propanediol meprobamate, a sedative that has tranquilizer (anxiolytic) properties only at intoxicating doses. Renamed chlordiazepoxide, RO 50690 was marketed in 1960 as Librium, a safe and effective anxiolytic agent.

Chlordiazepoxide turned out to have rather remarkable pharmacological properties and tremendous potential as a pharmacotherapeutic product, but it possessed a number of unacceptable physical chemical properties. In an effort to enhance its “pharmaceutical elegance,” structural modifications of chlordiazepoxide were undertaken that eventually led to the synthesis of diazepam in 1959. In contrast to the maxim that basic groups impart biological

activity, diazepam contains no basic nitrogen moiety. Diazepam, however, was found to be 3- to 10-fold more potent than chlordiazepoxide and was marketed in 1963 as the still enormously popular anxiolytic drug Valium. Subsequently, thousands of benzodiazepine derivatives were synthesized, and more than two dozen benzodiazepines are in clinical use in the United States (Fig. 22.16).

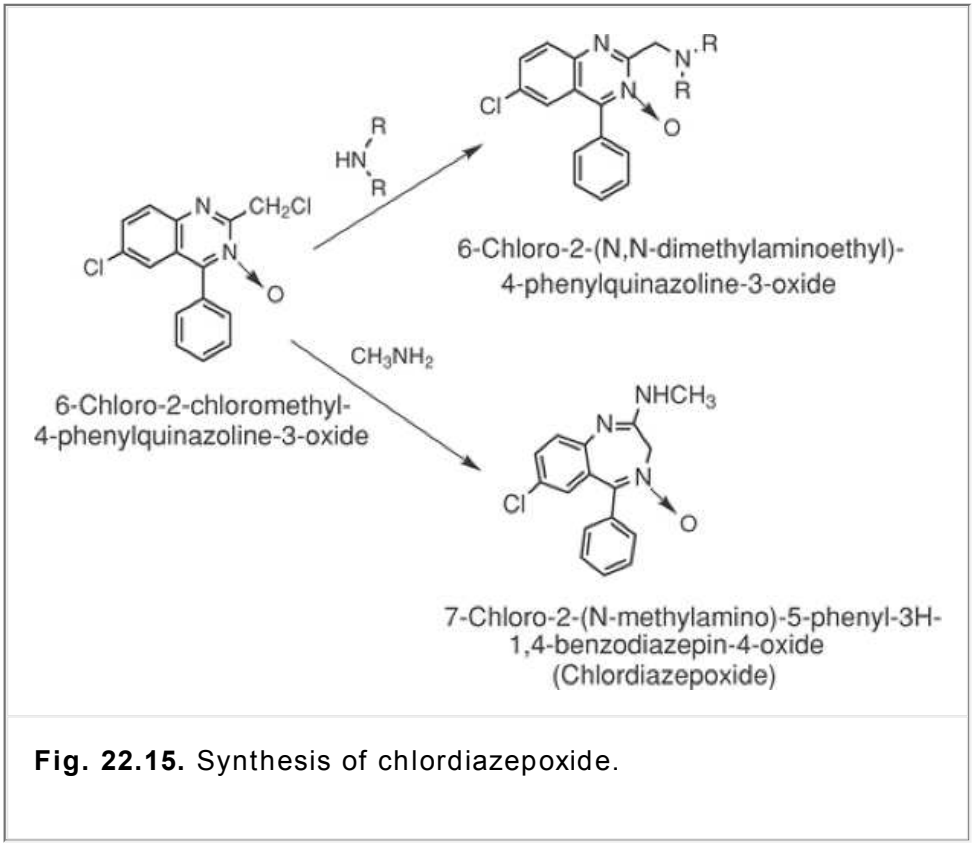

Fig. 22.15. Synthesis of chlordiazepoxide.

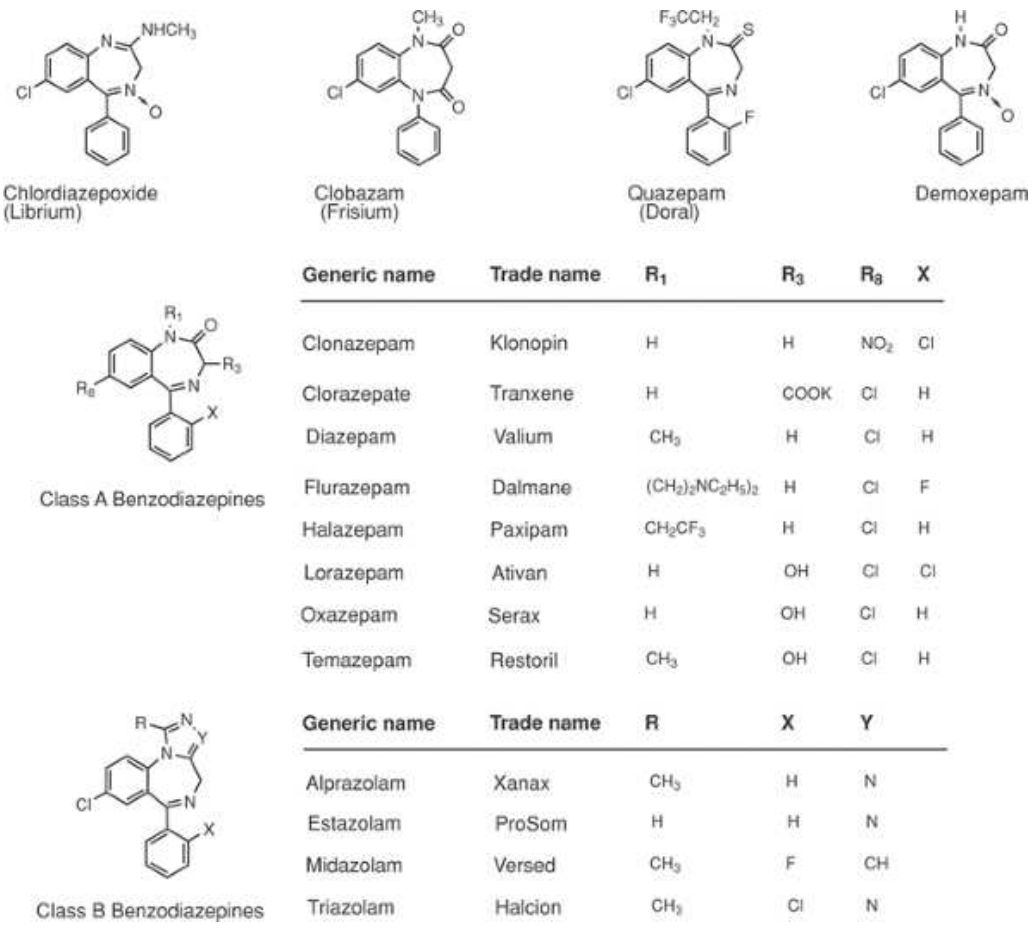

Generic name	Trade name	R_1	R_3	R_8	X
Clonazepam	Klonopin	H	H	NO_2	Cl
Clorazepate	Tranxene	H	COOK	Cl	H
Diazepam	Valium	CH_3	H	Cl	H
Flurazepam	Dalmane	$(CH_2)_2NC_2H_5)_2$	H	Cl	F
Halazepam	Paxipam	CH_2CF_3	H	Cl	H
Lorazepam	Ativan	H	OH	Cl	Cl
Oxazepam	Serax	H	OH	Cl	H
Temazepam	Restoril	CH_3	OH	Cl	H

Generic name	Trade name	R	X	Y
Alprazolam	Xanax	CH_3	H	N
Estazolam	ProSom	H	H	N
Midazolam	Versed	CH_3	F	CH
Triazolam	Halcion	CH_3	Cl	N

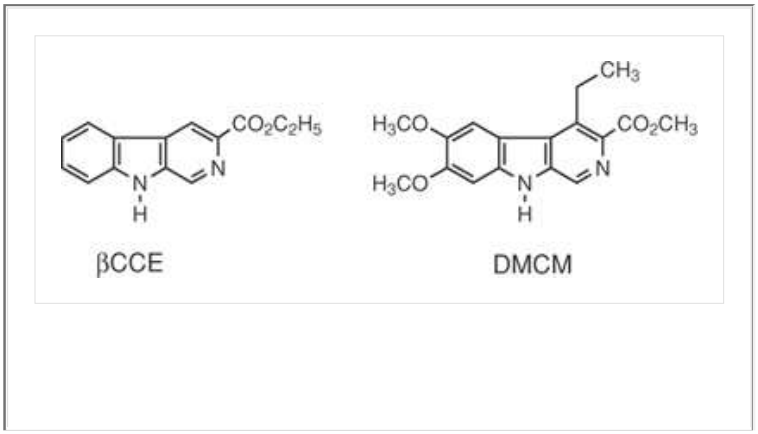
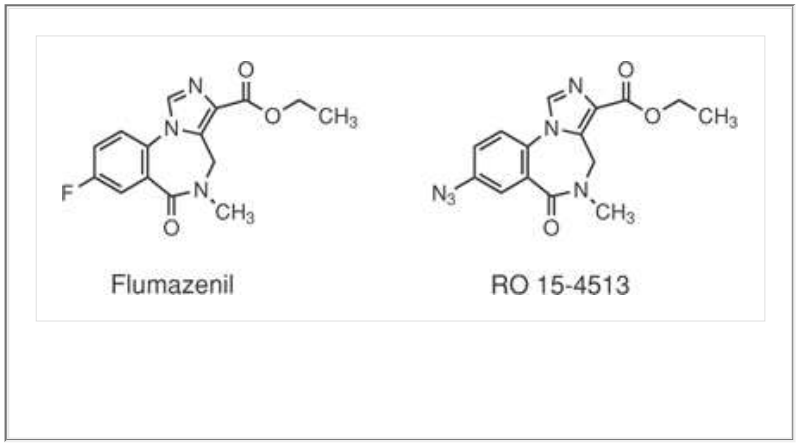
Endogenous BZR Ligands

An endogenous ligand with affinity for the CNS benzodiazepine receptor (BZR) of the $GABA_A$ receptor complex has not been conclusively identified. Several compounds of endogenous origin, however, that inhibit the binding of radiolabeled benzodiazepines to the BZR have been reported. In 1980, Braestrup et al. (98) reported the presence in normal human urine of β-carboline-3-carboxylic acid ethyl ester (βCCE), which has very high affinity for the BZR complex. It was subsequently shown, however, that βCCE formed as an artifact from Braestrup's extraction procedure, during which the urine extract was heated with ethanol at pH 1, a condition favoring formation of the ethyl ester from β-carboline-3-carboxylic acid, a tryptophan metabolite.



Although βCCE actually was shown not to be of endogenous origin, its discovery as a high-affinity BZR ligand stimulated research that led to the synthesis of a series of β-carboline derivatives with a variety of intrinsic activities, presumably mediated through the BZR that is associated with the $GABA_A$ receptor complex. For example, although βCCE is considered to be a partial inverse agonist at this site, 6,7-dimethoxy-4-ethyl-β-carboline-3-carboxylic acid methyl ester (DMCM) appears to be a full inverse agonist (99). In fact, βCCE blocks the convulsions produced by the very potent convulsant DMCM (100). These effects are even more complex and interesting in light of the approximately 10-fold higher affinity that βCCE shows for the BZR labeled by [^{3}H]diazepam when compared to DMCM (101). The β-carbolines currently are important research tools to probe the agonist, competitive antagonist, inverse agonist, and partial agonist/inverse agonist pharmacophores of the BZR/GABA receptor complex

A major advance in the BZR field was made in 1981 with the first report that the imidazobenzodiazepinone derivative, flumazenil, binds with high affinity to the BZR and blocks the pharmacological effects of the classical benzodiazepines in vitro and in vivo (102). Unlike agonists, binding of [^{3}H]flumazenil to the BZR is not affected by modulators such as GABA and several ions that induce changes in receptors (103). The insensitivity of flumazenil to changes in BZR conformation suggests that the ligand does not induce a conformational change in the receptor to trigger a biological response and is a pure antagonist (104). Such benzodiazepine antagonists are being used to characterize the pharmacological nature of the BZR, and several of these agents, including flumazenil, are used to treat benzodiazepine overdose. Other imidazobenzodiazepinone derivatives are not true BZR antagonists but, rather, have inverse agonist activity. For example, RO 15-4513, is reported to be a partial inverse agonist that produces anxiogenic-like effects in rats (105), a pharmacological activity quite different from a true BZR competitive antagonist, such as flumazenil.



Mechanism of action of anxiolytic benzodiazepines

The BZR ligands, regardless of intrinsic activity, do not directly alter transmembrane chloride conduction to produce their observed characteristic physiologic anxiolytic or anxiogenic effects. The BZR is an allosteric modulator of GABA binding to the $GABA_A$ receptor complex that, in turn, modulates the transmembrane conductance of chloride. In the presence of BZR agonists or partial agonists, affinity and functional potency of GABA at $GABA_A$ receptors is enhanced maximally or submaximally, respectively, and conductance of chloride is increased. Inverse agonists and partial inverse agonists reduce the effect of GABA and $GABA_A$ receptor–mediated conductance of chloride is accordingly decreased. The $GABA_A$ receptor–chloride channels thus become either more or less sensitive to GABA in the presence of BZR agonists or inverse agonists, respectively. BZR competitive antagonists block access of agonists to the BZR but have no intrinsic activity to affect GABA-modulated conductance of chloride.

A representation of the relationship between ligand interaction with the BZR and intrinsic activity to modulate $GABA_A$ receptor function is shown in Figure 22.17. The interaction of agonists, competitive antagonists, and inverse agonists with the BZR, as shown in the figure, is a simplistic rendering of the proposed three-state model of the BZR and $GABA_A$ receptor interrelationship (106,107). This model is based on the hypothesis that the BZR and $GABA_A$ receptor exist in three spontaneously oscillating conformational states, functionally described as “active” or agonist, “neutral” or “resting,” and “inactive” or inverse agonist. The BZR agonists and partial agonists bind to and stabilize the “active” state, inducing a conformational change in the $GABA_A$ receptor complex that results in chloride channel opening, which may lead to an anticonvulsant or anxiolytic effect. The BZR inverse agonists and partial

inverse agonists bind to and stabilize the "inactive" state, resulting in the chloride channel remaining closed, that may lead to a convulsant or anxiogenic effect. The BZR competitive antagonists

presumably bind equally well to both states (hence, they bind to a "neutral" state) and affect no change in $GABA_A$ receptor function or chloride conductance, but access of agonists to the BZR is blocked.

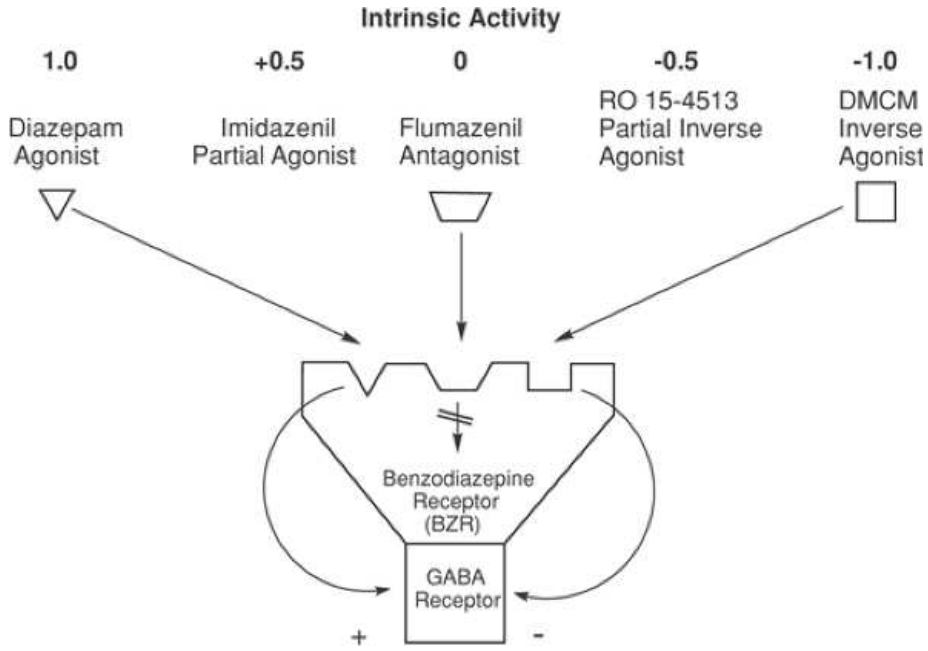


Fig. 22.17. Ligand interaction with the γ-aminobutyric $acid_A$ ($GABA_A$)/benzodiazepine receptor complex.

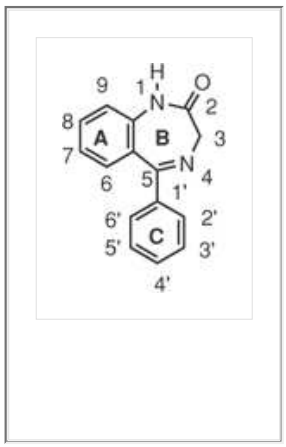
The classical BZR is located on the $GABA_A$ receptor complex mainly at the interface of the α and γ subunits that can be rendered benzodiazepine-insensitive by a point mutation in the α subunit, replacing a critical histidine residue for arginine (108). Different α and γ subunit compositions give rise to subtypes of the BZR receptor that are pharmacologically distinct with regard to ligand affinity and intrinsic activity (109,110,111), providing a mechanistic basis for development of ligands that are anxioselective (i.e., anxiolysis in the absence of sedation, muscle relaxation, amnesia, and ataxia). Thus, current drug discovery approaches target specific α and γ molecular subunits of the $GABA_A$ receptor complex in the quest for benzodiazepine and nonbenzodiazepine (see below) drugs that demonstrate anxioselectivity. As a group, currently used benzodiazepines are not α subtype-selective. Interestingly, in recent studies using nonhuman primates, it has been suggested that $GABA_A$ α_2, α_3, and α_5 subunits mediate anxiolytic and muscle relaxant effects of benzodiazepines, whereas α_1 receptors mediate the sedative effects (112). Several putative anxioselective compounds have reached the clinic; however, they have not exhibited the degree of anxioselectivity predicted from preclinical testing and, usually, have lower efficacy than standard benzodiazepines (84). Of possible clinical importance, "uncoupling" of the BZR/$GABA_A$ receptor complex has been observed in response to chronic benzodiazepine exposure both in vitro (113) and in vivo (114). In the absence of exogenous influences, however, coupling efficiency appears to be determined by the composition and stoichiometry of the α subunits (109), whereas benzodiazepine affinity, intrinsic activity, and efficacy is determined by the nature of both the *a* and *g* subunits (84,110,111).



Structure–activity relationships

The structure–activity relationship for classical 5-phenyl-1,4-benzodiazepine-2-one anxiolytic agents has been described by Sternbach and other investigators (94,104,106,115). Thousands of benzodiazepine derivatives with a variety of substituents have been synthesized that interact with the BZR; however, classical quantitative structure–activity relationship and molecular modeling techniques have been used to reduce this myriad of structures to the minimal common molecular features necessary for binding (116,117,118). The pharmacological activity continuum (agonist, antagonist, inverse agonist) displayed by BZR ligands would seem to suggest that such diverse functional activity be mediated by ligand interaction with different sites on the $GABA_A$ receptor-chloride channel complex. This continuum of activity, however, is displayed by ligands within the same chemical class, and small modifications in the chemical structure of a ligand can shift the intrinsic activity from agonist to antagonist to inverse agonist. Moreover, each functional class of BZR ligands can competitively inhibit the binding of the other two classes as well as functionally antagonize each other. These observations suggest that the binding sites of functionally diverse BZR receptor ligands, at least,

overlap. Nevertheless, most BZR pharmacophore models that describe ligand functional activity are based initially on the BZR pharmacophore for ligand binding activity at a single binding domain, and this approach is used here to summarize the structure–activity relationship for benzodiazepine derivatives at the BZR receptor.

Ring A

In general, the minimum requirements for binding of 5-phenyl-1,4-benzodiazepin-2-one derivatives to the BZR includes an aromatic or heteroaromatic ring (ring A), which is believed to participate in π-π stacking with aromatic amino acid residues of the receptor. Substituents on ring A have varied effects on binding of benzodiazepines to the BZR, but such effects are not predictable on the basis of electronic or (within reasonable limits) steric properties. It is generally true, however, that an electronegative group (e.g., halogen or nitro) substituted at the 7-position markedly increases functional anxiolytic activity, albeit effects on binding affinity in vitro are not as dramatic. On the other hand, substituents at positions 6, 8, or 9 generally decrease anxiolytic activity. Other 1,4-diazepine derivatives in which ring A is replaced by a heterocycle generally show weak binding affinity in vitro and even less pharmacological activity in vivo when compared to phenyl-substituted analogues.

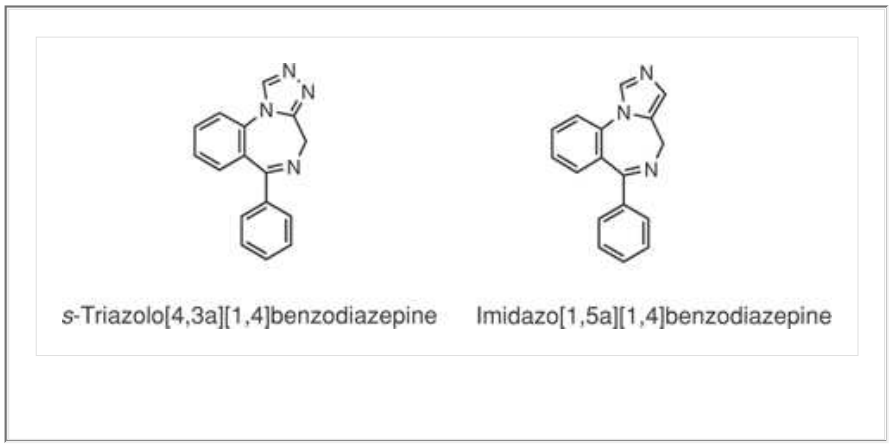
Ring B

A proton-accepting group is believed to be a structural requirement of both benzodiazepine and nonbenzodiazepine ligand binding to the $GABA_A$ receptor, putatively for interactions with a histidine residue that serves as a proton source in the $GABA_A$ α_1 subunit (119). For the benzodiazepines, optimal affinity occurs when the proton-accepting group in the 2-position of ring B (i.e., the carbonyl moiety) is in a coplanar spatial orientation with the aromatic ring A. Substitution of sulfur for oxygen at the 2-position (as in quazepam) may affect selectivity for binding to GABA BZR subpopulations, but anxiolytic activity is maintained. Substitution of the methylene 3-position or the imine nitrogen is sterically unfavorable for antagonist activity but has no effect on agonist (i.e., anxiolytic) activity (e.g., clobazam). Derivatives substituted with a 3-hydroxy moiety have comparable potency to nonhydroxylated analogues and are excreted faster. Esterification of a 3-hydroxy moiety also is possible without loss of potency. Neither the 1-position amide nitrogen nor its substituent is required for in vitro binding to the BZR, and many clinically used analogues are not N-alkylated (Fig. 22.16). Although even relatively long N-alkyl side chains do not dramatically decrease BZR affinity, sterically bulky substituents like tert-butyl drastically reduce receptor affinity and in vivo activity. Neither the 4,5-double bond, nor the 4-position nitrogen (the 4,5-[methyleneimino] group) in ring B is

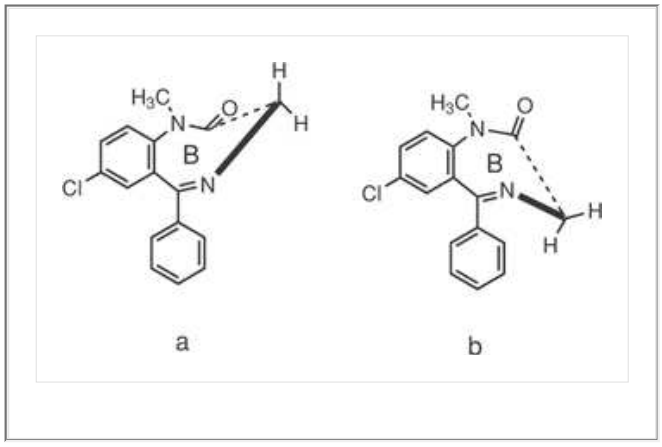
required for in vivo anxiolytic activity, albeit in vitro BZR affinity is decreased if the C=N bond is reduced to C–N. It is proposed that in vivo activity of such derivatives results from oxidation back to C=N (69). It follows that the 4-oxide moiety of chlordiazepoxide can be removed without loss of anxiolytic activity.

Ring C

The 5-phenyl ring C is not required for binding to the BZR in vitro. This accessory aromatic ring may contribute favorable hydrophobic or steric interactions to receptor binding, however, and its relationship to ring A planarity may be important. Substitution at the 4′-(para)-position of an appended 5-phenyl ring is unfavorable for agonist activity, but 2′-(ortho)-substituents are not detrimental to agonist activity, suggesting that limitations at the para position are steric, rather than electronic, in nature.



Annelating the 1,2-bond of ring B with an additional “electron-rich” (i.e., proton acceptor) ring, such as *s*-triazole or imidazole, also results in pharmacologically active benzodiazepine derivatives with high affinity for the BZR (Fig. 22.17). For example, the *s*-triazolo-benzodiazepines triazolam, alprazolam, and estazolam and the imidazo-benzodiazepine midazolam are popularly prescribed, clinically effective anxiolytic agents (Fig. 22.16).



Stereochemistry

Most clinically useful benzodiazepines do not have a chiral center; however, the 7-membered ring B may adopt one of two possible boat conformations, *a* and *b*, that are “enantiomeric” (mirror images) to each other. Nuclear magnetic resonance studies indicate that the two conformations can easily interconvert at room temperature, making it impossible to predict which conformation is active at the BZR, a priori. Evidence for stereospecificity for binding to the BZR was provided by introducing a 3-substituent into the benzodiazepine nucleus to provide a chiral center and enantiomeric pairs of derivatives (104). In vitro BZR binding affinity and in vivo anxiolytic activity of several 3-methylated enantiomers was found to reside in the *S*-isomer. Moreover, the *S*-enantiomer of 3-methyldiazepam was shown to stabilize conformation *a* for ring B, whereas the *R*-enantiomer stabilizes conformation *b*. Also, the 3-*S* configuration and *a* conformation for ring B is present in both the crystalline state (120) and in solution (121) for 3-methyldiazepam. In spite of the enantioselectivity

demonstrated for benzodiazepines, the commonly used 3-hydroxylated derivatives (e.g., lorazepam and oxazepam)

are commercially available only as racemic mixtures.

Physiochemical and pharmacokinetics

The physiochemical and pharmacokinetic properties of the various benzodiazepines vary widely, and these properties have clinical implications. For example, depending on the nature of substituents, particularly with regard to electronegative substituents, the lipophilicity of the benzodiazepines may vary by more than three orders of magnitude, affecting absorption, distribution, and metabolism of individual agents. In general, most benzodiazepines have relatively high lipid:water partition coefficients (log P values) and are completely absorbed after oral administration and rapidly distributed to the brain and other highly perfused organs. A notable exception is clorazepate, which is rapidly decarboxylated at the 3-position to N-desmethyldiazepam and, subsequently, quickly absorbed. Also, most benzodiazepines and their metabolites bind to plasma proteins. The degree of protein binding is dependent on lipophilicity of the compound and varies from approximately 70% for more polar benzodiazepines, such as alprazolam, to 99% for very lipophilic derivatives, such as diazepam. Hepatic microsomal oxidation, including N-dealkylation and aliphatic hydroxylation, accounts for the major metabolic disposition of most benzodiazepines. Subsequent conjugation of microsomal metabolites by glucuronyl transferases yields polar glucuronides that are excreted in urine. In general, the rate and product of benzodiazepine metabolism varies, depending on route of administration and the individual drug.

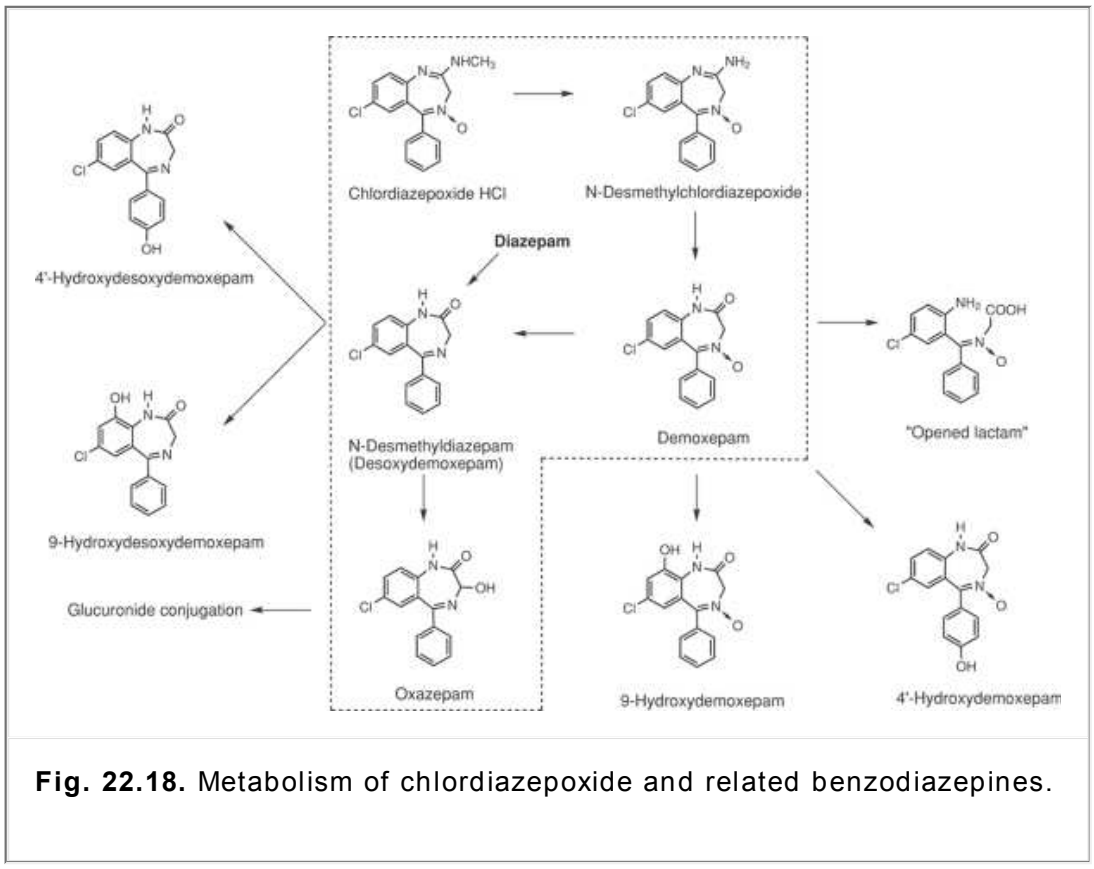


Fig. 22.18. Metabolism of chlordiazepoxide and related benzodiazepines.

Chlordiazepoxide

Chlordiazepoxide is well absorbed after oral administration, and peak blood concentration usually is reached in approximately 4 hours. Intramuscular absorption of chlordiazepoxide, however, is slower and erratic. The half-life of chlordiazepoxide is variable but usually quite long (6–30 hours). The initial N-demethylation product, N-desmethylchloridiazepoxide, undergoes deamination to form the demoxepam (Fig. 22.18), which is extensively metabolized, and less than 1% of a dose of chlordiazepoxide is excreted as demoxepam. Demoxepam can undergo four different metabolic fates. Removal of the N-oxide moiety yields the active metabolite, N-desmethyldiazepam (desoxydemoxepam). This product is a metabolite of both chlordiazepoxide and diazepam and can be hydroxylated to yield oxazepam, another active metabolite that is rapidly glucuronidated

and excreted in the urine. Another possibility for metabolism of demoxepam is hydrolysis to the “opened lactam,” which is inactive. The two other metabolites of demoxepam are the products of ring A hydroxylation (9-hydroxydemoxepam) or ring C hydroxylation (4′-hydroxydemoxepam), both of which are inactive. The majority of a

dose of chlordiazepoxide is excreted as glucuronide conjugates of oxazepam and other phenolic (9- or 4′-hydroxylated) metabolites. As with diazepam (vide infra), repeated administration of chlordiazepoxide can result in accumulation of parent drug and its active metabolites, which may have important clinical implications, including excessive sedation (4,5).

Diazepam

Diazepam is rapidly and completely absorbed after oral administration. Maximum peak blood concentration occurs in 2 hours, and elimination is slow, with a half-life of approximately 20 to 50 hours. As with chlordiazepoxide, the major metabolic product of diazepam is N-desmethyldiazepam, which is pharmacologically active and undergoes even slower metabolism than its parent compound. Repeated administration of diazepam or chlordiazepoxide leads to accumulation of N-desmethyldiazepam, which can be detected in the blood for more than 1 week after discontinuation of the drug. Hydroxylation of N-desmethyldiazepam at the 3-position gives the active metabolite oxazepam (Fig. 22.18).

Oxazepam

Oxazepam is an active metabolite of both chlordiazepoxide and diazepam and is marketed separately, as a short-acting anxiolytic agent. Oxazepam is rapidly inactivated to glucuronidated metabolites that are excreted in the urine (Fig. 22.18). The half-life of oxazepam is approximately 4 to 8 hours, and cumulative effects with chronic therapy are much less than with long-acting benzodiazepines, such as chlordiazepoxide and diazepam. Lorazepam is the 2′-chloro derivative of oxazepam and has a similarly short half-life (2–6 hours) and pharmacological activity.

Flurazepam

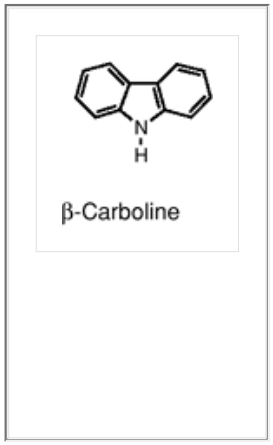
Flurazepam is administered orally as the dihydrochloride salt. It is rapidly ^{1}N-dealkylated to give the 2′-fluoro derivative of N-desmethyldiazepam, and it subsequently follows the same metabolic pathways as chlordiazepoxide and diazepam (Fig. 22.18). The half-life of flurazepam is fairly long (~7 hours); consequently, it has the same potential as chlordiazepoxide and diazepam to produce cumulative clinical effects and side effects (e.g., excessive sedation) and residual pharmacological activity, even after discontinuation. Chlorazepate is yet another benzodiazepine that is rapidly metabolized (3-decarboxylation) to N-desmethyldiazepam and so shares similar clinical and pharmacokinetic properties to chlordiazepoxide and diazepam.

Detailed pharmacokinetic analysis

Detailed pharmacokinetic analysis for most benzodiazepines is complex. Two-compartment models may be adequate to describe the disposition of most derivatives, but three-compartment models are necessary for highly lipophilic agents, such as diazepam. The distribution of such lipophilic drugs is further complicated by enterohepatic circulation. Thus, the usually stated elimination half-life of benzodiazepines may not adequately account for the pharmacodynamics of the distributive phase of the drug, which can be clinically important. For example, the distributive (α) half-life of diazepam is approximately 1 hour, whereas the elimination (β) half-life is approximately 1.5 days, acutely, and even longer after chronic dosing that results in accumulation of drug (4,5). Furthermore, plasma concentration and clinical effectiveness of benzodiazepines is difficult to correlate, and only a two-fold increase in clinically effective levels produces sedative side effects. Consequently, in spite of the long half-life of many benzodiazepines, they are not safe or effective when given in one daily dose and usually are divided into two to four doses per day for treatment of daytime anxiety (4,5). Both therapeutic and toxic effects may persist several days after discontinuation of chronically administered, long-acting benzodiazepines, such as chlordiazepoxide and diazepam. Thus, short-acting benzodiazepines, such as oxazepam, that are rapidly metabolized to inactive products should be considered in elderly or hepatocompromised patients.

Nonbenzodiazepine Agonists at the Benzodiazepine Receptor

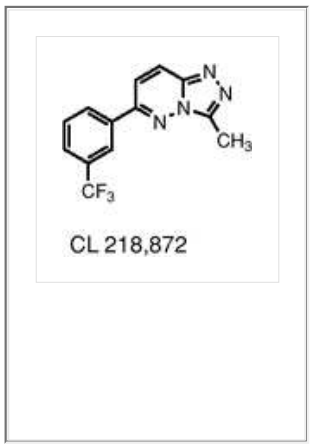
Relatively few structural classes of nonbenzodiazepine compounds have clinically relevant affinity for the BZR and show pharmacological activity in vivo. Examples of these classes include the β-carbolines, triazolopyridazines, cyclopyrrolones, pyrazolopyrimidines, and imidazopyridines. Representative drugs of these classes in current clinical use are the pyrazolopyrimidine zaleplon, the cyclopyrrolone eszopiclone, and the imidazopyridazine zolpidem. These nonbenzodiazepine BZR ligands show greater selectivity for $GABA_A$ receptors containing the α_1 subunit; however, it should be noted that the α_2, α_3, α_5, and γ subunits may be important in mediating anxiolytic effects of BRZ agonists (84).



β-Carboline

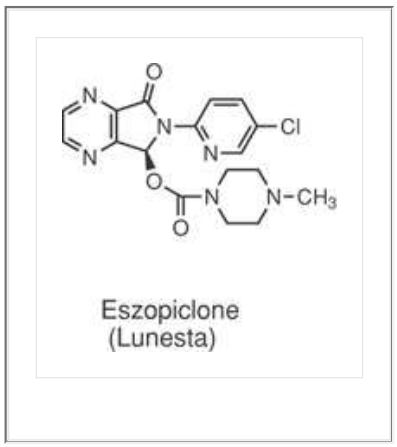
Several β-carbolines have approximately 10-fold higher affinity for the BZR when compared to diazepam. The ethyl ester of β-carboline-3-carboxylic acid (βCCE), identified in human urine extracts as an artifact of the extraction procedure, has very high affinity for the BZR. Although βCCE and other β-carbolines are not endogenous BZR ligands (vide supra) and are not currently approved for clinical use, they are used to characterize different $GABA_A$/BZR subtypes (based on *a* and *g* subunit composition) and function (e.g., the partial agonist abecarnil) toward the discovery of anxioselective drugs. In this regard, the β-carboline ring system is planar in comparison

to the boat conformation of the 1,4-benzodiazepines (see the discussion of stereochemistry); thus, β-carbolines have been useful to extend structure–activity relationship information for the agonist, antagonist, and inverse agonist pharmacophores of the various $GABA_A$/BZR subtypes.



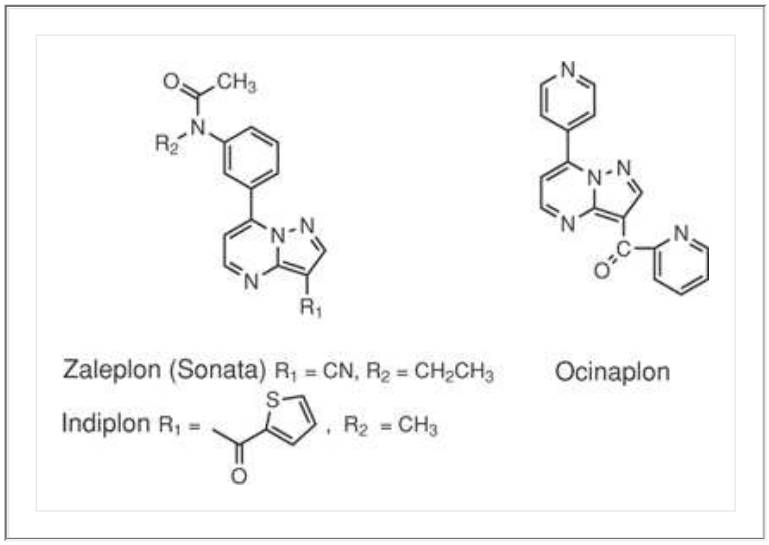
CL 218,872

The triazolopyridazine CL 218,872 is another research tool used to probe BZR heterogeneity, because it is known to have selective high affinity at BZR subtypes containing the a1 subunit, hypothesized to mediate anxioselective actions (84,122). CL 218,872 has lower efficacy than benzodiazepines in potentiating GABA-gated chloride currents, but it produces anxiolytic effects in animal models at substantially lower doses than those required to produce untoward side effects (e.g., sedation, ataxia, and muscle relaxation) (78,122).



Eszopiclone

The cyclopyrrole zopiclone is described as a "superagonist" at BZRs with the subunit composition $\alpha_1\beta_2\gamma_2$ and $\alpha_1\beta_2\gamma_3$, because it potentiates the GABA-gated current more than the benzodiazepine (flunitrazepam) reference agonist (123). Racemic zopiclone has been available in Europe since 199,2 and the higher affinity *S*-enantiomer (eszopiclone) was marketed in the United States in 2005, primarily to treat insomnia, because of its rapid onset and moderate duration (half-life, ~6 hours) of hypnotic-sedative effect (124). Less than 10% of orally administered eszopiclone is excreted unchanged, because it undergoes extensive CYP3A4- and CYP2E1-catalyzed oxidation and demethylation to metabolites excreted primarily in urine.

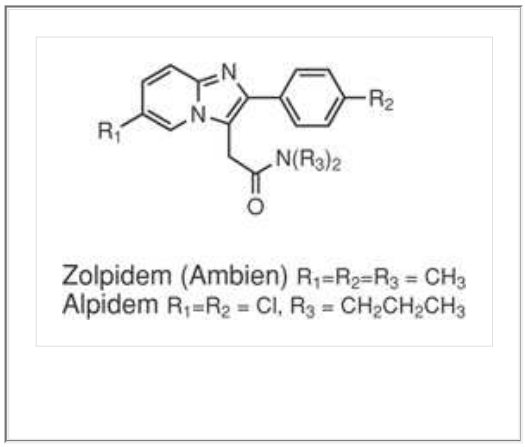


Pyrazolopyrimidines

The pyrazolopyrimidines zaleplon, indiplon, and ocinaplon have selective high affinity for α_1-containing BZRs but also produce effects at other BZR/$GABA_A$ subtypes. Animal studies show that both zaleplon and indiplon are effective sedative-hypnotics (125). In patients with insomnia, zaleplon is effective to decrease sleep latency and does not appear to induce withdrawal symptoms or rebound insomnia on discontinuation. Indiplon is similar and currently under review by the U.S. FDA. Zaleplon is absorbed rapidly and reaches peak plasma concentrations in approximately 1 hour, with a half-life approximately 1 hour as well. Less than 1% of a dose of zaleplon is excreted unchanged, because most is oxidized by aldehyde dehydrogenase and CYP3A4 to inactive metabolites, which are converted to glucuronides and eliminated in urine.

Ocinaplon, on the other hand, is being studied for its putative anxioselective activity rather than for its sedative effects. In rats, ocinaplon produces muscle relaxation, ataxia, and sedation only at doses 25-fold higher than the effective anxiolytic dose (122). Likewise, in patients with generalized anxiety disorder, ocinaplon produces anxiolytic effects at doses that do not cause greater incidence of sedation or dizziness than placebo. As a group, the pyrazolopyrimidines may be useful compounds to study discrepancies observed using molecular ($GABA_A$ subunit-selective) approaches versus transgenic animals and other in vivo models in the quest for anxioselective drugs. For example, for some compounds, partial agonism at a particular α subunit may be sufficient to produce a

full anxiolytic activity in vivo, whereas other compounds must be full agonists for clinically relevant anxiolysis. Currently, it appears that high relative potency and high relative efficacy at multiple receptor subtypes can account for anxioselective properties of certain compounds, including for ocinaplon (122), which currently is under U.S. FDA review.



Imidazopyridines

The imidazopyridines, zolpidem and alpidem, represent another example of α_1 subunit-selective BZR/$GABA_A$ ligands that have clinical profiles different from those of typical benzodiazepines. For example, although the agonist effects of zolpidem on $GABA_A$ receptors qualitatively resemble those of benzodiazepines, clinically it shows a weaker anticonvulsant effect and a stronger sedative effect, which may mask anxiolytic effects. Zolpidem was marketed as a sedative-hypnotic in the United States in 1993, and it appears to be effective in shortening sleep latency and prolonging total sleep time, without affecting sleep stages, in patients

with insomnia (126). Zolpidem is readily absorbed from the gastrointestinal tract and is extensively metabolized by the liver to inactive oxidized products, with a half-life of approximately 2 hours. Alpidem is similar to zolpidem in that it apparently induces no significant changes in sleep parameters (127) and has no effect on memory or muscle tone (128). Alpidem was found to be of at least equal efficacy to lorazepam in the treatment of patients with generalized anxiety disorder (129); however, it recently was withdrawn because of hepatotoxicity (130).

$GABA_A$ Partial Allosteric Modulators

Partial agonists of the $GABA_A$ receptor complex offer some theoretical and practical advantages over full agonists. For example, compared to the benzodiazepine-type full agonists, partial agonists seem to have lesser side effects, such as sedation, ataxia, and potentiation of alcohol. Also, there may be less abuse potential associated with partial agonists. Three partial agonists of $GABA_A$ receptors currently are being investigated: imidazenil, bretazenil, and abecarnil (Fig. 22.19). Abecarnil is reported by some investigators to have preferential affinity for BZR/$GABA_A$ α_1 subunits, whereas imidazenil and bretazenil are not subtype selective. In any event, abecarnil as well as bretazenil exhibit anxioselectivity in animal models, but data from clinical trials do not support the anxioselective profile predicted from preclinical results (84).

Imidazenil is an imidazobenzodiazepine carboxamide that has higher BZR affinity than diazepam but is only about half as efficacious at modulating GABA effects on chloride currents. Consistent with the general pharmacological principle that partial agonists may show antagonist functional effects in competition with a more efficacious agonist, imidazenil blocks the sedative and ataxic effects of diazepam (131). Interestingly, however, imidazenil does not block the anticonvulsant effects of diazepam; accordingly, it has been proposed as an alternative to flumazenil in the alleviation of benzodiazepine-induced withdrawal symptoms (131). Bretazenil has qualitatively similar binding and clinical characteristics as imidazenil (132). Its anxiolytic activity comes with significant sedation, however, and this led to discontinuation of its development. Abecarnil is a β-carboline with anxiolytic properties. Typical of other partial allosteric modulators, abecarnil demonstrates antianxiety and anticonvulsant activities, with little or no development of tolerance to these effects (133). Like bretazenil, however, doses of abecarnil required to produce anxiolysis also produce sedation, and it is unlikely that this drug lead will be developed (84).

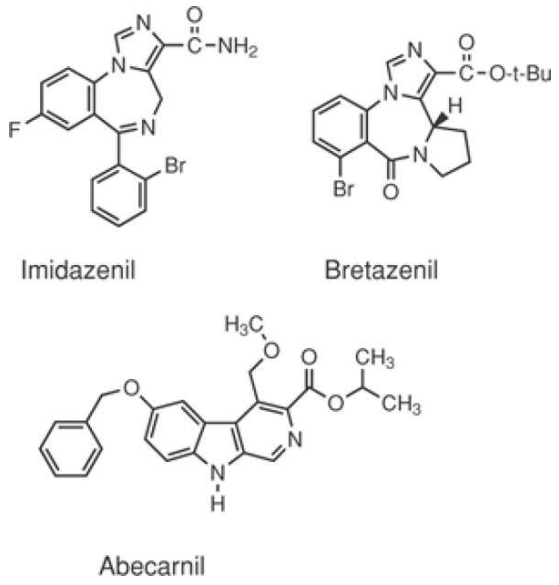


Fig. 22.19. Structures of γ-aminobutyric acid$_A$ (GABA$_A$) receptor partial agonists.

Miscellaneous Anxiolytic Agents

Serotonin receptor–active agents

In the development of anxiolytic agents that do not act via the GABA$_A$ receptor complex, serotonin receptors have been the focus of intensive research in recent years, because preclinical and clinical evidence supports the involvement of serotonin in anxiety (134,135). For example, serotonin 5-HT$_{1A}$ receptors are found in relatively high density in the septohippocampal region of the brain, which is involved in the modulation of anxiety (136). In the structures of the limbic system, 5-HT$_{1A}$ receptors are predominantly postsynaptic, whereas presynaptic 5-HT$_{1A}$ are found in the dorsal and median raphe nuclei. Presynaptic 5-HT$_{1A}$ receptors function as autoreceptors to inhibit serotonergic neurotransmission, and postsynaptic receptor activation also results in decreased neuronal activity.

The pyrimidinylbutylpiperazines (azapirones), buspirone, ipsaperone, and gepirone (Fig. 22.20) partial agonists at brain 5-HT$_{1A}$ receptors and have anxiolytic activity in humans (135,137). Their anxiolytic effects appear only after several days of treatment, and although it is well

established that agonistic activity is required, the optimal level of intrinsic activity is still a matter of debate. Thus, it is unclear whether their mechanism of action is to acutely increase serotonergic activity or chronically decrease serotonergic activity (138). Buspirone is the only one of these agents currently marketed in the United States. It also has antidopaminergic activity that complicates interpretation of its interaction with 5-HT$_{1A}$ receptors regarding anxiolytic effects. In any event, busiprone is shown to be effective in the treatment of generalized anxiety disorders that are mild to moderate in severity, but it is not useful for severe anxiety (e.g., with panic attacks).

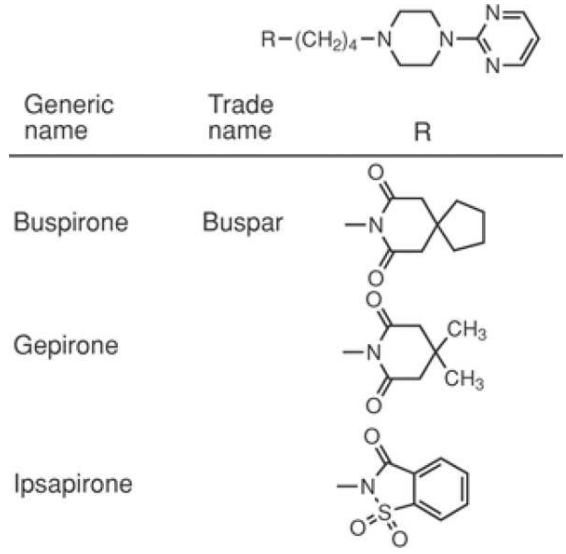

Fig. 22.20. Structures of 5-HT_{1A} partial agonists.

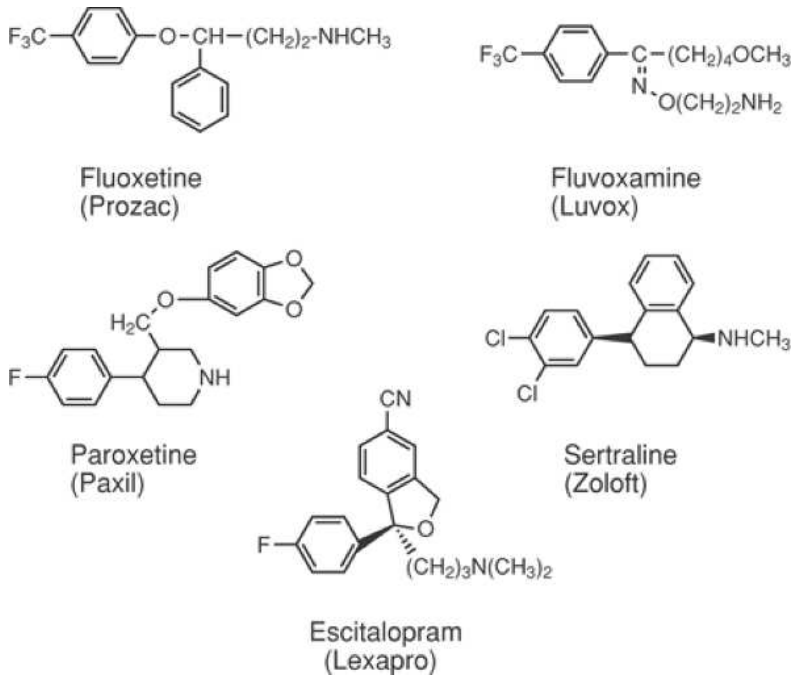

Fig. 22.21. Structures of the selective serotonin reuptake inhibitors (SSRIs) fluoxetine, fluvoxamine, paroxetine, sertraline, and escitalopram.

Serotonin reuptake inhibitors

Several selective serotonin reuptake inhibitors (SSRIs), including escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline (Fig. 22.21), are effective as first-line treatment of some anxiety disorders, with the purported advantage that they lack the addictive properties of benzodiazepines (135). Specifically, the SSRIs have been shown to be effective in obsessive-compulsive disorder (139), panic disorder (140), and social phobia (141). The mechanism of action of these agents in anxiety may differ with their role in the treatment of depression; however,

current understanding centers on functional imaging studies that show SSRI treatment can dampen brain excitability (135).

Acknowledgment

The author wishes to express his gratitude to Drs. John L. Neumeyer and Ross J. Baldessarini for the training and guidance involved in preparing this chapter.

Case Study

Victoria F. Roche

S. William Zito

RP is a 45-year-old Caucasian male whose increasingly impulsive, agitated, and antisocial behaviors have culminated in a diagnosis of schizophrenia. This is a particularly difficult situation given that for the past several years, he has been exhibiting symptoms of premature Parkinson's disease, with gait and balance being his most adversely affected abilities. RP's Parkinson's disease is currently being treated with levodopa/carbidopa (Sinemet 25/100 t.i.d.), although he is still experiencing periods of rigidity and unsteadiness in his movements. He is of the poor 2D6 metabolizer phenotype but the compounds in Sinemet (the only drug he is taking) are known to be metabolized by CYP2D6.

RP is single and, since the onset of the Parkinson's disease, has lived with his brother's family, which includes his wife and 6-year-old twin boys. He has a high school education and contributes to the household income through his job as a host at a nearby pancake restaurant. In the small Midwestern community in which he lives, he has received emotional support from his friends and neighbors (including those who frequent the restaurant), but there is concern about the impact of this new diagnosis on his ability to retain his job, particularly because he has recently had his first auditory hallucination. In addition, RP's sister-in-law is becoming concerned about the impact of his behavior on her two young sons. Consider the structures of the antipsychotic agents drawn below, and prepare to make a recommendation to RP's psychiatrist.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure-activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 23

Hallucinogens, Stimulants, and Related Drugs of Abuse

Richard A. Glennon

Psychotomimetic/Hallucinogenic Agents

Introduction

Why study psychotomimetic agents? In the past, it was argued that investigations of such agents might shed light on mental illness and its treatment. Although studies with psychotomimetic agents have certainly contributed to our understanding of these disorders, it is now recognized that there are many kinds of mental illnesses and that the actions—and putative mechanisms of action—of psychotomimetic agents are only tangentially related to their etiology or treatment. It also has been argued that investigations of psychotomimetic agents might contribute to a greater general understanding of basic neurochemical mechanisms and neurotransmitter function. This research approach has been more rewarding. Studies with psychotomimetic agents have contributed significantly to what is currently known about G protein–coupled receptors (e.g., cannabinoid receptors and serotonin receptors) and ion channel receptors (e.g., phencyclidine [PCP] receptors and excitatory amino acid receptors). Subsequent work with these receptors has identified new receptor subtypes that are being targeted for the development of novel therapeutic agents. Indeed, the past 10 years have witnessed an explosion of interest in the investigation of psychoactive substances because of their relevance to neurochemical mechanisms. Perhaps the most important reason to study psychotomimetic agents, however, is because these agents represent a large group of abused substances, and pharmacists generally serve as one of the first lines of defense for the dissemination of drug abuse prevention and treatment information. In addition, the past one or two decades have seen the popularization of controlled substance analogues (i.e., designer drugs), and the future will likely witness the introduction of yet more designer drugs. So, a second reason to study these agents is to prepare for the future: An understanding of the presently available agents and their structure–activity relationships (SARs) will be instructive, because many designer drugs result from the clandestine application of these same structure–activity principles at the street level. Lastly, some agents currently in clinical use possess an abuse liability that should be recognized. An understanding of how these drugs of abuse work can lead to new treatment modalities.

Definitions and Classification

"Psychotomimetic" and "hallucinogenic" are commonly used terms, and they frequently are used interchangeably. Little agreement, however, exists regarding what constitutes such agents or exactly what they do. Because the actions of these agents are largely subjective, the best information should come from those who are experiencing the agents, yet by experiencing their effect, one may not be in a position to accurately describe the effects they produce (1). In contrast, an outside observer can never fully and accurately describe the effects of the agents. This has led to problems of definition. Perhaps the best and most widely accepted definition of a psychotomimetic substance is that provided by Hollister (2): Psychotomimetic/hallucinogenic agents are those that on administration of a single effective dose consistently produce changes in thought, mood, and perception with little memory impairment; produce little stupor, narcosis, or excessive stimulation; produce minimal autonomic side effects; and are nonaddicting. Although certain opioid analgesics occasionally produce psychotomimetic effects, they are effectively eliminated from this category of agents, because they do not meet the necessary criteria (e.g., they can be addicting). Likewise, chronic administration of high doses of stimulants, such as amphetamine and cocaine, sometimes produce hallucinogenic episodes (i.e., amphetamine psychosis and cocaine psychosis). These agents are not considered to be hallucinogens, however, because multiple doses typically are required to produce this effect. The Hollister criteria have served a very useful function in narrowing the list of agents that belong to this category of drugs. Nevertheless, Hollister was still able to identify several classes of psychotomimetic agents: lysergic acid derivatives (e.g., lysergic acid diethylamide [LSD]), phenylethylamines (e.g., mescaline), indolealkylamines (e.g., N,N-dimethyltryptamine), other indolic derivatives (e.g., ibogaine and the harmala derivatives), piperidyl benzilate esters (e.g., JB-329), phenylcyclohexyl compounds (e.g., PCP), and miscellaneous agents (e.g., kawain, dimethylacetamide, and cannabinoids) (2).

Over time, it has been demonstrated that psychotomimetic agents represent a behaviorally heterogeneous class of psychoactive agents. For example, human subjects can differentiate between the actions produced by certain compounds in this category, and cross-tolerance develops among some of these agents but not between others. Likewise, it is possible to differentiate between certain of these agents using various animal procedures. Subcategorization was necessary. Today, it is recognized that some hallucinogens act primarily via a serotonergic

mechanism, that the cannabinoids probably produce their behavioral effects via cannabinoid receptors, and that PCP likely produces its effects via PCP receptors. This is not to imply that a full understanding of how these agents work now exists, but it does support

the concept that the agents do not belong to a homogeneous mechanistic class.

Human Versus Animal Studies: Applicability of Animal Models

Human subjects should be best suited to provide the most reliable assessment of the actions and potency of psychotomimetic agents, and considerable human data are available for some agents. Much less information, however, is available for most. Often, what information is available comes from studies that were not well controlled, that included limited subject populations, or that investigated only a few drug doses. Some of what is known even comes from anecdotal reports. Very few clinical studies with psychotomimetic agents were sanctioned following the early 1960s. Although some limited human evaluation has been allowed since in the early 1990s, for a period of approximately 30 years information concerning psychotomimetic substances relied—and continues to rely—heavily on the use of animal studies. This raises several questions: Do animal models exist that can accurately reflect human hallucinogenic activity? Indeed, do animals hallucinate? Many attempts have been made to develop animal models of psychotomimetic or hallucinogenic activity, but to date, no single animal model accounts for the actions of these agents as a class (3).

drug discrimination paradigm

One animal technique that has seen widespread application for the investigation of psychoactive agents is the drug discrimination paradigm (4). It must be emphasized at the outset that this method does not represent a model of psychotomimetic activity. Indeed, the technique has general applicability and has been employed to study a wide variety of centrally acting agents, including stimulants, barbiturates, anxiolytics, opiates, and many other drug classes. The technique may be viewed as a “drug detection” procedure. Specifically, animals (typically rats, pigeons, or monkeys) are trained to recognize or discriminate the stimulus effects of a training drug from vehicle; humans also have been used as subjects in some drug discrimination studies. Many centrally acting agents produce an interoceptive cue or stimulus that that subjects recognize. When animals are used, they are taught to make a particular response (e.g., to respond on one lever of a two-lever operant apparatus or Skinner box) when administered a training drug and to make a different response (e.g., to respond on the second of the two levers) when administered saline vehicle. After a period of time, the animals learn the stimulus cue and associate it with one of the two levers; that is, the animals make more than 80% of their responses on the training-drug lever (i.e., >80% drug-appropriate responding) when administered the training dose of the training drug and less than 20% of their responses on the same lever when administered vehicle. Doses of training drug less than those of the training dose result in a decrease in percentage drug-appropriate responding. The effect is dose related, and a dose–response curve can be constructed. A median effective dose (ED50) also can be calculated as a measure of potency.

Once trained, these animals can be used in what are referred to as tests of substitution or stimulus transfer or, more commonly, as tests of stimulus generalization. In such tests, other agents (i.e., challenge drugs) are administered to the animals to determine if they produce stimulus effects similar to those of the training drug. Stimulus generalization is said to have occurred when animals make more than 80% of their responses on the training drug–appropriate lever following administration of some dose of challenge drug. Stimulus generalization or substitution implies that the challenge drug and the training drug are producing similar stimulus effects in the animals. It should be noted that no claim has ever been made that the agents—the training drug and a challenge drug—are producing identical effects; rather, there is an implication that the agents are capable of producing a common stimulus effect or a behavioral cue common to the two agents (e.g., a drug that produces effects A and B may be recognized by animals trained to a drug that produces effects B and C; although this may not be a common occurrence, it should be recognized that it is possible). Thus, not only is it possible to determine if two agents are producing similar stimulus effects, it also is possible to compare their relative potencies by calculating an ED50 for the challenge drug.

Other studies that can be conducted are tests of stimulus antagonism. That is, a specific training drug can be administered together with another agent; if the combination results in less than 20% training drug–appropriate responding, stimulus antagonism is said to have occurred. Although this technique can be employed in the development of novel antagonists for a series of agents for which an antagonist is unknown, it is more common to use a receptor-selective antagonist to investigate mechanisms of action. Drug discrimination, then, is a very powerful tool for investigating the actions and mechanisms of action of many different kinds of centrally acting agents. Specific examples of stimulus generalization and stimulus antagonists will be described later.

The drug discrimination procedure has seen broad application in the investigation of centrally acting agents, and a wide variety of different training drugs has been employed. When a psychotomimetic agent is used as the training drug, it should be possible to identify other agents that produce similar stimulus effects (5). In this manner, it has

been demonstrated that the psychotomimetics represent a behaviorally heterogeneous group of agents, much in the same way that humans have been able to differentiate the effects of these agents. Animals trained to discriminate LSD, for example, do not recognize PCP, and animals trained to discriminate PCP do not recognize LSD. Neither LSD-

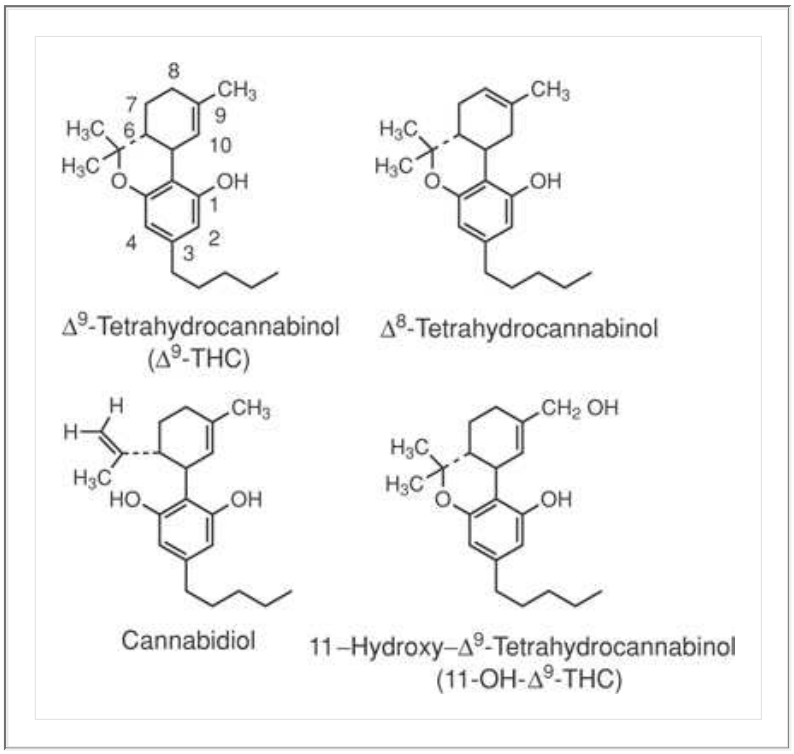
nor PCP-trained animals recognize tetrahydrocannabinol (THC). However, LSD-trained animals recognize mescaline, 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane (DOM), and certain other hallucinogens. Using this technique, then, it has been possible to identify what are termed the "classical hallucinogens" (6). The classical hallucinogens are LSD-like agents that share common stimulus properties and that may act via a common mechanism of action. The remaining psychotomimetic agents will be referred to here as nonclassical agents; these groups of agents act by different mechanisms and produce distinct effects common to members within each group.

Psychoactive Drugs of Abuse: Nonclassical Hallucinogens

The term "nonclassical hallucinogen" is used here to differentiate these psychoactive agents from the classical hallucinogens that will be discussed later in this chapter. Several categories of agents are described, but there is no implication that these classes produce similar effects or act via similar mechanisms.

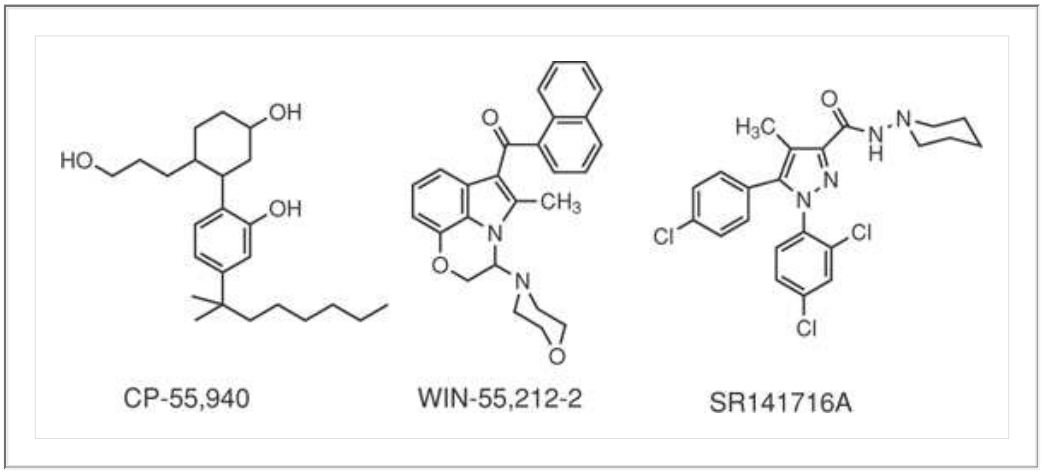
Cannabinoids

The marijuana or cannabis plant represents one of the oldest and most widely used psychoactive substances in the world. Botanically, there are three major species of the plant—*Cannabis sativa, Cannabis indica*, and *Cannabis ruderalis*—and cannabis has been cultivated since approximately 6,000 BC. Reference is made to three preparations, listed here in order of increasing potency: bhang, ganja, and hashish. Bhang typically refers to the leaves and stems of the plant, ganja is prepared from the flowering tops of the plant, and hashish is the pure resin. Although marijuana is active orally, inhalation by smoking is a more frequently used route of administration. One of the major active constituents of the plant is Δ^9-THC (often referred to simply as THC). THC is rapidly and efficiently absorbed by inhalation; it is absorbed into body tissue and slowly released back into circulation. Deuterium-labeled THC has been detected in human plasma up to nearly 2 weeks postadministration. A major metabolite of THC is 11-hydroxy-Δ^9-THC. Evidence suggests that tolerance develops to THC and that THC does not generally lead to physical dependence. Marijuana can produce impairment of performance, memory, and learning; controversy exists over whether it produces an amotivational syndrome. There are many claims for the medicinal use of marijuana and THC.



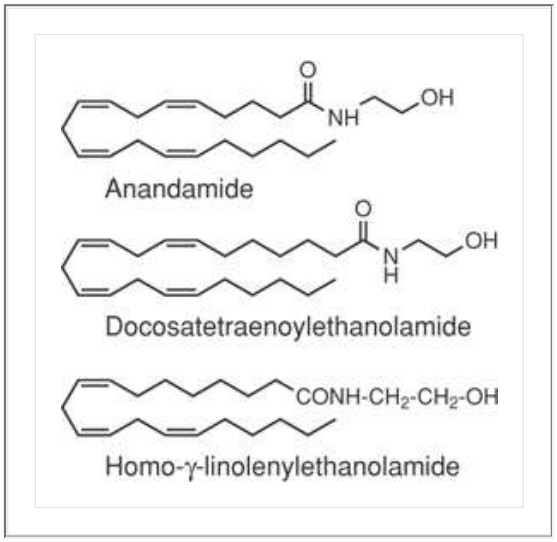
Over the years, many cannabinoids and related structures, such as CP-55,940, were synthesized and evaluated. Noncannabinoids, such as WIN-55,212-2, also were shown to possess THC-like actions. Few compounds displayed cannabinoid antagonist properties, and an extensive search was conducted to find possible candidates that would be

useful for better defining the actions of THC. A number of compounds were explored, and the pyrazole analogue SR141716A (rimonabant) has been found to be one of the most effective. SR141716A attenuates the effects of WIN-55,212-2 and THC (7) as well as the stimulus effects of THC. Thus, in addition to cannabinoids and cannabinoid-related structures such as CP-55,940, there are other structural classes of cannabinoid ligands, including indolic derivatives such as WIN-55,212–2, pyrazoles such as SR141716A, and fatty acid derivatives such as anandamide (discussed below).



Mechanism of action

For many years, it was thought that cannabinoids were acting in a nonspecific manner, but in the early 1990s, two populations of cannabinoid receptors were identified: CB-1, and CB-2 (8,9). Human forms of these receptors have been cloned. Both types are G protein–coupled, seven-helix transmembrane-spanning receptors. These receptors are differentially expressed: CB-1 receptors, which may mediate the psychoactive effects of THC-related agents, are found primarily in the brain, whereas CB-2 receptors, which possibly are involved in immunomodulatory actions, are found almost exclusively in the periphery. The identification of such receptors suggested the possible existence of endogenous ligands, and claims for several have been published. The best investigated of these is the eicosanoid derivative arachidonylethanolamide or anandamide, which initially was isolated from porcine brain. Anandamide (K_i = 52 nM) binds at CB-1 receptors with an affinity similar to that of THC (46 nM) (10). Related structures also have been detected in brain, including docosatetraenylethanolamide (K_i = 34.4 nM) and homo-γ-linolenyllathanolamide (K_i = 53.4 nM) (10). A related compound, palmitoylethanolamide, may show selectivity for CB-2 receptors. Anandamide seems to be a THC-like agent. Although the actions of anandamide may not be identical to those of THC, particularly regarding in vivo studies, differences may be related to the metabolic instability of anandamide. For example, in drug discrimination studies, a THC stimulus failed to consistently or reliably generalize to anandamide; however, the more metabolically stable methanandamide, a chain-methylated analogue of anandamide, produced THC-like effects. Furthermore, methanandamide has been used as a training drug, and the methanandamide stimulus generalizes to THC (11).

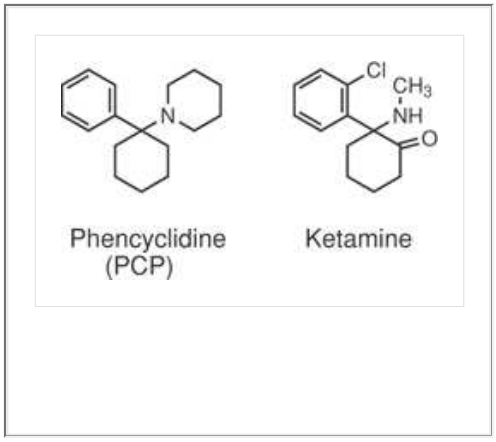


Structure–activity relationships

Structure–activity relationships both for THC-like actions and for CB receptor binding have been formulated (7). Structure–activity studies can be discussed on the basis of several different types of behavioral assays in rodents, and it has been shown for 60 cannabinoids that behavioral potencies are highly correlated with receptor binding affinities (12). THC-like discriminative effects probably offer a more specific method of detecting and measuring cannabimimetic effects and are particularly useful for formulating SARs (4). Using this approach, it has been demonstrated that SARs for THC-like stimulus effects are not necessarily identical to those for the analgesic, antiemetic, or anticonvulsant actions of cannabinoids. An early study showed that animals trained to discriminate intraperitoneal dosing of THC recognized hashish smoke and that animals trained to discriminate hashish smoke recognized THC, supporting the concept that THC likely accounts for the stimulus actions of hashish. A number of cannabinoids now have been evaluated. Cannabidiol, for example, does not produce THC-like stimulus effects. Relative to Δ^9-THC (ED50 = 0.43 mg/kg IP), some 11-hydroxy metabolites are quite potent, such as 11-OH Δ^9-THC (ED50 = 0.10 mg/kg) and 11-OH Δ^8-THC (ED50 = 0.38 mg/kg). One of the more potent cannabinoids is Δ^8-THC-DMH (ED50 = 0.05 mg/kg), in which the 4-pentyl moiety of THC has been replaced with a 1,1-dimethylheptyl (i.e., DMH) group; its 11-hydroxyl analogue, 11-OH Δ^8-THC-DMH (ED50 = 0.002 mg/kg), is even more potent (4). One of the most extensively studied cannabinoid ligands is WIN-55,212-2 (13). Molecular modeling and site-directed mutagenesis studies suggest that cannabinoids, CP-55,940, and anandamide bind in a similar fashion but in a manner that differs from the binding of WIN-55,212-2. Two distinct pharmacophores have been proposed (13,14). Attempts also are being made to identify CB-1 versus CB-2 pharmacophoric features (14).

The discovery of CB receptors, and novel chemical tools with which to investigate these receptors (7,15), has generated renewed interest in the cannabinoids; in fact, during the past 18 months as of this writing, more than 600 scientific papers have been published regarding cannabinoid research. In particular, the discovery of cannabinoid antagonists, endogenous cannabinoids, subpopulations of CB receptors, and agents showing selectivity for the two subpopulations finally promise that the mechanism of action of THC will be unraveled and that novel therapeutic agents lacking THC's psychoactive effects will be developed. For example, cannabinoid receptor agents might be of value in the treatment of glaucoma, spasticity associated with multiple sclerosis, Tourette's syndrome, neuropathic pain, Parkinson's disease, epilepsy, drug abuse, immune disorders, and several types of neuropsychiatric disorders (16). Because THC has been shown to result in decreased appetite, cannabinoids also have been examined for the control of appetite. Currently, SR141716A (rimonabant) is in late-phase clinical trials for the treatment of obesity (17).

PCP-Related Agents



Phencyclidine, or 1-(1-phenylcyclohexyl)piperidine (PCP), was introduced as a dissociative anesthetic during the late 1950s. Shortly after its introduction, clinical studies were terminated because of the occurrence of schizophrenic-like psychotomimetic effects, particularly during emergence from anesthesia. This might have been the end of the story except that 1) additional attempts were made to exploit the anesthetic effects of PCP, leading to the development of novel agents, such as ketamine; 2) it was theorized that PCP-like states might provide a good model for investigating schizophrenia, leading to studies of PCP's mechanism of action; and 3) PCP (e.g., “Angel Dust”), administered by inhalation, injection, or smoking (as with PCP-laced parsley, tobacco, or marijuana), and ketamine (e.g., “Special K”) emerged as drugs of abuse, leading to investigations of their abuse liability. Shortly thereafter, it was discovered that PCP behaves as an N-methyl-D-aspartate (NMDA) antagonist. Because NMDA receptors had been implicated in seizures and trauma, PCP and related arylcycloalkylamines were explored as potential antiepileptics and

neuroprotective agents.

Actions

In humans, PCP can produce disorientation, confusion, incoordination, delirium, impaired memory, and euphoria (18). Additionally, PCP has a history of producing aggression and violent behavior. Because PCP often is consumed together with other substances, however, it sometimes has been difficult to establish exactly which effects are produced by PCP and which may be related to possible drug interactions. PCP has seen extensive investigation in animals, and it appears to produce effects similar to those of amphetamine-like stimulants and central depressants. PCP is self-administered by animals, and tolerance develops to the behavioral effects of PCP on repeated exposure to the drug (18). PCP has both direct and indirect effects on dopaminergic systems; this may account, at least in part, for some of the amphetamine-like effects of PCP and may contribute to the production of its schizophrenic-like actions. The PCP model of schizophrenia was particularly attractive, because PCP seemed to produce both the positive and negative symptoms associated with this disorder. PCP also has been widely investigated as a training drug in animals during drug discrimination studies.

Mechanism of action

N-Allylnormetazocine (NANM; SKF-10047) produces some effects reminiscent of those produced by PCP. At one time, NANM was considered a prototypic σ opiate receptor ligand. It is now recognized that the σ receptors likely are not a class of opioid receptors and that the low-affinity NANM is only one of very few opiates that bind at these receptors. Subsequent structure–activity studies showed that NANM simply possesses certain minimal pharmacophoric features that are required for σ receptor binding (19). Nevertheless, the behavioral similarities between NANM and PCP led to early investigations regarding the binding of PCP at σ receptors. and because of its affinity (albeit low) for these receptors, the σ receptors were renamed NANM-PCP receptors, or σ/PCP receptors. This confusion continued for several years, until it was demonstrated that agents with much higher affinity and selectivity than PCP for σ receptors failed to produce PCP-like actions in animals (18). Later, it was shown that PCP antagonizes the effects of the excitatory amino acid NMDA. [^{3}H]PCP has been used to label putative PCP binding sites, and PCP binding and NMDA binding has displayed similar regional distribution in brain. It is established that PCP is a noncompetitive NMDA receptor antagonist.

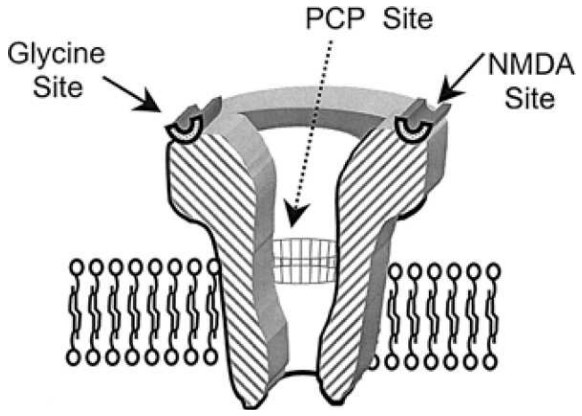


Fig. 23.1. NMDA ion channel receptor showing binding sites for glycine, NMDA, and PCP.

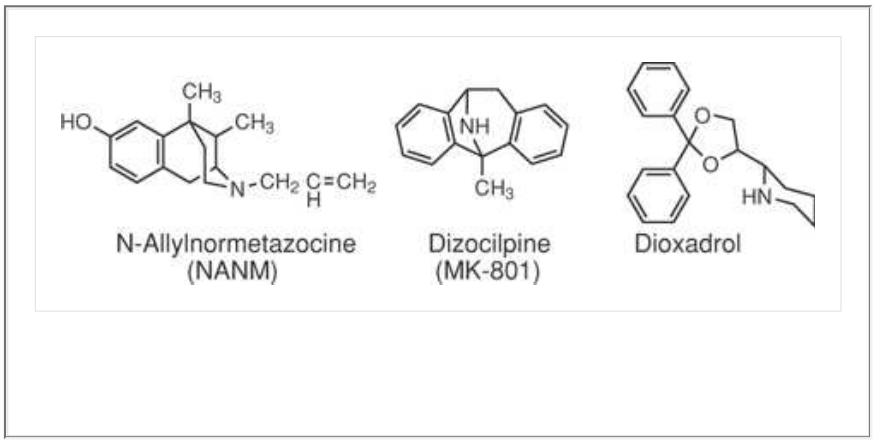
The NMDA receptor (Fig. 23.1) is a ligand-gated ion channel receptor that regulates the flow of cations (Na^+, Ca^{2+}) into certain neurons. The receptor complex possesses multiple binding sites, similar to the benzodiazepine/γ-aminobutyric acid (GABA) receptor complex, that allows the binding of glutamate, glycine, polyamines, and other ligands that can modulate the actions of NMDA. Like the NMDA antagonist dizocilpine (MK-801), PCP binds at a site (i.e., the PCP site) that is believed to be located within the ion channel. Drug discrimination studies have shown that PCP-trained animals recognize NMDA antagonists that bind at PCP receptors; for example, MK-801 is nearly 10-fold more potent than PCP. Furthermore, animals trained to discriminate MK-801 recognize PCP and other PCP-related agents. Consistent with early findings that PCP produces a psychotic state in humans, PCP has been shown to produce a pattern of metabolic, neurochemical, and behavioral changes in animals that reproduce almost exactly those seen in patients with schizophrenia. Consequently, this provides new insight regarding the mechanisms

underlying such disorders, and it offers an animal model for the evaluation of novel antipsychotic agents (20).

Structure–activity relationships

Structure–activity relationships for PCP-like actions have not been particularly well defined, and what little is known stems primarily from drug discrimination studies. The PCP stimulus does not generalize to opioids, sympathomimetic stimulants, anticholinergic agents, or classical hallucinogens and only partially generalizes to depressants, such as barbiturates; in

general, the stimulus properties of PCP are not shared by members of other drug classes (21). The PCP stimulus generalizes to ketamine and other structurally related derivatives of PCP, such as TCP, an analogue of PCP in which the phenyl ring has been replaced by the isosteric 2-thienyl group.



PCP does not possess a chiral center. Several 1,3-dioxolanes possessing an asymmetric center produce PCP-like effects and have proven to be useful for investigating PCP-like actions. Dioxadrol, or 2-(2,2-diphenyl-1,3-dioxolan-4-yl) piperidine, and etoxadrol (i.e., dioxadrol in which one of the phenyl groups has been replaced by an ethyl group) are examples of such dioxolanes. The (+)-isomer of dioxadrol, dexoxodrol, but not the (–)-isomer levoxadrol, binds at PCP receptors and is recognized by PCP-trained animals (21).

Psychoactive Drugs of Abuse: Classical Hallucinogens

Classical hallucinogens are agents that meet the Hollister definition (2) and, in addition, bind at 5-HT_2 serotonin receptors and are recognized by DOM-trained animals in tests of stimulus generalization (5). The classical hallucinogens all possess the general structure Ar-C-C-N, where Ar is a substituted phenyl, 3-indolyl, or substituted 3-indolyl moiety; C-C is an ethyl or branched ethyl chain; and N is a primary, secondary, or tertiary amine. This will be further discussed. (See Chapter 14 for additional information on serotonin receptors.)

Classification

There are two major structural categories of classical or arylalkylamine hallucinogens: the indolealkylamines, and the phenylalkylamines. The indolealkylamines are further divided into the simple N-substituted tryptamines, the α-alkyltryptamines, the ergolines (or lysergamides), and tentatively, the β-carbolines. The phenylalkylamines consist of the phenylethylamines and the phenylisopropylamines. In humans, examples from the different categories seem to produce similar effects. It should be noted, however, that relatively few agents have been examined in comprehensive and carefully controlled clinical situations. Furthermore, no claim is made that these agents produce identical effects in humans. Each category—and, indeed, even certain examples from within a given category—may produce effects that make them somewhat different from the others. As if to underscore the behavioral similarity among these agents, however, examples from each of the above categories produce common DOM-like stimulus effects in animals (Table 23.1).

Table 23.1. Results of Stimulus Generalization Studies with Examples from the Various Categories of Classical Hallucinogens Using Animals Trained to Discriminate DOM from Vehicle

Category	Examplea	ED50 Value for DOM-Stimulus Generalization (mg/kg)b

N-Alkyltryptamines	DMT	5.8
α-Alkyltryptamines	α-MeT	3.1
Lysergamides	(+)LSD	0.05
β-Carbolines	Harmaline	6.2
Phenylethylamines	Mescaline	14.6
Phenylisopropylamines	DOB	0.2

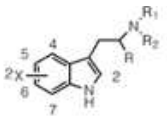
Indolealkylamines

N-Alkyltryptamines

One of the best-investigated hallucinogens is N,N-dimethyltryptamine (DMT) (Table 23.2), which is considered to be the prototype of this subclass of agents. Although readily synthesized in the laboratory, DMT also is a naturally occurring substance. Its actions are characterized by a rapid onset (typically <5 minutes) and short duration of action (~30 minutes). Like some other members of this family, DMT is not active via oral administration; it generally is administered by inhalation or by smoking. Although less common, DMT also can be injected. Some indolealkylamines are sensitive to the acidic conditions of the stomach. The corresponding secondary amine, N-monomethyltryptamine, and primary amine, tryptamine, are inactive as psychoactive substances, both because they are not sufficiently lipophilic to readily penetrate the blood-brain barrier and because what little does get into the brain is rapidly metabolized by monoamine oxidase (MAO). Other tertiary amine derivatives, such as the N-ethyl-N-methyltryptamine, N,N-diethyltryptamine (DET), N,N-di-n-propyltryptamine (DPT), and some secondary amines, also are hallucinogenic in humans. If the N-alkyl or N,N-dialkyl substituents are bulky and lipophilic enough, these tryptamines can be orally active (Table 23.2).

The effect of substitution in the pyrrole portion of DMT has not been extensively investigated in humans. In contrast, substitution in the benzenoid ring can enhance or diminish potency depending on the specific nature and location of the substituents. Table 23.2 shows some of the more frequently encountered derivatives of DMT, their common names, and their approximate human potency. Serotonin is not hallucinogenic and does not readily penetrate the blood-brain barrier

when administered systemically. N,N-Dimethylserotonin (bufotenine [5-OH DMT]) has been reported to be a weak hallucinogen, but the results of human studies are controversial. It, too, likely does not readily penetrate the blood-brain barrier and produces considerable peripheral effects (e.g., facial flushing and cardiovascular actions) that prevent evaluation of an extended dose range. O-Methylation of bufotenine results in 5-OMe DMT, one of the more potent N-alkyltryptamines. A naturally occurring substance, 5-OMe DMT is a constituent of a number of plants used in various concoctions prepared by South American Indians for ceremonial and visionary purposes. Bufotenine and 5-OMe DMT also are found in the skin of certain frogs and may have given rise to the phenomenon of "toad licking." Psilocin is 4-hydroxy DMT. Like bufotenine, with a polar hydroxyl group, psilocin might not have been expected to enter the brain, yet it is hallucinogenic. Although this phenomenon has never been adequately explained, it has been speculated that the 4-hydroxyl group forms a hydrogen bond with the terminal amine and that this reduces polarity just enough that psilocin penetrates the blood-brain barrier. Psilocin and its phosphate ester, psilocybin, are widely found in certain species of mushrooms and have given rise to the terms "shrooms" and "shrooming." There are no reports that 6-methoxy DMT or 7-methoxy DMT are hallucinogenic. It is quite difficult to make strict potency comparisons within this series because the different routes of administration that have been used (Table 23.2).



Agent	Common Name	R_1/R_2	R	X	Approximate Hallucinogenic Dose (mg)*	DOM Stimulus Generalization Potency (mg/kg)**
Tryptamine		H/H	H	H	Likely inactive	Inactive
N-Methyltryptamine	NMT	CH_3/H	H	H	Likely inactive	Inactive

Table 23.2. Psychoactive Indolealkylamine and Related Agents

In tests of stimulus generalization, the DOM stimulus has been shown to generalize to DMT, DET, DPT, 4-OMe DMT, 5-OMe DMT, and a number of other DMT analogues, but not to 5-OH DMT, 6-OMe DMT, or 7-OMe DMT.

The metabolism of these agents has not been well investigated. The indolealkylamine 5-HT is a substrate for oxidative deamination by MAO. What evidence exists suggests that other indolealkylamines also are substrates for this enzyme system.

α-Alkyltryptamines

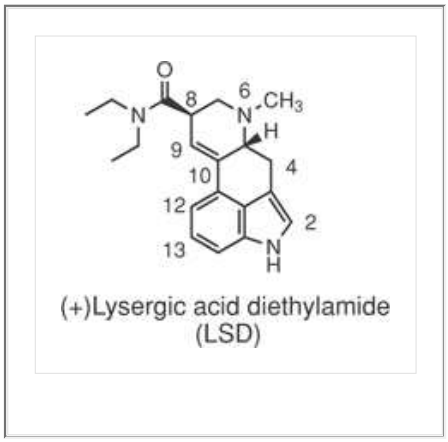
Tryptamine is not psychoactive. Introduction of an α-methyl group seemingly enhances lipophilicity and sufficiently protects against metabolism such that α-methyltryptamine (α-MeT) (Table 23.2) is approximately twice as potent as DMT. As a general rule of thumb, α-methyltryptamines, when such agents have been investigated, typically are twice as potent as their corresponding DMT counterpart. Otherwise, their SAR is essentially the same as that of the DMT analogues. For example, 5-methoxy-α-methyltryptamine (5-OMe α-MeT) is approximately twice as potent as 5-OMe DMT. Introduction of the α-methyl group results in the creation of an asymmetric center and the S-(+)-isomers of α-methyltryptamines are more potent than their R-(–)-enantiomers. Homologation of the α-methyl group to an

α-ethyl group affords α-ethyltryptamines. α-Ethyltryptamine (α-EtT) has been reported to be hallucinogenic, with effects somewhat distinguishable by human subjects from those of LSD and mescaline (23). Interestingly, α-EtT was clinically available during the early 1960s as an antidepressant because of its actions as an MAO inhibitor; however, it was removed from the market about a year after its introduction. It may be the MAO inhibitory effect that allowed the actions of α-EtT to be distinguished from those of LSD and mescaline (see also the section below on designer drugs). During the mid-1990s, α-ET made an appearance on the clandestine market as a designer drug (i.e., "ET"). (±)-α-Methyltryptamine, (±)-5-methoxy-α-methyltryptamine and both of its optical isomers, and (±)-α-ethyltryptamine are recognized by DOM-trained animals in tests of stimulus generalization.

Ergolines or lysergamides

(+)-LSD is perhaps the best known—and, certainly, one of the most potent—of the classical hallucinogens. Although LSD itself is not naturally occurring, many related ergolines are found in nature. In terms of potency, LSD is at least 3,000-fold more potent than mescaline, with doses of 100 μg showing activity. Certain structurally modified analogues of LSD retain hallucinogenic activity; although many derivatives are possible, relatively few have been investigated in humans. Structural changes often can reduce the activity of a pharmacologically active substance.

Here is an instance in which a structural change resulting in even a 1,000-fold decrease in potency can afford a very active agent. Some work has been reported on the SARs of LSD (24,25).



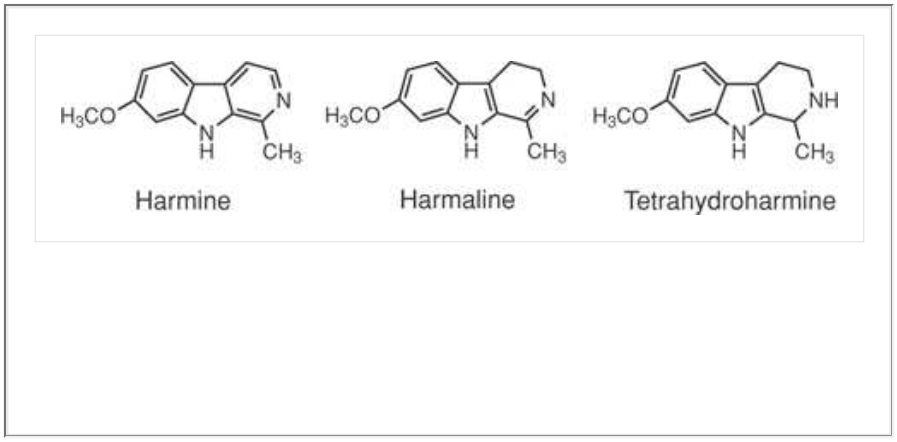
(+)Lysergic acid diethylamide (LSD)

In humans, LSD has been thoroughly investigated (24); no other hallucinogen has been as extensively studied as this agent. Its actions in humans can be divided into three major categories: perceptual (altered shapes and colors, heightened sense of hearing), psychic (alterations in mood, depersonalization, visual hallucinations, altered sense of time), and somatic (nausea, blurred vision, dizziness). In terms of principal effects, there seems to be little difference between LSD, psilocybin, and mescaline.

Although LSD has been sold on the clandestine market in tablet form, it is not uncommon to find this material available on "blotter paper" because of its high potency. A sheet of porous paper is impregnated with a solution of LSD, and the sheet can later be cut to afford the appropriate dose.

β-Carbolines

The β-carbolines represent a very interesting class of agents generally referred to as the harmala alkaloids. Several are naturally occurring. In South America, β-carbolines are found in certain vines and lianas (e.g., *Banisteriopsis caapi*), and in the Old World, β-carbolines are constituents of Syrian Rue (*Pegnum harmala*). South American Indians prepare a variety of concoctions and snuffs, the most notable of which is Ayahuasca, that are used for their hallucinogenic and visionary healing properties. In fact, the first written account of the use of these substances was made by a member of the Columbus expedition in 1493. There is little question that the concoctions are psychoactive; however, these plant preparations usually consist of admixtures in which certain tryptamines, such as DMT or 5-OMe DMT, sometimes have been identified. Some β-carbolines possess activity as MAO inhibitors; thus, the MAO inhibitory effect of the β-carbolines might be simply potentiating the effect of any tryptaminergic hallucinogens possibly present in an admixture by interfering with their metabolism. Studies with individual β-carbolines, especially under carefully controlled clinical settings, have been very limited. The three most commonly occurring β-carbolines are harmine, harmaline, and tetrahydroharmine, and evidence suggests that harmine and harmaline are hallucinogenic in humans (with potencies not greater than that of DMT) (27). Harmaline has seen some limited experimental application as an adjunct to psychotherapy (28). Like other classical hallucinogens, certain β-carbolines bind at 5-HT_{2A} receptors, and in animal studies, DOM stimulus generalization occurs to harmaline (28). Using harmaline-trained animals, harmaline stimulus generalization occurs to DOM. To date, however, very few β-carbolines have been investigated, so they are only tentatively categorized as classical hallucinogens.



Although the scientific community has been aware of the psychoactive effects of the β-carbolines or β-carboline–containing natural substances for more than 100 years, only in the past decade or so have they become popular "on the street." The use of β-carboline–containing plants has moved out of the jungle and given rise to a variety of religious movements in some South American cities. Recent books and movies also are helping to popularize the use of these preparations, and they are now being encountered in North America.

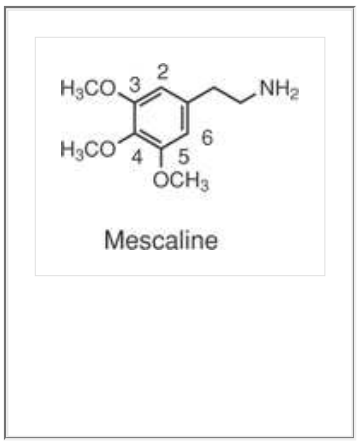
Phenylalkylamines

Phenylalkylamines, the phenylethylamines and the phenylisopropylamines, represent the largest group of classical hallucinogens (29,30). The phenylethylamines are the α-desmethyl counterparts of the phenylisopropylamines; as with the indolealkylamines, the presence of the α-methyl group increases

the agent's lipophilicity and reduces its susceptibility to metabolism by MAO. As a consequence, the phenylethylamines typically produce effects that are qualitatively similar to those of their corresponding phenylisopropylamines but typically less potent. Phenylethylamine counterparts of weak phenylisopropylamines might be inactive. Literally hundreds of analogues have been examined in human and in animal studies (29).

Phenylethylamines

Phenylethylamines are usually less-potent analogues of the phenylisopropylamines. Some hallucinogenic phenylisopropylamines are claimed to possess some stimulant character that may be minimized or altogether absent in the corresponding phenylethylamines. The phenylisopropylamines also possess a chiral center that is absent in the phenylethylamines. Otherwise, the SARs of the two groups of agents are relatively similar; consequently, the phenylethylamines will not be discussed in detail here. The most common—and, indeed, one of the oldest known—phenylethylamine hallucinogens is mescaline. A constituent of peyote (and other) cactus, mescaline is a relatively weak hallucinogenic agent (total human dose ~ 350 mg). Like many of the hallucinogens, mescaline is listed as a Schedule I substance; however, the use of peyote in certain native American Indian religious practices is sanctioned.



Phenylisopropylamines

Structural modification of mescaline and related substances by introduction of an α-methyl group and by deletion or rearrangement of the position of its methoxy groups results in a series of agents known as the

phenylisopropylamines. As might have been expected, introduction of an α-methyl group, to afford 3,4,5-TMA or α-methylmescaline, doubles the potency of mescaline. Although different nomenclatures exist for the dimethoxy- and trimethoxyphenylisopropylamines, the one used herein is a commonly used nomenclature: The position of methoxy groups is given by indicating its position, and the number of methoxy groups is indicated by a prefix. For example, α-methylmescaline is 3,4,5-TMA, indicating that it is a trimethoxy analogue and that the methoxy groups are situated at the 3-, 4-, and 5-positions. Dimethoxy analogues are referred to as DMAs.

There are three possible monomethoxyphenylisopropylamines: the ortho-methoxy analogue OMA, the meta-methoxy analogue MMA, and the para-methoxy analogue PMA (Table 23.3). Although PMA is specifically listed as a Schedule I substance, none of these three analogues is hallucinogenic. PMA possesses weak central stimulant actions and is an abused substance; several deaths have been attributed to PMA overdose within the past few years.

There are six isomeric DMA analogues. These have not been thoroughly investigated in humans, and few produce DOM-like stimulus effects in animals (Table 23.3). None is more potent than DOM. The most potent agent, and one that has been evaluated in humans, is 1-(2,5-dimethoxyphenyl)-2-aminopropane, or 2,5-DMA. There also are six different TMA analogues (Table 23.3). Here, most show some activity, but the 2,4,5-timethoxy analogue 2,4,5-TMA (sometimes referred to simply as TMA) is the most potent of the series. Most of the trimethoxy analogues are recognized by DOM-trained animals, but none is more potent than DOM itself (5). The presence of the 2,5-methoxy substitution pattern in 2,5-DMA and 2,4,5-TMA might be noted.

The DMAs and TMAs are methoxy-substituted derivatives of the parent phenylisopropylamine known as amphetamine (Fig. 23.2). Amphetamine undergoes several different routes of metabolism; one of these is para-hydroxylation (a route that seems more important in rodents than in humans). Initially, it was thought that the greater potency of 2,4,5-TMA over that of 2,5-DMA might be related to the 4-position of the former being blocked to metabolism by para-hydroxylation. Keeping the 2,5-dimethoxy substitution intact, different 4-position substituents were examined. This led to a series of agents, such as DOM and DOB (Table 23.3). These 4-substituted 2,5-dimethoxy analogues represent some of the most potent members of the series.

1-(2,5-Dimethoxy-4-methylphenyl)-2-aminopropane (DOM) represents the prototype member of this family of agents. Increasing the length of this 4-methyl group to an ethyl or n-propyl group (i.e., DOET and DOPR, respectively) results in enhanced potency on a molar basis. Further extension of the alkyl chain results in a decrease in potency or loss of action. Substitution at the 4-position by electron-withdrawing groups, particularly those with hydrophobic character, also results in active agents, such as DOB (Table 23.3), which is quite a potent agent and has been misrepresented on the clandestine market as LSD both in tablet and “blotter” form.

When optical isomers have been examined, activity resides primarily with the R-(–)-isomer; the S-(+)-isomers typically are less active, inactive, or have received little study. For example, although not well investigated, it appears that R-(–)-DOM and R-(–)-DOB show activity at total human doses of less than 4 and less than 1 mg, respectively. N-monomethylation reduces potency or abolishes activity; for example, the N-monomethyl analogues of DOM and DOB are approximately 10% as potent as their primary amine counterparts. The SARs for the DOM-like actions of phenylisopropylamines are summarized in Table 23.3 and Figure 23.2.

Table 23.3 also provides a comparison of the approximate human doses of various phenylisopropylamines when administered via the oral route. These agents represent a mere sampling of the agents that have been

examined; it can be imagined, using only those functional groups shown in the table, how many different analogues are possible on the basis of structural rearrangement. There is no reason to suspect that each of these agents produces identical effects. In fact, the actions of some of these agents have been reported to be quite unique, ranging from hallucinations and closed-eye imagery to intellectual and sensory enhancement to erotic arousal (29).

Classical Hallucinogens: Mechanism of Action

Given that the arylalkylamines may not be producing identical effects, a common mechanism of action may not be expected. LSD was one of the first hallucinogens to be investigated mechanistically; another agent to see extensive investigation is mescaline. Interestingly, from a potency perspective, these two agents seem to represent opposite extremes. LSD has been proposed to produce its effects via numerous mechanisms, including those involving serotonergic, dopaminergic, histaminergic, adrenergic, and other receptors. LSD binds with high affinity at many different receptor populations and acts as an agonist at some, an antagonist at others, and a partial agonist at yet others. For many years, it was supposed that mescaline might be acting via a dopaminergic or adrenergic mechanism because of its structural similarity to dopamine and norepinephrine. As early as the late 1950s, it was speculated, because of its structural similarity to 5-HT, that LSD might be working through a serotonergic mechanism. Significant experimental evidence supported this claim. Controversy exists, however, regarding whether LSD was a serotonergic agonist or antagonist. Furthermore, later studies revealed the existence of at least 14 populations of 5-HT receptors (see Chapter 14). With the subsequent availability of 5-HT_2 selective antagonists, it was demonstrated that several of these antagonists (e.g., ketanserin and pirenperone) were particularly effective in blocking the stimulus effects of DOM, and of DOM stimulus generalization to other hallucinogens, such as LSD, in tests of stimulus antagonism. It was later shown that the classical hallucinogens bind at 5-HT_2 serotonin receptors and that their receptor affinities were significantly correlated with both their DOM stimulus generalization potencies and their human hallucinogenic potencies (30). The classical hallucinogens are now thought to produce their effect by acting as agonists at 5-HT_2 receptors in the brain (i.e., the 5-HT_2 hypothesis of hallucinogen action). Radiolabeled analogues of DOB and DOI (e.g., [^{3}H]DOB and [^{125}I]DOI, respectively) are now available for the investigation of 5-HT_2 pharmacology.

More recently, it has been demonstrated that 5-HT_2 receptors actually represent a family of 5-HT receptors that consist of 5-HT_{2A}, 5-HT_{2B}, and 5-HT_{2C} receptor subpopulations. Fewer than three dozen arylalkylamines have been compared, but it appears that they show little selectivity for one subpopulation versus another. Various pharmacological studies with selective antagonists or employing antagonist correlation analysis, however, suggest that it may be the 5-HT_{2A} subtype that plays a predominant role in the behavioral actions of these agents (30,31). Although the 5-HT_{2A} receptors might be responsible for those actions that the classical hallucinogens have in common, other neurochemical mechanisms may account for their differences. For example, LSD is a very promiscuous agent that binds with high affinity at many receptor populations for which most other classical hallucinogens show little to no affinity. Many of the indolealkylamines bind with high affinity at multiple populations of 5-HT receptors, and some display comparable or higher

affinity at these receptors (e.g., 5-HT_{1A}, h5-HT_{1D}, and 5-HT_6) than they do at 5-HT_{2A} receptors. The phenylalkylamines are quite selective for 5-HT_2 receptors but, as mentioned above, display little selectivity for the three 5-HT_2 subpopulations. Some β-carbolines, although they bind at 5-HT_2 receptors, also possess activity as MAO inhibitors. Thus, these differences might account for their somewhat different actions. The one feature that all the classical hallucinogens have in common (i.e., the common component hypothesis) is that they bind at 5-HT_{2A} receptors (5).

Central Stimulants

Introduction, Classification, and Definitions

Stimulants can be divided into several categories. The term "stimulant," or "behavioral stimulant," typically refers to agents with a central stimulatory effect for which the actions are manifested mostly in motor activity, whereas the term "analeptics" refers to agents that have a stimulant effect primarily on autonomic centers, such as those involved in the regulation of respiration and circulation. Nicotine and related nicotinic agents also possess stimulant properties but are best discussed with other cholinergic agents. Analeptics include agents such as pentylenetetrazol, nikethamide, and strychnine. The boundary between analeptics and behavioral stimulants is not sharply defined. Caffeine, for example, has been classified as an analeptic, but high doses produce a stimulant effects. Caffeine is probably the best known of a series of xanthines; in fact, caffeine, which is found in coffee, tea, chocolate, and other naturally occurring substances, is probably the most widely used psychoactive substance in the world. Although most analeptics do not represent significant abuse problems, evidence does exist for caffeine abuse (32). However, because caffeine, particularly in the form of its naturally occurring products, is not subject to legal constraints, it will not be discussed here.

The term "stimulant" typically conjures up substances such as the phenylisopropylamine amphetamine and the tropane analogue cocaine. The following discussion will focus primarily on such substances.

Phenylisopropylamine Stimulants: Amphetamine-Related Agents

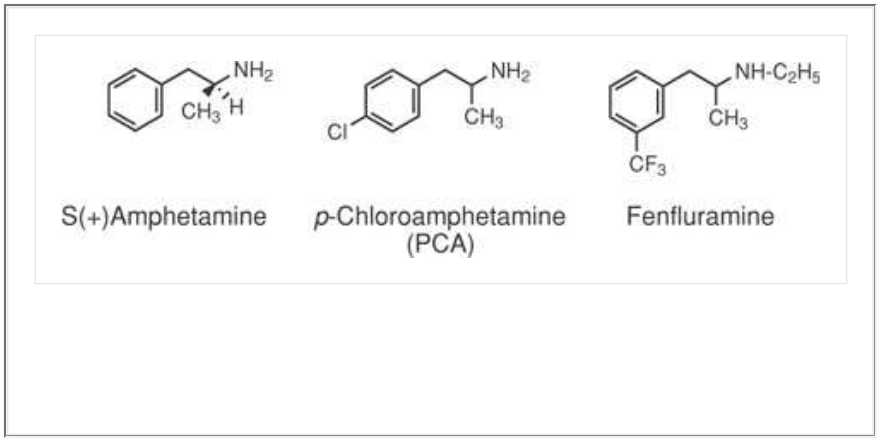
The simplest unsubstituted phenylisopropylamine is 1-phenyl-2-aminopropane, or amphetamine. Amphetamine possesses central stimulant, anorectic, and sympathomimetic actions, and it is the prototype member of this class (33). It is common to refer to amphetaminergic structures and amphetaminergic activity, but amphetamine may be more of an exception than a rule. Most substituted derivatives of amphetamine (i.e., phenylisopropylamine) lack central stimulant activity; in fact, pharmacologically, there are a greater number of "non-amphetamine-like" derivatives of amphetamine than there are "amphetamine-like" derivatives of amphetamine. Relatively few derivatives of amphetamine retain the activity of amphetamine; still fewer retain the potency of amphetamine. The present section will focus almost exclusively on the central stimulant actions of amphetamine, and it should be recognized that these SARs are not necessarily identical to those for anorectic or sympathomimetic actions.

Structure–Activity Relationships for Amphetamine-like Stimulant Action

In general, the SARs for amphetamine-like actions of the phenylisopropylamines are quite distinct from those for the DOM-like actions of the phenylisopropylamines, even though both share a common structural skeleton. The SARs for the two actions are summarized in Figure 23.2. The stimulus effects of amphetamine analogues have been reviewed elsewhere (34).

Aryl-substituted derivatives

In general, incorporation of substituents into the aromatic ring of amphetamine reduces or abolishes amphetamine-like stimulant activity. The sympathomimetic agent 4-hydroxyamphetamine lacks central stimulant action and is unlikely to penetrate the blood-brain barrier because of the presence of the polar aromatic hydroxyl group. Masking of the hydroxyl group in the form of its methyl ether affords the Schedule I substance PMA (para-methoxyamphetamine, also known as 4-methoxyamphetamine). PMA is a weak central stimulant with approximately 10% of the potency of amphetamine. 4-Methylamphetamine (1-(para-tolyl)-2-aminopropane [pTAP]) also has been found on the clandestine market and is, at best, a weak central stimulant. Incorporation of electron-withdrawing substituents results in agents that generally lack central stimulant properties. For example, PCA, or para-chloroamphetamine, is a 5-HT–releasing agent that saw evaluation as a potential antidepressant. Another related analogue is the 5-HT–releasing agent fenfluramine, which was used for some time as an appetite suppressant. Both of these latter agents are still widely employed as pharmacological tools in basic neuroscience research.



Amine substitution

In general, the primary amines are more potent than the secondary amines, and the secondary amines are more potent than the tertiary amines, as central stimulants. With regard to secondary amines, as the length of the amine substituent increases, activity decreases; the N-monoethyl and N-mono-n-propyl amines retain stimulant character but are somewhat less potent than amphetamine itself. Larger substituents typically

result in agents with little to no stimulant character. The one exception is the N-monomethyl derivative methamphetamine. Methamphetamine (e.g., “crystal,” “ice,” or “meth”) is at least as potent as amphetamine as a central stimulant; in most studies, it may be two- to threefold more potent than amphetamine. Methamphetamine is the most widely abused synthetic substance in the world. N-Hydroxylation of amphetamine has little effect on stimulant action. N,N-Dimethylamphetamine has been seized from clandestine laboratories, but it has never been certain whether this agent was being prepared for its possible stimulant actions or as a by-product of methamphetamine synthesis.

α-Substituents

Amphetamine possesses an α-methyl group. As already mentioned at the beginning of this chapter, α-demethylation (to afford phenylethylamine or 2-phenyl-1-aminoethane in the case of amphetamine) results in agents with decreased lipophilicity and increased susceptibility to metabolism. Phenylethylamine lacks central stimulant activity. Homologation of the α-methyl group to, for example, an α-ethyl or α-n-propyl group results in a decrease or loss of central stimulant activity. The presence of the α-methyl group in amphetamine creates a chiral center; hence, amphetamine exists as a pair of optical isomers. With respect to central stimulant actions, the S-(+)-isomer (i.e., dextroamphetamine) is several-fold more potent than its R-(–)- enantiomer (i.e., levamphetamine); this is not necessarily the case with other actions produced by amphetamine, particularly those produced in the periphery, such as its cardiovascular actions.

β-Substituents

The β-position has not been particularly well investigated. Perhaps the best-studied derivatives are ephedrine and norephedrine—and even these agents have not been especially well investigated. Ephedrine and norephedrine are phenylpropanolamines that may be viewed as the β-hydroxy analogues of methamphetamine and amphetamine, respectively. Actually, β-hydroxylation of amphetamine or methamphetamine results in the creation of a new chiral center; hence, a total of four optical isomers result from hydroxylation in each case. These eight structures are shown in Figure 23.3. Relatively little comparative information is available regarding the central stimulant actions of these phenylpropanolamine isomers.

During the 1970s, there was a problem with what were termed “look-alike drugs.” Look-alikes available on the clandestine market were made to resemble amphetamine and methamphetamine, both in action and physical appearance, to circumvent the control of amphetamine. The major constituents of these agents were various combinations of ephedrine, norephedrine, and caffeine. Although the look-alikes are no longer a major problem, the 1990s witnessed the introduction of “herbal dietary supplements.” These supplements were—and still are—legally available in some health food and herbal shops; several dozen such preparations have appeared on the market. The major ingredients of many of these preparations are various combinations of ephedrine and caffeine (or of ephedrine-containing natural products [e.g., ma huang or ephedra] or caffeine-containing natural products [e.g., guarana or kola nut]). Interestingly, although ephedrine and caffeine possess stimulant character of their own, evidence suggests that these agents may potentiate one another's actions (35). The exact mechanism by which they

do so, however, is unknown.

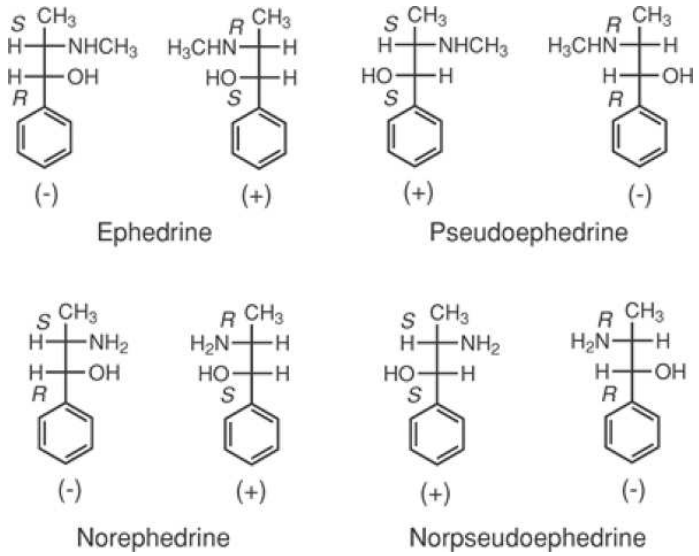


Fig. 23.3. Structures of β-oxidized analogues of methamphetamine (ephedrine and pseudoephedrine) and amphetamine (norephedrine and norpseudoephedrine). Note that norpseudoephedrine also is known as cathine.

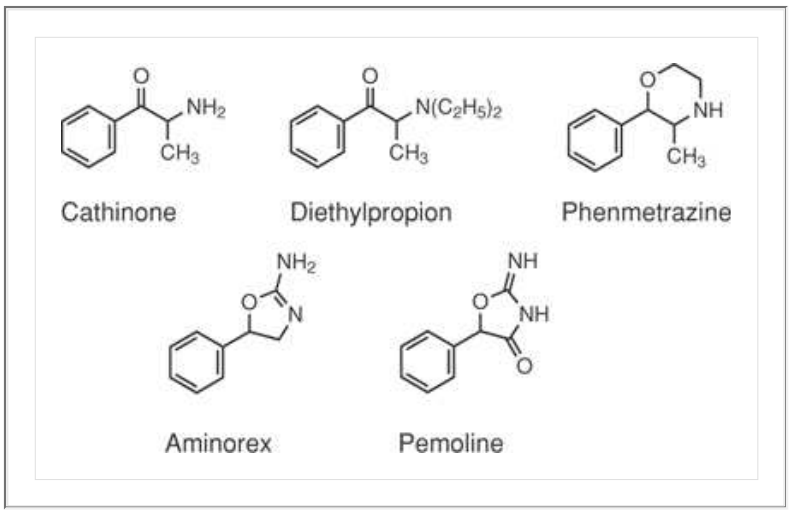
Although β-hydroxylation of amphetamine results in decreased central stimulant actions, this may be the result of the decreased ability of norephedrine to penetrate the blood-brain barrier, or it may be a clue that the presence of a β-oxygen substituent is inherently detrimental to activity. Support for the former possibility is derived from the shrub *Catha edulis*. Commonly known as khat or kat, *C. edulis* is a plant indigenous to certain regions of the Middle East and eastern portion of Africa. The fresh shrub is sold openly in local markets and is used for its central stimulant character, much in the same way as the West uses coffee. Khat is used to prepare an infusion, or the fresh leaves are simply chewed. For more than 50 years, it was thought that the active constituent was the phenylpropanolamine cathine or (+)-norpseudoephedrine (Fig. 23.3). In the late 1970s, however, a more potent compound was isolated from fresh leaves and shown to be what is now called cathinone. Cathinone, which is simply β-ketoamphetamine or an oxidized analogue of norephedrine, is at least as potent as amphetamine as a central stimulant. Certain anorectic agents, such as diethylpropion, also possess a benzylic keto group. The anorectic agent phenmetrazine or 3-methyl-2-phenylmorpholine and aminorex possess a benzylic oxygen atom in the form of an ether. All three of these agents possess stimulant character. A related stimulant is pemoline (available as a magnesium salt). Hence,

it is specifically the hydroxyl analogues that seem to possess weak stimulant actions, and this is likely a result of their reduced lipophilicity and not because they simply possess an oxygen atom at the β or benzylic position.



Metabolism of Amphetamine

In humans, (+)-amphetamine has a half-life of approximately 7 hours. Some of the metabolic products of amphetamine metabolism are shown in Figure 23.4. Although a significant portion of amphetamine is excreted unchanged, it also undergoes both Phase I (functionalization to more polar derivatives) and Phase II (conjugation) metabolism (36). The Phase I metabolism of amphetamine analogues is catalyzed by two enzyme systems: cytochrome P450, and flavin monooxygenase. The latter system oxidizes secondary and tertiary amine analogues of amphetamine. Amphetamine undergoes hydroxylation on the α-carbon, the β-carbon, the terminal amine, and on the aromatic ring. These metabolites are subsequently oxidized, where possible, or conjugated.

Amphetamine is oxidized to phenylacetone via a presumed carbinolamine intermediate. The phenylacetone is further oxidized directly to benzoic acid or, first, to a hydroxy keto analogue that is subsequently converted to benzoic acid. Amphetamine also can undergo aromatic hydroxylation to parahydroxyamphetamine. Initial work with rats indicated that para-hydroxylation is a major route of metabolism; however, subsequent studies showed that benzoic acid is the major metabolite in humans. Subsequent oxidation at the benzylic position by dopamine β-hydroxylase affords parahydroxynorephedrine. Alternatively, direct oxidation of amphetamine by dopamine β-hydroxylase can afford norephedrine. Amphetamine and related derivatives also undergo N-hydroxyalation, and the N-hydroxy derivatives can be further oxidized to nitroso, nitro, and oximino compounds. Some evidence suggests that the oximino derivative is hydrolyzed to phenylacetone. Additional metabolites are possible as well. In Phase II reactions, ring-hydroxylated metabolites are conjugated to their corresponding glucuronides. Sulfation of the enol form of phenylacetone has been reported. Approximately 23% of methamphetamine is excreted unchanged, 18% as parahydroxymethamphetamine, and 14% as the demethylated product (36).

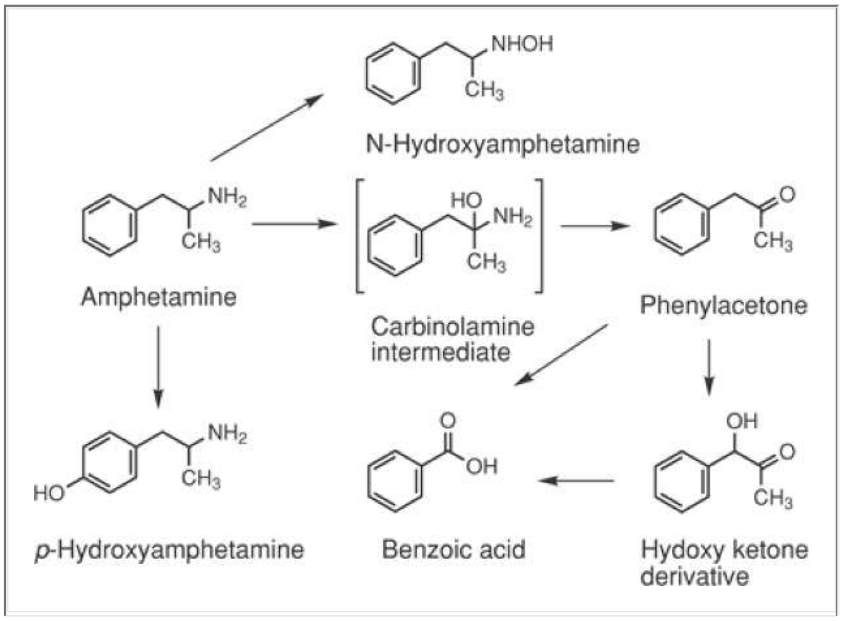


Fig. 23.4. Some products of amphetamine metabolism.

Mechanism of Action of Amphetamine

Amphetamine is an indirect-acting dopaminergic and noradrenergic agonist; that is, amphetamine causes an increase in the synaptic concentrations of these neurotransmitters. The central stimulant actions of amphetamine primarily involve the dopamine system; amphetamine enhances the release of dopamine and, to a lesser extent, prevents the reuptake of dopamine into presynaptic terminals (Fig. 23.5). The stimulant actions of amphetamine can be attenuated by the administration of dopamine antagonists, such as the antipsychotic phenothiazine chlorpromazine and the butyrophenone haloperidol. Chronic administration of high doses of amphetamine may result in "amphetamine psychosis," which exhibits symptoms similar to those of acute paranoid psychosis. This is consistent with a role for dopamine in the central actions of amphetamine and,

further, with the dopamine antagonist mechanisms proposed for certain antipsychotic agents. Similar psychotic episodes have been associated with khat ("khat psychosis" or "cathinone psychosis") and cocaine ("cocaine psychosis").

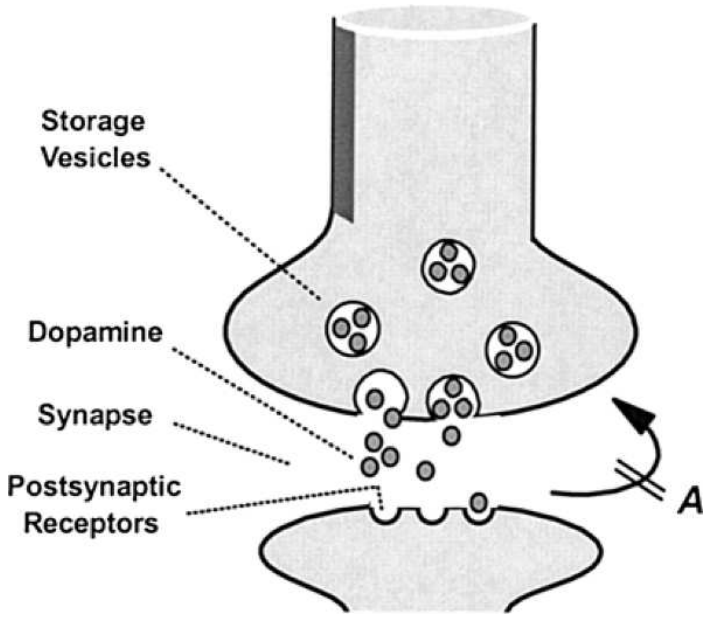

Fig. 23.5. Schematic of a dopaminergic nerve terminal. Amphetamine increases synaptic concentration of dopamine primarily by causing its release from presynaptic terminals, whereas cocaine increases synaptic concentration by preventing its reuptake (α).

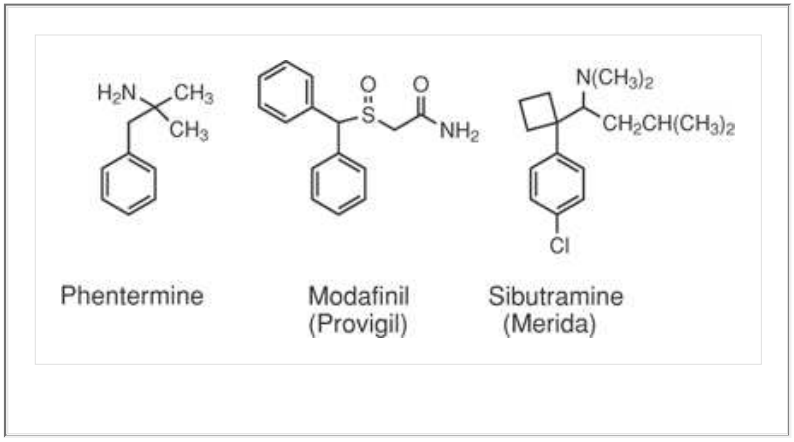
Clinical Applications

Although phenylisopropylamines generally are known for their abuse liability, several have gained clinical acceptance. Indeed, certain of these agents display reduced stimulant character and/or are infrequently abused. Ephedrine (and, later, phenylpropanolamine) and amphetamine were two of the first agents used to treat obesity. Caffeine also has been used to treat obesity, and when given in combination with ephedrine, the combination has a supra-additive effect (37,38). Alternatives to the synthetic products include herbal preparations that contain ephedrine (e.g., ma huang) or caffeine (e.g., guarana). Recent studies indicate that ephedrine–caffeine combinations are associated with an increased risk of psychiatric, autonomic, cardiovascular, and other side effects (38). The central stimulant actions of the phenylispropylamines led to their structural modification and the subsequent introduction of anorectic agents, such as diethylpropion, phenmetrazine, and phentermine. Despite a lack of widespread abuse, many of these agents retain central stimulant properties. (±)-Fenfluramine was developed in the

1960s and marketed as Pondimin®. Although structurally related to amphetamine, fenfluramine is devoid of stimulant character. Unlike amphetamine-related agents that act primarily via noradrenergic and dopaminergic mechanisms, fenfluramine is primarily a serotonin-releasing agent. The more potent isomer in reducing food intake, (+)-fenfluramine (i.e., dexfenfluramine), was introduced clinically during the 1980s. Fenfluramine also was available in combination with phentermine (i.e., phen-fen). Unfortunately, some patients treated with this combination displayed symptoms of valvular heart disease, resulting in the voluntary withdrawal from the market in 1997 of fenfluramine-containing anorectic agents. (±)-Fenfluramine is metabolized to its primary amine norfenfluramine, and evidence suggests that valvulopathy might be the result of the agonist action of norfenfluramine on cardiac 5-HT_{2B} receptors (39,40). Today, it is not unusual for new drug candidates to be examined for 5-HT_{2B} agonist action during the early stages of their development.

Other serotonergic agents have been evaluated for their antiobesity actions including selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine) (37) (see Chapter 21). Sibutramine, an agent with an amphetamine-like structural skeleton that was initially developed as an antidepressant, is an inhibitor of serotonin and norepinephrine reuptake. Animal studies indicate that sibutramine reduces food intake by decreasing meal duration rather than feeding frequency, suggesting an effect on satiation mechanisms (37). Sibutramine stimulates thermogenesis and effectively reduces amounts of visceral fat (41). Side effects of sibutramine include increased heart rate and blood pressure that have been attributed to its adrenergic action. These and other approaches and strategies to the treatment of obesity have been recently reviewed elsewhere (37,41).



Causes of excessive daytime sleepiness are numerous and include intrinsic sleep disorders, such as obstructive sleep apnea/hypopnea syndrome and narcolepsy; circadian rhythm sleep disorders, such as jet lag; and sleep disorders associated with neuropsychiatric conditions, such as anxiety and depression (42). In many instances, excessive daytime sleepiness is treated by addressing the underlying cause; however, the specific etiology of narcolepsy is unknown. Narcolepsy also can be characterized by brief periods of muscle paralysis (cataplexy). Hence, a need exists for agents that can effectively treat narcolepsy and cataplexy. Because of the increased behavioral activation (i.e., arousal, alertness, and motor activity) caused by psychostimulants, their use has been the mainstay for the treatment of narcolepsy. Agents such as methylphenidate and amphetamine frequently are used, and methamphetamine and caffeine are used less commonly. Pemoline (Cyclert) also has seen some application but has been reported to produce liver toxicity (42,43,44). Adderall, a combination of amphetamine salts (equal amounts of (+)-amphetamine saccharate, (+)-amphetamine sulfate, amphetamine aspartate, and amphetamine sulfate), was introduced in 1996; although used primarily for the treatment of attention-deficit hyperactivity disorder (ADHD), it also is used in the treatment of narcolepsy. Newer agents include sodium oxybate ($HO\text{-}CH_2CH_2CH_2COO^-\ Na^+$; presumed to act through a gabaminergic mechanism) and modafanil. Modafinil (Provigil) is a new agent that seems to promote wakefulness without producing the arousing effects associated with many other stimulants; it also has been approved for the treatment of obstructive sleep apnea/hypopnea syndrome (45). The exact mechanism of action of modafinil is unknown but has been shown by various investigators to involve dopamine, norepinephrine, histamine, serotonin, and/or GABA receptors; modafinil also binds at hypocretin (orexin receptors) (46,47). Modafinil showed reduced stimulant character relative to methylphenidate, and its potential for abuse in patients with narcolepsy has been demonstrated to be low (42). Hepatic metabolism responsible for the clearance of modafinil include amide hydrolysis to modafinil acid, its primary inactive metabolite. S-oxidation and aromatic ring hydroxylation occurred via CYP2C9. Less than 10% is excreted as unchanged drug.

Motor suppression seen in patients with cataplexy is similar to the motor suppression seen in healthy individuals during REM sleep. Consequently, agents previously found to decrease REM sleep have been evaluated for the

treatment of cataplexy (44,46). Agents that suppress REM sleep include those that increase noradrenergic,

serotonergic, and dopaminergic signaling. Tricyclic antidepressants, certain SSRIs, selective norepinephrine–serotonin reuptake inhibitors (e.g., venlafaxine) and MAO inhibitors have found application in the treatment of cataplexy, as has sodium oxybate (46,47). Psychostimulants also might be of some anticataplexic benefit, but modafinil generally produces little improvement (46).

Cocaine-Related Agents

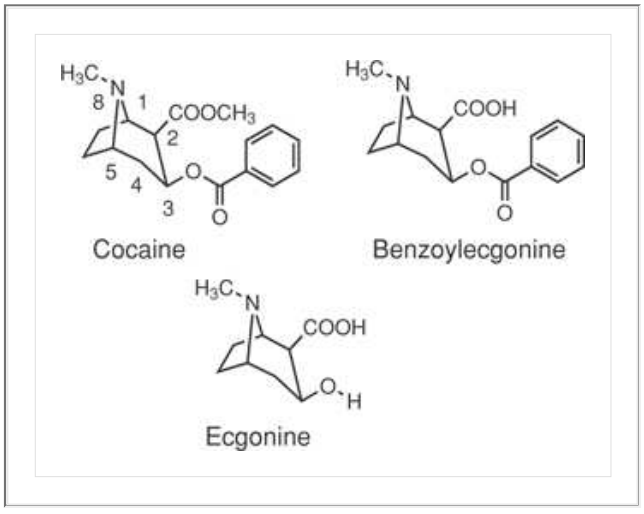
There are eight possible stereoisomeric forms of methyl 3-(benzoyloxy)-8-methyl-azabicyclo[3.2.1]octan-2-carboxylate, of which one, R-cocaine, is simply referred to as "cocaine." Chemically, cocaine is known as 2R-carbomethoxy-3S-benzyloxy-1R-tropane. Cocaine is naturally occurring in a variety of plants belonging to the *Erythroxylon coca* species, which is indigenous to some countries in South America. In addition to its stimulant actions, cocaine possesses vasoconstrictor actions and is a local anesthetic; it has served as a template for the development of other therapeutically useful agents, including local anesthetics and 5-HT_3 serotonin antagonists.

Cocaine has a very interesting history. The coca plant was used by South American Indians for religious and mystical purposes and as a stimulant both to increase endurance and to alleviate hunger. It was introduced into Europe during the 1800s, and at the end of the 19th century, cocaine use was popular and socially acceptable. Various cocaine-containing preparations were available, and it also was used to "fortify" wines (e.g., Vin Coca). For a period of approximately 20 years, until just after the turn of the century, it was a constituent of the soft drink Coca-Cola. Additionally, cocaine was used for therapeutic reasons but was later supplanted by amphetamine.

Cocaine is active via nearly every possible route of administration; however, insufflation of "snow" or "coke" represents one of the most popular routes. Administered in this manner, peak effects and plasma levels are achieved within 30 minutes (48). Smoking the freebase form of cocaine ("crack") results in an even more rapid effect. The freebase form rather than the hydrochloride salt is used for smoking, because the temperatures required for vaporization of the salt result in considerable decomposition (48). Intravenously administered cocaine can achieve peak blood levels within a few minutes. Cocaine is metabolized to benzoylecgonine, the methyl ester of ecgonine, and to a lesser extent, to ecgonine, norcocaine, and hydroxylated derivatives.

Mechanism of Action of Cocaine

Cocaine has been shown to block the reuptake of norepinephrine, serotonin, and dopamine; however, the reinforcing and stimulant nature of cocaine seems to be related primarily to blockade of dopamine reuptake, leading to the "dopamine hypothesis" of cocaine's actions (49). [^{3}H]Cocaine was used in an attempt to identify the "cocaine receptor," and this was later shown to be similar to the dopamine transporter. Currently, it is thought that cocaine produces it reinforcing effects by interfering with dopamine reuptake (Fig. 23.5) by blocking the dopamine transporter (50). Although the human dopamine transporter has been cloned, it is unknown if the dopamine and cocaine binding domains are identical or how much they overlap (49).

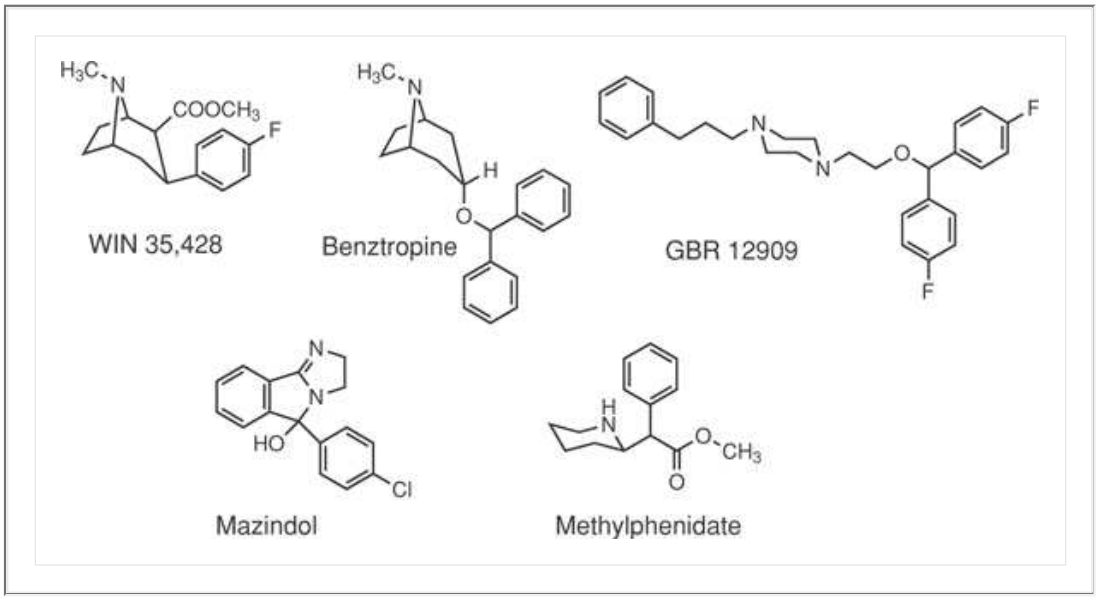


Cocaine-like structure–activity relationships and cocaine-like agents

Because cocaine binds at the dopamine transporter, this provides a convenient method for the investigation and formulation of SARs; these have been recently reviewed elsewhere (48,49). Important features for the binding of cocaine analogues include configuration, substituent at C_2, stereochemistry at C_2, substituent at N_8, and substituents at C_3. With respect to cocaine analogues, inversion of configuration can decrease activity. The C_2-position is quite important: Epimerization from β to α reduces activity by 30- to 200-fold, and hydrolysis of the

ester to the acid (i.e., benzoylecgonine) reduces activity by more than 1,500-fold. Although an ester function seems to be important, the methyl group can be replaced by other substituents (e.g., phenyl or benzyl) with relatively little effect. A basic nitrogen atom appears to be optimal. Replacement of the N_8-methyl group by other substituents, such as small alkyl or benzyl, has only a small negative influence on activity, whereas quaternization or acylation (of norcocaine) reduces activity by 33- and 111-fold, respectively (49).

Other dopamine transport blockers are known, and their SARs have been investigated (50). One of the oldest and most widely investigated is WIN 35,428, and [^{3}H]WIN 35,428 is available as a radioligand. Others include benztropine, GBR 12909, mazindol, and methylphenidate (50,51). These latter compounds produce varying degrees of cocaine-like actions and, thus, are being examined as structural leads for the development of therapies for the treatment of cocaine abuse (50). Because there are currently more than 1.7 million cocaine users in the United States, various novel pharmacotherapies are being pursued, including gabaminergic agents, dopaminergic agents, adrenoceptor antagonists, vasodilators, and cocaine vaccines (52).



Designer Drugs

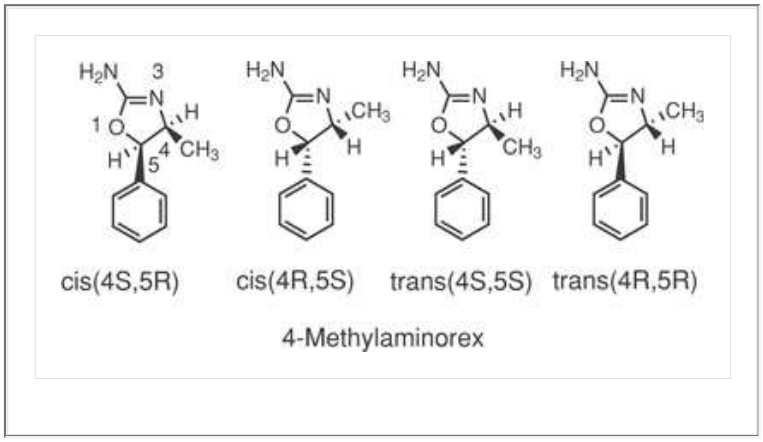
Introduction

Designer drugs, or controlled substance analogues, are the end result of the application of SARs at the clandestine level. That is, knowledge of the established SARs of a particular class of abused substances can be applied at the clandestine level for the development of novel agents of abuse. What is particularly frightening about this concept is that the novel agents are not necessarily—or even commonly—examined for action or toxicity before they are put on the illicit market. The term “designer drug” was first introduced in reference to novel opiate-related analogues that appeared on the clandestine market approximately three decades ago; today, the term is applied more generically to any class of abusable substance. Furthermore, the term is now commonly applied to nearly any substance, novel or not, that is new to the street scene. Designer drugs have appeared that are structurally related to the hallucinogens and stimulants discussed above; the present discussion will focus on some of these agents.

Specific Examples

Because some designer drugs result from the clandestine application of SARs, it should be possible to legitimately forecast the actions and, perhaps, even the approximate potencies of novel street drugs on the basis of the same SAR data. In fact, this sometimes is the case. For example, “Nexus” made an appearance on the east coast of the United States in the early 1990s. Nexus is α-desmethyl DOB, or 2-(4-bromo-2,5-dimethoxyphenyl)-1-aminoethane. Knowing that DOB is a potent phenylisopropylamine hallucinogen and that α-demethylation typically reduces the potency of phenylisopropylamines, it might be suspected that Nexus would be a DOB-like agent with reduced potency. This has been supported by the results of drug discrimination studies in animals. Furthermore, this material, also known as 2C-B, has been shown to be active in humans at 12 to 24 mg relative to approximately 2 mg for DOB (29). In the last year or two, a number of related agents have been found on the clandestine market and, like 2C-B, are phenylethylamine analogues of their phenylisopropylamine counterparts; for example, 2C-C, 2C-I, 2C-N, 2C-E, and 2C-P are the phenylethylamine analogues of DOC, DOI, DON, DOET, and DOPR, respectively (Table 23.3) (Fig.

23.6). Another agent attracting recent attention is 2C-T-7 (e.g., "Blue Mystic" or "Tripstasy") (53), which has been recently controlled as a Schedule I substance. Recently controlled indolealkylamine analogues include α-MeT (AMT), α-EtT ("ET"), and 5-methoxy-N,N-diisopropyltryptamine ("Foxy Methoxy") (Fig. 23.6); these agents had been previously shown to produce DOM-like stimulus effects in animals (54).



Stimulant designer drugs also have appeared. For example, CAT, or methcathinone, has been found on the illicit American market. Interestingly, it seems that methcathinone was a popular drug of abuse in the former Soviet Union (where it was known under a variety of names including ephedrone), but reports of this agent were never published in either the scientific or lay literature of that time. Methcathinone is the N-monomethyl analogue of cathinone. Indeed, structurally, methcathinone is to cathinone what methamphetamine is to amphetamine. Methcathinone, which may be viewed as an oxidation product of ephedrine (hence the name ephedrone) is a potent central stimulant that is at least as potent as methamphetamine. Another example of a stimulant designer drug is 4-methylaminorex (U4Euh), which has been misrepresented on the illicit market as cocaine or methamphetamine. 4-Methylaminorex, an alkylated version of the anorectic/stimulant aminorex,

contains two chiral centers and, hence, exists as four optical isomers. Typically, it is a mixture of the two *cis* isomers that has been confiscated by law enforcement officials, and *cis* 4-methylaminorex is now classified as a Schedule I substance. Interestingly, all four isomers behave as amphetamine-like agents, with the *trans*-(4S,5S) isomer being the most active, having a potency slightly greater than that of (+)-amphetamine itself. Yet other examples include the piperazines. Several piperazine analogues have been reported to produce amphetamine-like effects in humans, and one in particular, N-benzylpiperazine (known either alone or in combination with other piperazines as "Rapture"), has been recently classified as a Schedule I substance (Fig. 23.6).

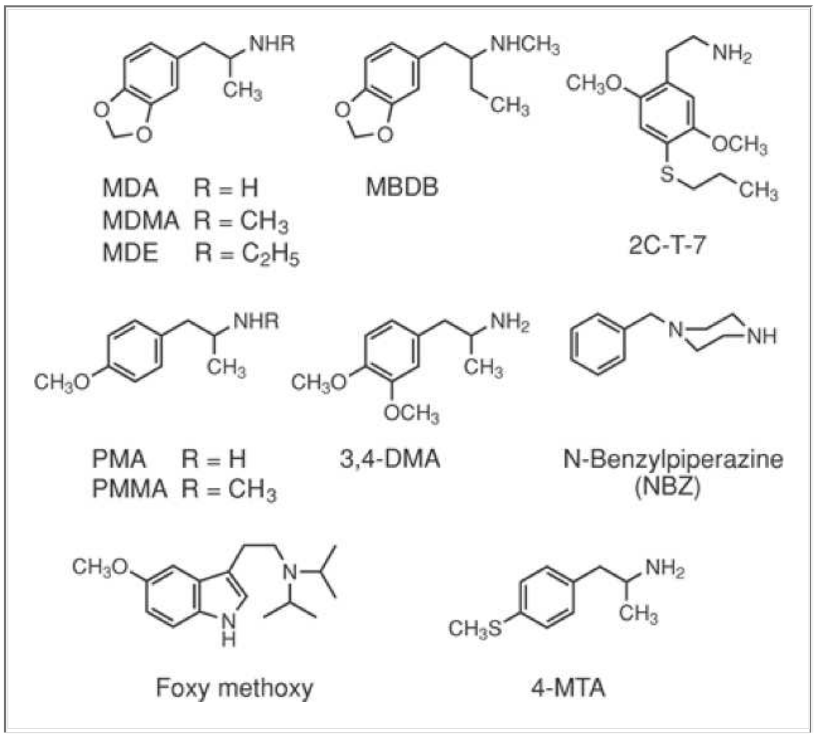


Fig. 23.6. Designer drugs.

Not all designer drugs result in actions that are entirely predictable. One of the most popular of such agents is MDMA, or N-methyl-1-(3,4-methylenedioxyphenyl)-2-aminopropane (e.g., "Ecstasy," "XTC," or "Adam") (Fig. 23.6). MDMA is the N-monomethyl analogue of MDA, or 1-(3,4-methylenedioxyphenyl)-2-aminopropane. MDA was popular during the 1960s, when it was known on the street as the "Love Drug." It was reported to produce effects in humans akin to a combination of cocaine and LSD. It has since been shown that MDA produces both amphetamine-like and DOM-like stimulus effects in animals and, furthermore, that animals trained to discriminate MDA recognize central stimulants, such as amphetamine and cocaine, as well as classical hallucinogens, such as LSD, mescaline, and DOM. Interestingly, the stimulant actions of MDA appear to be associated with the S-(+)-isomer, whereas the DOM-like actions are associated with the R-(–)-isomer. Knowing that N-monomethylation of phenylisopropylamine stimulants enhances their potency, whereas the corresponding change is detrimental to DOM-like actions, it would have been predicted that MDMA would probably behave as an amphetamine-like stimulant. Consistent with this prediction, amphetamine-trained (but not DOM-trained) animals recognized MDMA in tests of stimulus generalization. Furthermore, animals trained to discriminate MDMA recognized amphetamine but not DOM. However, MDMA was claimed to produce empathogenic effects in humans (i.e., increased empathy and sociability and enhanced feelings of well being) and was used for several years as an adjunct to psychotherapy before emergency scheduling under the Controlled Substances Act as a Schedule I substance. It was argued that MDMA produced a unique, nonamphetamine-like effect (55). Although both optical isomers are active, the S-(+)-isomer is the more active of the two. A closely related agent is its N-ethyl homologue MDE ("Eve"). The general consensus today is that MDMA is probably an empathogen with amphetamine-like stimulant side effects. Homologation of the α-methyl group of phenylisopropylamine stimulants and hallucinogens typically diminishes their potency or abolishes their activity; however, the α-ethyl analogue of MDMA (MBDB, or N-methyl-1-(3,4-methylenedioxyphenyl)-2-aminobutane) retains MDMA-like actions (56) (Fig. 23.6). Another agent, sold as a substitute for MDMA, is 4-MTA (e.g., "Flatliners" or "Golden Eagles") (Fig. 23.6); this agent produces MDMA-like stimulus effects in animals but did not produce either DOM-like or cocaine-like effects (53).

A closely related agent is PMMA, or N-methyl-1-(4-methoxyphenyl)-2-aminopropane. PMMA is a hybrid structure of two phenylisopropylamine stimulants: PMA, and methamphetamine (Fig. 23.6) Surprisingly, PMMA lacks significant central stimulant actions, and unlike PMA and methamphetamine, PMMA is not recognized by (+)-amphetamine–trained animals. Because PMMA is structurally related to metabolites of MDMA, it was examined in MDMA-trained animals and found to be several-fold more potent than MDMA. Animals have been trained to discriminate PMMA from vehicle, and PMMA stimulus generalization occurred to (±)-MDMA and S-(+)-MDMA, but not to DOM, (+)-amphetamine, R-(–)-MDMA, or R-(–)-PMMA. Another psychoactive agent that has not been well investigated is 3,4-DMA (Table 23.3). 3,4-DMA may be viewed as an O-methyl ring-opened analogue of MDA (Fig. 23.6). Although 3,4-DMA was not recognized by either DOM- or (+)-amphetamine–trained animals, it was recognized by MDA- and PMMA-trained animals. These results, coupled with the above discussion of MDMA, suggest that phenylisopropylamines may not be best described as merely central stimulants or hallucinogens; a third action needs to be accounted for. Although MDMA is widely abused, a contributing factor may be related to its amphetaminergic actions. It is not yet known if agents that fall into this third pharmacological category possess abuse potential; consequently, they have been referred to simply as "other" agents. It has been proposed that the behavioral actions of the phenylisopropylamines can be described by the Venn diagram shown as Figure 23.7. As depicted in that figure, the three types of actions are classical hallucinogen (*H*), stimulant (*S*), and PMMA-like (*P*) (57). Because MDMA

possesses both PMMA-like and (+)-amphetamine–like activity, it is perhaps best represented by Intersect 2. As mentioned above, R-(–)-MDA is hallucinogenic, and S-(+)-MDA is a stimulant. Both isomers possess PMMA-like activity. Thus, R-(–)-MDA is best represented by Intersect 3, whereas S-(+)-MDA is best represented by Intersect 2. The common intersect (shaded area) describes the actions of (±)-MDA. Using this classification system, it should be possible to classify the various phenylisopropylamines as falling into one or more categories. Furthermore, there is no reason to suspect that this classification system will be limited to the phenylisopropylamines; that is, there is evidence that the indolealkylamines might be classified in a similar manner. For example, S-(+)-α-EtT produces both DOM- and PMMA-like effects, but not (+)-amphetamine–like effects, whereas R-(–)-α-EtT produces (+)-amphetamine– and PMMA-like effects, but not DOM-like effects (58). The classification scheme suggests that there will be three different SARs and three different mechanisms of action. Certain agents, because they fall into more than one category, may represent mechanistic and structure–activity composites. The same may be said of arylalkylamine designer drugs; indeed, it may be the particular "mix" of actions that makes certain designer drugs so attractive as drugs of abuse.

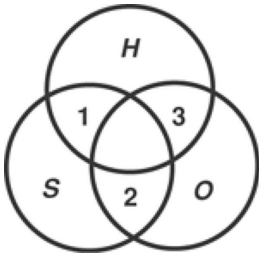

Fig. 23.7. The behavioral effects of arylalkylamines may be described as falling into one or more of three different stimulus categories: classical hallucinogen (*H*), central stimulant (*S*) or PMMA-like (*O*). See text for further discussion.

Perhaps the most worrisome things about designer drugs are that almost none has been investigated under controlled clinical settings, that relatively little is known about their toxicity or long-term effects, and that medical professionals generally are unfamiliar with them (or with the treatment of their overdose) in emergency room settings. The situation is further exacerbated by the broad availability of Web sites describing such agents to potential users (59).

Neuronal Plasticity and Drugs of Abuse

Release of neurotransmitter from presynaptic terminals results in the activation of postsynaptic neurotransmitter receptors that can be coupled to complex effector mechanisms. Through modulation of postsynaptic pathways, the state of the neuron can be altered such that neurons become more or less responsive to the neurotransmitter (60). This process is referred to as functional plasticity. One of the most exciting recent findings with implications for the treatment of drug abuse (as well as other neuropsychiatric disorders) involves the regulation of DARPP-32, an integrator of intracellular signaling. Interaction of dopamine at D_1-like receptors (D_1/D_5) activates adenylate cyclase, which increases cyclic adenosine monophosphate (cAMP) levels; this, in turn, can regulate phosphorylation of DARPP-32 (dopamine- and cAMP-regulated phosphoprotein of 32 kDa) by protein kinase A

(PKA). Interaction of dopamine at D_2-like receptors ($D_2/D_3/D_4$, which are negatively coupled to cAMP) has an effect that is essentially opposite that of activation of D_1 receptors. Phosphorylation of a specific amino acid residue (threonine^{34} [Thr^{34}]), induced by D_1 agonists, converts DARPP-32 to an inhibitor of protein phosphatase-1 (PP-1); thus, when phosphorylated at Thr^{34}, DARPP-32 behaves as an amplifier of PKA-mediated signaling through its ability to inhibit PP-1. The actions of DARPP-32 also can be modulated by phosphorylation (or dephosphorylation) of Thr^{75} (Fig. 23.8). Activation of D_1 receptors decreases the phosphorylation state of DARPP-32 at Thr^{75} by a process that involves PKA-dependent activation of protein phosphatase-2A (PP-2A); this disinhibits phosphorylation of Thr^{34} by PKA (i.e., results in enhanced phosphorylation of Thr^{34}). The result is potentiation of dopaminergic signaling. Together, PKA and PP-1 regulate the phosphorylation state of downstream neuronal effector proteins. Additionally, DARPP-32 can be phosphorylated at serine^{137} (Ser^{137}), and this phosphorylation decreases the rate of dephosphorylation of Thr^{34}.

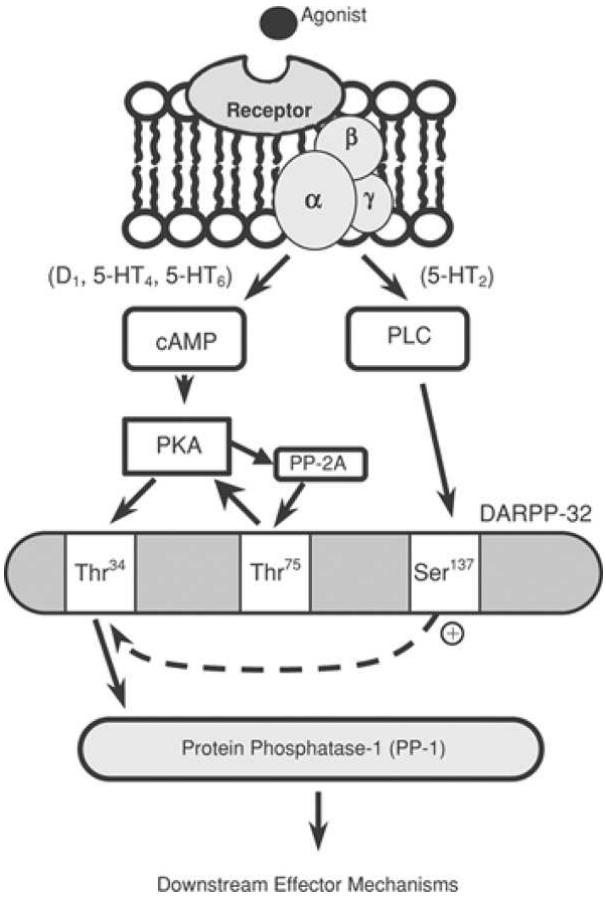

Fig. 23.8. A simplistic schematic showing the proposed involvement of DARPP-32 in neurotransmission. Agonists (e.g., DA and 5-HT) can interact with certain postsynaptic G protein–coupled receptors to activate second messenger systems. Agonist action at D_1 receptors increases cAMP levels and causes PKA to phosphorylate DARPP-32 at Thr^{34}; activation of D_1 receptors also decreases the phosphorylation state of DARPP-32 at Thr^{75} by what appears to involve PKA-dependent activation of a protein phosphatase (PP-2A). Likewise, the action of 5-HT at 5-HT_4 and 5-HT_6 receptors increases phosphorylation of Thr^{34} and decreases phosphorylation of Thr^{75}. Interaction of 5-HT at 5-HT_2 receptors activates phospholipase C (PLC) and promotes phosphorylation of DARPP-32 at Ser^{137}. Phosphorylation at Thr^{34} inhibits protein phosphatase-1 (PP-1). Inhibition of PP-1 enhances signaling. Phosphorylation of Thr^{75} has an inhibitory effect on Thr^{34} phosphorylation (conversely, decreased Thr^{75} phosphorylation disinhibits PKA to increase Thr^{34} phosphorylation), whereas phosphorylation of Ser^{137} prevents dephosphorylation of Thr^{34}. Other receptors can impinge on this mechanism (60,61,62,63,64,65).

Serotonin causes an increase in phosphorylation of Thr^{34} (via activation of 5-HT_4 and 5-HT_6 receptors, which are positively coupled to cAMP) and Ser^{137} (via activation of 5-HT_2 receptors–receptors coupled to phospholipase C), and a decrease in the phosphorylation of Thr^{75} (via activation of 5-HT_4 and 5-HT_6 receptors). Hence, serotonin inhibits PP-1 through what might be considered a synergistic mechanism (61). Other receptors that might modulate DARPP-32 include glutamate, GABA, adenosine, nitrous oxide, and opioid receptors. Hence, it has been speculated that various drugs of abuse, including amphetamine, methamphetamine, cocaine, caffeine, opioids (e.g., morphine),

nicotine, and ethanol involve a DARPP-32 mechanism; furthermore, agents such as antidepressants, antipsychotics, and antiparkinsonian drugs have been shown to influence phosphorylation of DARPP-32. Classical hallucinogens, as described above, are thought to act by activation of 5-HT_{2A} receptors. It has been shown that LSD increases phosphorylation of Ser^{137} (62). In theory, DARPP-32 should be modulated by various designer drugs that act via a dopaminergic or serotonergic mechanism. Only selected aspects of intracellular integration have been mentioned here, and others already have been implicated. The state of the art has been recently described (61,62,63,64,65). Nevertheless, the actions of many drugs of abuse might involve such postsynaptic events and certainly require further attention.

Case Study

Victoria F. Roche

S. William Zito

EW, a 25-year-old wildhair who has always been “just this side” of the law, is on a solo motorcycle trip through the desert Southwest with an ultimate destination of Mendocino, California. He is traveling light, but he did take care to pack enough grass to last the trip—or so he thought. Somewhere around Gallup, New Mexico, he met up with some other “born to be wild” folks heading south to Mexico, and they pooled their stashes and partied together until everything was gone. As he crossed into Arizona and entered the Navajo Nation a few hours later (still half-stoned), he was wondering how in the heck he was going to make it to California without the aid of illicit pharmaceuticals. When he rode by a Native-American church building, he exercised some very poor judgment in turning around, breaking in, and stealing a small quantity of botanical intended to be used in a sacred manner to facilitate spiritual communion with the Creator.

Afraid of being caught with his stolen property, EW decided to consume what he had taken and, a few hours later, began to have visual hallucinations that distorted his image of the road ahead. The mesas appeared to be on fire and, feeling dizzy and abruptly “seeing” the ocean right in front of him, he turned sharply, ran off the road at 75 mph, and was thrown from his bike into a wash. The tribal police now have him in custody, and he was taken to the health care facility in Chinle for treatment of his injuries. As the IHS pharmacist in charge, you and your rotation student are now about to see him as you make your morning rounds. You ask your student to take the lead on the consultation, beginning by identifying the hallucinogenic substance from the structural choices provided below.

1. Identify the therapeutic problem(s) where the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented SAR analysis of all structures provided in the case.
4. Counsel your patient

Chapter 24

Opioid Analgesics

David S. Fries

Introduction

Agents that decrease pain are referred to as analgesics, or analgetics. Although analgetic is grammatically correct, common use has made analgesic preferable to analgetic for the description of the pain-killing drugs. Pain relieving agents also are called antinociceptives.

A number of classes of drugs are used to relieve pain. The nonsteroidal anti-inflammatory agents have primarily a peripheral site of action, are useful for mild to moderate pain, and often have an anti-inflammatory effect associated with their pain-killing action. Local anesthetics inhibit pain transmission by inhibition of voltage-regulated sodium channels. These agents often are highly toxic when used in concentrations sufficient to relieve chronic or acute pain in ambulatory patients. Dissociative anesthetics (ketamine), and other compounds that act as inhibitors of N-methyl-D-aspartate (NMDA)–activated glutamate receptors in the brain, are effective antinociceptive agents when used alone or in combination with opioids. Compounds, such as the antiseizure drug pregabulin, which inhibits voltage regulated Ca^{2+} ion channels, are useful in treating neuropathic pain. Most central nervous system (CNS) depressants (e.g., ethanol, barbiturates, and antipsychotics) will cause a decrease in pain perception. Inhibitors of serotonin and norepinephrine reuptake (i.e., antidepressant drugs) are useful either alone and in combination with opioids in treating certain cases of chronic pain. Current research into the antinociceptive effects of centrally acting α-adrenergic-, cannabinoid-, and nicotinic-receptor agonists may yield clinically useful analgesics working by nonopioid mechanisms. Research in one or more of the above areas may lead to new drugs, but at present, severe acute or chronic pain generally is treated most effectively with opioid agents.

Historically, opioid analgesics have been called narcotic analgesics. Narcotic analgesic literally means that the agents cause sleep or loss of consciousness (narcosis) in conjunction with their analgesic effect. The term “narcotic” has become associated with the addictive properties of opioids and other CNS depressants. Because the great therapeutic value of the opioids is their ability to induce analgesia without causing narcosis, and because not all opioids are addicting, the term “narcotic analgesic” is misleading and will not be used further in this chapter.

History

The juice (*opium* in Greek) or latex from the unripe seed pods of the poppy *Papaver somniferum* is among the oldest recorded medications used by humans. The writings of Theophrastus around 200 BC describe the use of opium in medicine; however, evidence suggests that opium was used in the Sumerian culture as early as 3500 BC. The initial use of opium was as a tonic, or it was smoked. The pharmacist Surtürner first isolated an alkaloid from opium in 1803. He named the alkaloid morphine, after Morpheus, the Greek god of dreams. Codeine, thebaine, and papaverine are other medically important alkaloids that were later isolated from the latex of opium poppies.

Morphine was among the first compounds to undergo structure modification. Ethylmorphine (the 3-ethyl ether of morphine) was introduced as a medicine in 1898. Diacetylmorphine (heroin), which may be considered to be the first synthetic pro-drug, was synthesized in 1874 and marketed as a nonaddicting analgesic, antidiarrheal, and antitussive agent in 1898.

Clinical Significance

Opioid agonists and partial agonist/antagonists generally act on δ, μ, and κ receptors. All of these receptors have subtypes that provide varying degrees of analgesia, euphoria or dysphoria, central nervous system depression, and perhaps, the potential for tolerance. By modifying their structures, properties can be changed to develop agents that require more or less hepatic metabolism and, thus, affect the duration of action and the bioavailability. Other changes in the chemical structures can yield agents with much higher affinity for analgesic receptors, which corresponds to more potency on a milligram-to-milligram basis. Other alterations of the chemical structures can lead to improved profiles regarding respiratory depression, emesis, tolerance, and allergenicity. By altering the affinities for some receptors more than others, the addictive properties also may be manipulated.

Through an understanding of the relationship of chemical structures to biological activity, the clinician can improve the selection of drug to the specific patient.

Opiate/Opioid

The use of the terms “opiate” and “opioid” requires clarification. Until the 1980s, the term “opiate” was used extensively to describe any natural or synthetic agent that was derived from morphine. One could say an opiate was any compound that was structurally related to morphine. In the mid-1970s, the discovery of peptides in the brain with pharmacological actions similar to morphine prompted a change in nomenclature. The peptides were not easily related to morphine structurally, yet their actions were like those produced by morphine. At this time, the term “opioid,” meaning opium- or morphine-like in terms of pharmacological action, was introduced. The broad group of opium alkaloids, synthetic derivatives related to the opium alkaloids, and the many naturally occurring and synthetic peptides with morphine-like pharmacological effects are called opioids. In addition to having pharmacological effects similar to morphine, a compound must be antagonized by an opioid antagonist, such as naloxone, to be classed as an opioid. The neuronal-located proteins to which opioid agents bind and initiate biological responses are called opioid receptors.

Endogenous Opioid Peptides and Their Physiological Functions

Scientists had postulated for some time, based on structure–activity relationships (SARs), that opioids bind to specific receptor sites to cause their actions. It also was reasoned that morphine and the synthetic opioid derivatives are not the natural ligands for the opioid receptors and that some analgesic substance must exist within the brain. Techniques to prove these two points were not developed until the mid-1970s. Hughes et al. (1) used the electrically stimulated contractions of guinea pig ileum and the mouse vas deferens, which are very sensitive to inhibition by opioids, as bioassays to follow the purification of compounds with morphine-like activity from mammalian brain tissue. These researchers were able to isolate and determine the structures of two pentapeptides, Tyr-Gly-Gly-Phe-Met (Met-enkephalin) and Tyr-Gly-Gly-Phe-Leu (Leu-enkephalin), that caused the opioid activity. The compounds were named enkephalins after the Greek word *Kaphale*, which

translates as “from the head.”

At about the same time as Hughes and coworkers were making their discoveries, three other laboratories, using a different assay technique, were able to identify endogenous opioids and opioid receptors in the brain (2,3,4). These scientists used radiolabeled opioid compounds (radioligands), with high specific activity, to bind to opioid receptors in brain homogenates (5). They demonstrated saturable binding (i.e., the tissue contains a finite number of binding sites that can all be occupied) of the radioligands and that the bound radioligands could be displaced stereoselectively by nonradiolabeled opioids. Discovery of the enkephalins was soon followed by the identification of other endogenous opioid peptides, including β-endorphin (6), the dynorphins (7), and the endomorphins (8).

The opioid peptides isolated from mammalian tissue are known collectively as endorphins, a word that is derived from a combination of endogenous and morphine. The opioid alkaloids and all of the synthetic opioid derivatives are exogenous opioids. Interestingly, the isolation of morphine and codeine in small amounts has been reported from mammalian brain (9). The functional significance of endogenous morphine remains unknown.

Opioid Peptides

The endogenous opioid peptides are synthesized as part of the structures of large precursor proteins (10). There is a different precursor protein for each of the major types of opioid peptides (Fig. 24.1). Proopiomelanocortin is the precursor for β-endorphin. Proenkephalin A is the precursor for Met- and Leu-enkephalin. Proenkephalin B (prodynorphin) is the precursor for dynorphin and

α-neoendorphin. The pronociceptin protein has been identified and contains only one copy of the active peptide, whereas the precursor protein for the endomorphins remains to be identified. All of the pro-opioid proteins are synthesized in the cell nucleus and transported to the terminals of the nerve cells from which they are released. The active peptides are hydrolyzed from the large proteins by processing proteases that recognize double basic amino acid sequences positioned just before and after the opioid peptide sequences.

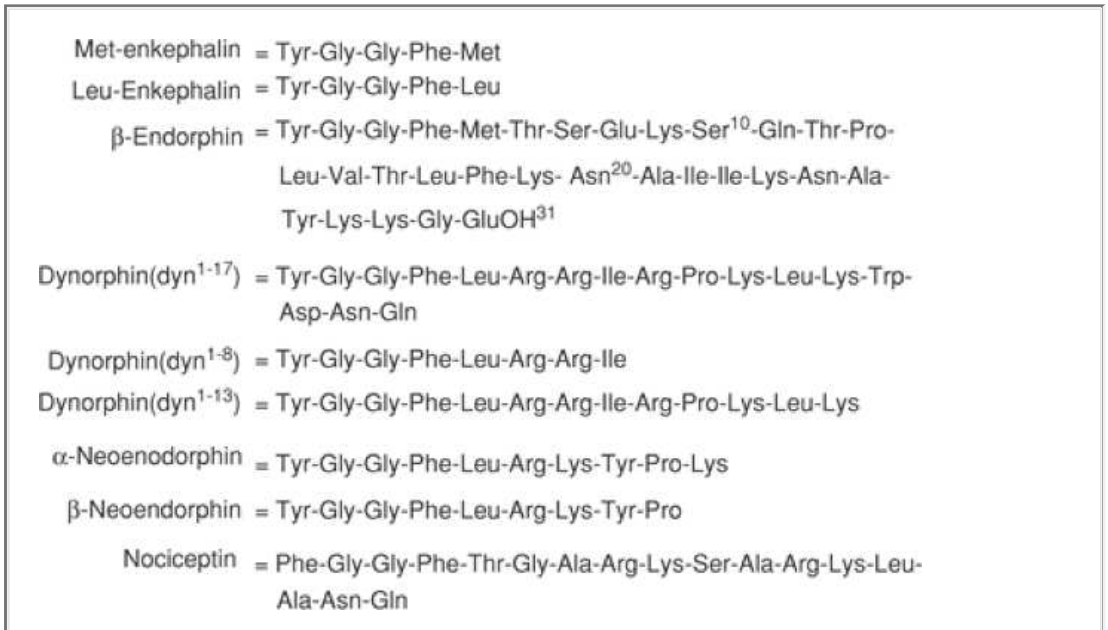

Fig. 24.1. Precursor proteins to the endogenous opioid peptides.

Peptides with opioid activity have been isolated from sources other than mammalian brain. The heptapeptide β-casomorphin (Tyr-Pro-Phe-Pro-Gly-Pro-Ile), found in cow's milk, is a μ opioid agonist (11). Dermorphin (Tyr-D-Ala-Phe-Gly-Tyr-Pro-Ser-NH2), a μ-selective peptide isolated from the skin of South American frogs, is approximately 100-fold more potent than morphine in in vitro tests (12).

The endogenous opioids exert their analgesic action at spinal and supraspinal sites (Fig. 24.2). They also produce analgesia by a peripheral mechanism of action associated with the inflammatory process. In the CNS, the opioids exert an inhibitory neurotransmitter or neuromodulator action on afferent pain-signaling neurons in the dorsal horn of the spinal cord and on interconnecting neuronal pathways for pain signals within the brain. In the brain, the arcuate nucleus, periaqueductal gray, and the thalamic areas are especially rich in opioid receptors and are sites at which opioids exert an analgesic action. In the spinal cord, concentrations of endogenous opioids are high in laminae 1, laminae 2, and trigeminal nucleus areas. All of the endogenous opioid peptides and the three major classes of opioid receptors appear to be at least partially involved in the modulation of pain. The actions of opioids at the synaptic level are described in Figure 24.3.

Analgesia that results from acupuncture or is self-induced by a placebo or biofeedback mechanisms is caused by release of endogenous endorphins. Analgesia produced by these procedures can be prevented by the previous dosage of a patient with an opioid antagonist. Electrical stimulation from electrodes properly placed in the brain causes endorphin release and analgesia. This procedure is used for the “self-stimulated” release of endorphins in patients with chronic pain who do not respond to any other medical treatment. As with exogenously administered opioid drugs, tolerance develops to all procedures that work by release of endogenous opioids.

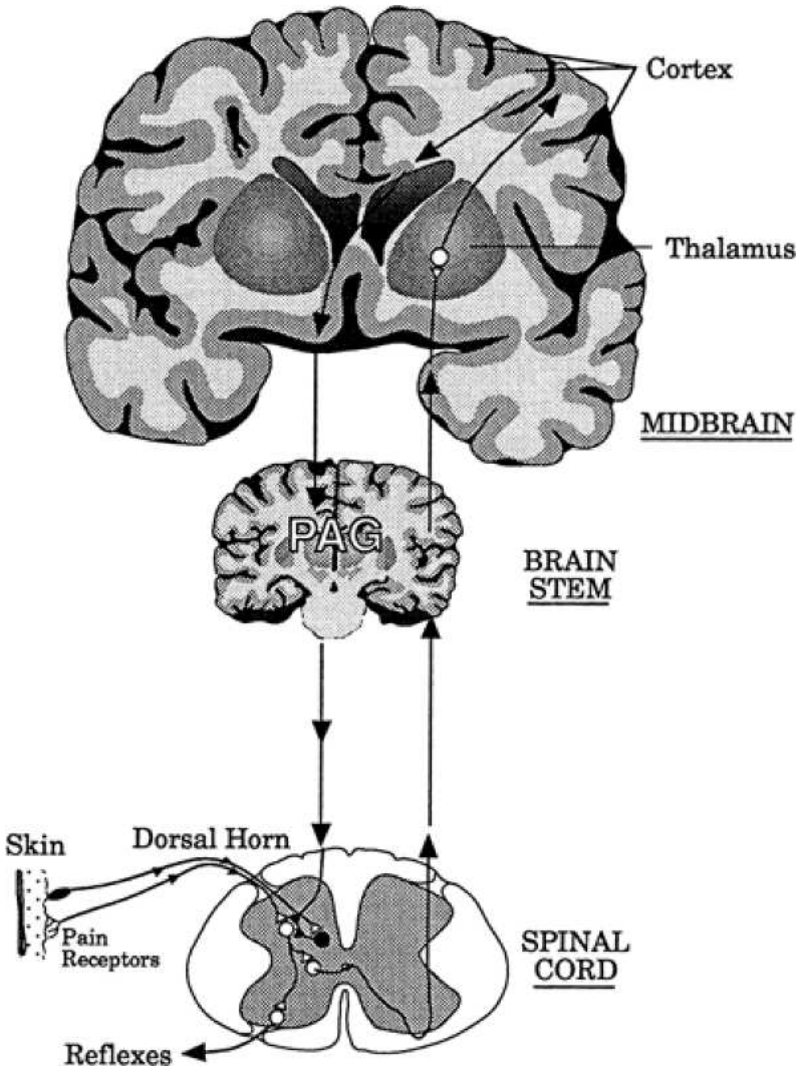

Fig. 24.2. Location of endogenous opioid nerve tracts in the central nervous system. Endorphins and opioid receptors in the dorsal horn of the spinal cord, thalamus, and periaqueductal gray (PAG) areas are associated with the transmission of pain signals.

Opioid Receptors

There are the three major types of opioid receptors: μ, κ (13), and δ (14). All three of the receptor types have been well characterized and cloned (15). A nomenclature adopted by the International Union of Pharmacology (IU PHAR) in 1996 classifies the three opioid receptors by the order in which they were cloned (16). By this classification, δ opioid receptors are OP_1 receptors, κ opioid receptors are OP_2 receptors, and μ opioid receptors are OP_3 receptors. The IUPHAR approved a new nomenclature in 2000, naming the receptors as MOP-μ, DOP-δ, and KOP-κ. In current literature, however, the opioid receptors often are referred to as DOR (δ), KOR (κ), and MOR (μ). There is evidence for subtypes of each of these receptors; however, the failure of researchers to find genomal evidence for

additional receptors indicates that the receptor subtypes are posttranslational modifications (splice

variants) of known receptor types (17). Receptor subtypes also may be known receptor types that are coupled to different signal transduction systems. Table 24.1 lists the opioid receptor types and subtypes, their known physiological functions, and selective agonists and antagonists for each of the receptors. All three of the opioid receptor types are located in human brain or spinal cord tissues, and each has a role in the mediation of pain. At this time, only μ and κ agonists are in clinical use as opioid analgesic drugs.

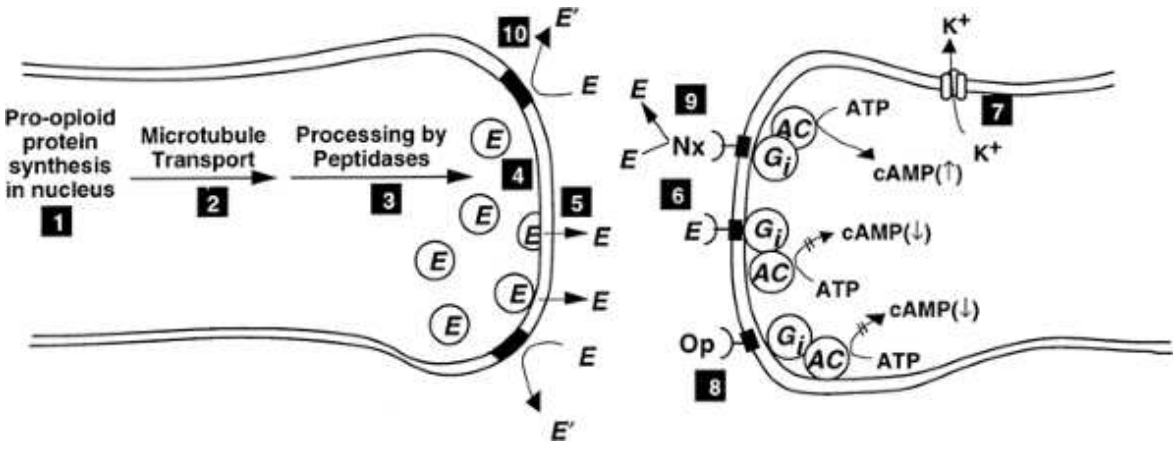

Fig. 24.3. Schematic representation of a δ enkephalinergic nerve terminal. (1) Pro-opioid proteins (proenkephalin A) are synthesized in the cell nucleus. (2) Pro-opioid proteins undergo microtubular transport to the nerve terminal. (3) Active endogenous opioids (E) are cleaved from the pro-opioid proteins by the action of "processing" proteases. (4) The active peptides (E) are taken up and stored in presynaptic vesicles. (5) The peptides are released when the presynaptic neuron fires. (6) The endogenous opioid peptides bind to postsynaptic receptors and activate second messenger systems. (7) For all opioid receptors, the second messenger effect is primarily mediated by a G-inhibitory ($G_{i/o}$) protein complex, which promotes the inactivation of adenylate cyclase (AC), a decrease in intracellular cyclic-adenosine-3′,5′-monophosphate (cAMP), and finally, an efflux of potassium ions (K^+) from the cell. The net effect is the hyperpolarization of the postsynaptic neuron and inhibition of cell firing. (8). Exogenous opioids (Op), such as morphine, combine with opioid receptors and mimic the actions of E. (9) Opioid antagonists, such as naloxone (Nx), combine with opioid receptors and competitively inhibit the actions of E or Op. (10) The action of E is terminated by a membrane-bound endopeptidase [EC3.4.24.11] (enkephalinase), which hydrolyze the Gly3-Phe4 peptide bond of enkephalin. Other endopeptidases may be employed in the metabolism of different endogenous opioid peptides.

Orphan Opioid Receptor

A fourth receptor has been identified and cloned (OP_4) based on homology with cDNA sequence of the known (μ, δ, and κ) opioid receptors (18). Despite the homology in cDNA sequence with known opioid receptors, this new receptor did not bind the classical opioid peptide or nonpeptide agonists

or antagonists with high affinity. Thus, the receptor was called the orphan opioid receptor (NOP). In subsequent studies, two research groups found a heptadecapeptide (Phe-Gly-Gly-Thr-Gly-Ala-Arg-Lys-Ser-Ala-Lys-Ala-Asn-Gln) to be the endogenous peptide for the orphan opioid receptor. One of the research groups (19) named the heptadecapeptide nociceptin, because they determined that it caused hyperalgesia (nociception) after intracerebral ventricular injection into mice. The other research group (20) named the heptapeptide orphanin FQ, after its affinity for the orphan opioid receptor and the first and last amino acids in the peptides sequence (i.e., F = Phe and Q = Gln) Nociceptin/orphanin FQ resembles dynorphin-A in structure, with the most notable difference being the replacement of Tyr at the N-terminus with Phe. Conflicting results have now been published regarding the ability of nociceptin/orphanin FQ to produce hyperalgesia versus analgesia in rodent pain assay models. One study has established this compound to be a potent initiator of pain signals in the periphery, where it acts by releasing substance P from nerve terminals (21). Injection of a nociceptin/orphanin antagonist into the brains of laboratory animals results in an analgesic effect, raising hope for the use of these agents in the management of pain (22).

Identification and Activation of Opioid Receptors

Identification of multiple opioid receptors has depended on the discovery of selective agonists and antagonists, the identification of sensitive assay techniques (23), and ultimately, the cloning of the receptor proteins (15). The techniques that have been especially useful are the radioligand binding assays on brain tissues and the electrically stimulated peripheral muscle preparations. Rodent brain tissue contains all three opioid receptor types, and special evaluation procedures (computer-assisted line fitting) or selective blocking (with reversible or irreversible binding

agents) of some of the receptor types must be used to sort out the receptor selectivity of test compounds. The myenteric plexus–containing longitudinal strips of guinea pig ileum contain μ and κ opioid receptors. The contraction of these muscle strips is initiated by electrical stimulation and is inhibited by opioids. The vas deferens from mouse contains μ, δ, and κ receptors and reacts similarly to the guinea pig ileum to electrical stimulation and to opioids. Homogenous populations of opioid receptors are found in rat (μ), hamster (δ), and rabbit (κ) vas deferentia.

Table 24.1. Opioid Receptor Types and Subtypes

Receptor Type (Natural Ligand)	Selective Agonists	Agonist Properties	Selective Antagonists
μ, mu, MOP, OP_3 (endomorphin 1) (endomorphin 2) (β-endorphin)	Morphine	Analgesia (morphine-like)	Naloxone
	Sufentanil	Euphoria	Naltrexone
	DAMGO (Tyr-D-Ala-MePhe-NH-$(CH_2)_2$OH	Increased gastrointestinal transit time	CTOP Cyprodime
	PLO17 (Tyr-Pro-MePhe-D-Pro-NH_2 BIT (affinity label)	Immune suppression Respiratory depression	β-FNA (affinity label)

		(volume)	
μ_1 (high affinity)	Meptazinol Etonitazene	Emetic effects Tolerance Physical dependence	Naloxonazine
μ_2 (low affinity)	TRIMU-5 (Tyr-D-Ala-Gly-NH-$(CH_2)_2$-CH-$(CH_3)_2$		
κ, kappa, KOP, OP_2 (dynorphins) (β-endorphin)	Ethylketocyclazocine (EKC) Bremazocine Mr2034 dyn (1–17) Trifluadom	Analgesia Sedation Miosis Diuresis Dysphoria	TENA nor-BNI
κ_1 (high affinity)	U-50,488 Spiradoline (U-62,066) U-69,593 PD 117302		UPHIT
κ_2	dyn 1–17		
κ_3	NalBzOH		
δ, delta, DOP, OP_1 (enkephalins) (β-endorphin)	DADLE (D-Ala^2-D-Leu^5- enkephalin) DSLET (Tyr-D-Ser-Gly-Phe-Leu-Thr) DPDPE (D-Pen^2-D-Pen^5-Convulsions (?) Enkephalin)	Analgesia Immune stimulation Respiratory depression (rate)	ICI 174864 FIT (affinity label) SUPERFIT (affinity label)
δ_2	DADLE		Naltrindole (NTI) BNTX
δ_2	D-Ala^2-deltorphin II		Naltriben (NTB) Naltrindol

		isothiocyanate (NTII)

The signal transduction mechanism for μ, δ, and κ receptors is through $G_{i/o}$ proteins. Activation of opioid receptors is linked through the G protein to an inhibition of adenylate cyclase* activity. The resultant decrease in cAMP production, efflux of potassium ions and closure of voltage-gated Ca^{2+} channels causes hyperpolarization of the nerve cell (24,25), and a strong inhibition of nerve firing.

μ Opioid Receptors

Endomorphin-1 (Tyr-Pro-Trp-Phe-NH_2) and endomorphin-2 (Try-Pro-Phe-Phe-NH_2) are endogenous opioid peptides with a high degree of selectivity for μ (MOP) receptors (8). A number of therapeutically useful compounds have been found that are selective for μ opioid receptors (Fig. 24.4). All of the opioid alkaloids and most of their synthetic derivatives are μ-selective agonists. Morphine, normorphine, and dihydromorphinone have 10- to 20-fold μ receptor selectivity and were particularly important in early studies to differentiate the opioid receptors. Sufentanil and the peptides DAMGO (26) and dermorphin (27), all with 100-fold selectivity for μ over other opioid receptors, frequently are used in the laboratory studies to demonstrate μ receptor-selectivity in cross-tolerance, receptor binding, and isolated smooth muscle assays. Studies with μ receptor knockout mice have confirmed that all the major pharmacological actions observed on injection of morphine (e.g., analgesia, respiratory depression, tolerance, withdrawal symptoms, decreased gastric motility, and emesis) occur by interactions with μ receptors (28).

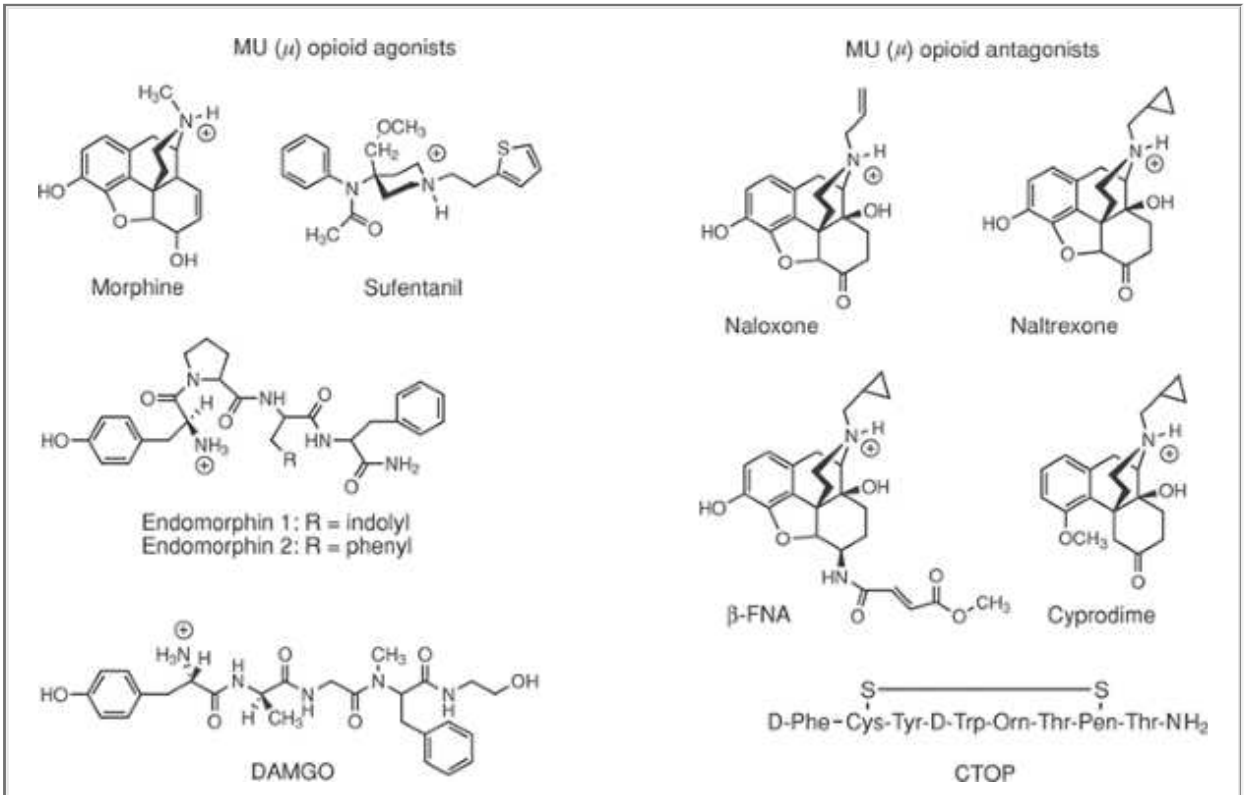

Fig. 24.4. Structures of compounds selective for μ (OP_3) opioid

receptors.

Naloxone and naltrexone are antagonists that have weak (5 to 10 times) selectivity for μ receptors. Cyprodime is a selective nonpeptide μ antagonist (~30-fold selective for μ over κ and 100-fold selective for μ over δ) available for laboratory use (29). CTOP, a cyclic peptide analogue of somatostatin, is a selective μ antagonist (30). There is evidence that μ_1 receptors are high-affinity binding sites that mediate pain neurotransmission, whereas μ_2 receptors control respiratory depression. Naloxoneazine is a selective inhibitor of μ_1 opioid receptors (31).

κ Opioid Receptors

Ethylketazocine and bremazocine are 6,7-benzomorphan derivatives with κ opioid receptor selectivity (Fig. 24.5). These two compounds were used in early studies to investigate κ (KOP) receptors. They are not highly selective, however, and their use in research has diminished. A number of arylacetamides derivatives, having a high selectivity for κ over μ or δ receptors, have been discovered. The first of these compounds, (±)-U50488, has a 50-fold selectivity for κ over μ receptors and has been extremely important in the characterization of κ opioid activity (32). Other important agents in this class are (±) PD-117302 (33) and (-) CI-977 (34). Each of these agents has 1,000-fold selectivity for κ over μ or δ receptors. Evidence suggests that the arylacetamides bind to a subtype of κ receptors. In general, κ agonists produce analgesia in animals, including humans. Other prominent effects are diuresis, sedation, and dysphoria. Compared to μ agonists, κ agonists lack respiratory depressant, constipating, and strong addictive (euphoria and physical dependence) properties. It was hoped that κ agonists would become useful strong analgesics that lacked addictive properties; however, clinical trials with several highly selective and potent κ agonists were aborted because of the occurrence of unacceptable sedative and dysphoric side effects. κ-Selective opioids with only a peripheral action have been shown to be effective in relieving inflammation and the pain associated with it (35). The scientific evidence suggesting κ_1, κ_2, and κ_3 subtypes of κ receptors; however, the physiological effects initiated by the κ receptor subtypes are not well defined (36).

The peptides related to dynorphin are the natural agonists for κ receptors. Their selectivity for κ over μ receptors is not very high. Synthetic peptide analogues have been reported that are more potent and more selective than dynorphin for κ receptors (37,38).

The major antagonist with good selectivity for κ receptors is nor-binaltorphimine (39). This compound has approximately 100-fold selectivity for κ over δ receptors and an even greater selectivity for κ over μ receptors when tested during competitive binding studies in monkey brain homogenate. No medical use for a κ antagonist has been found.

δ Opioid Receptors

Enkephalins, the natural ligands at δ (DOP) receptors, are only slightly selective for δ over μ receptors. Changes

in the amino acid composition of the enkephalins can give compounds with high potency and selectivity for δ receptors. The peptides most often used as selective δ receptor ligands (Fig. 24.6) are [D-Ala^2, D-Leu^5] enkephalin (DADLE) (40), [D-Ser^2, Leu^5] enkephalin-Thr (DSLET) (41), and the cyclic peptide [D-Pen^2, D-Pen^5] enkephalin (DPDPE) (42). These and other δ receptor selective peptides have been useful for in vitro studies, but their metabolic instability and poor distribution properties (i.e., penetration of the blood-brain barrier is limited by their hydrophilicity) has limited their usefulness for in vivo studies. Nonpeptide agonists that are selective for δ receptors have been reported. Derivatives of morphindoles were the first nonpeptide molecules to

show δ selectivity in in vitro assays (43). SNC-80 is a newer and more selective δ opioid receptor agonist (44). This compound produces analgesia after oral dose in several rodent models and side effects appear minimal. Clinical trials with SCN-80 and other nonpeptide δ receptor agonists were attempted and aborted, primarily because of the convulsant action of δ receptor agonists. Radioligand binding studies in rodent brain tissue and in electrically stimulated vas deferentia have provided evidence of δ_1 and δ_2 receptors (45). The functional significance of this differentiation has not been determined.

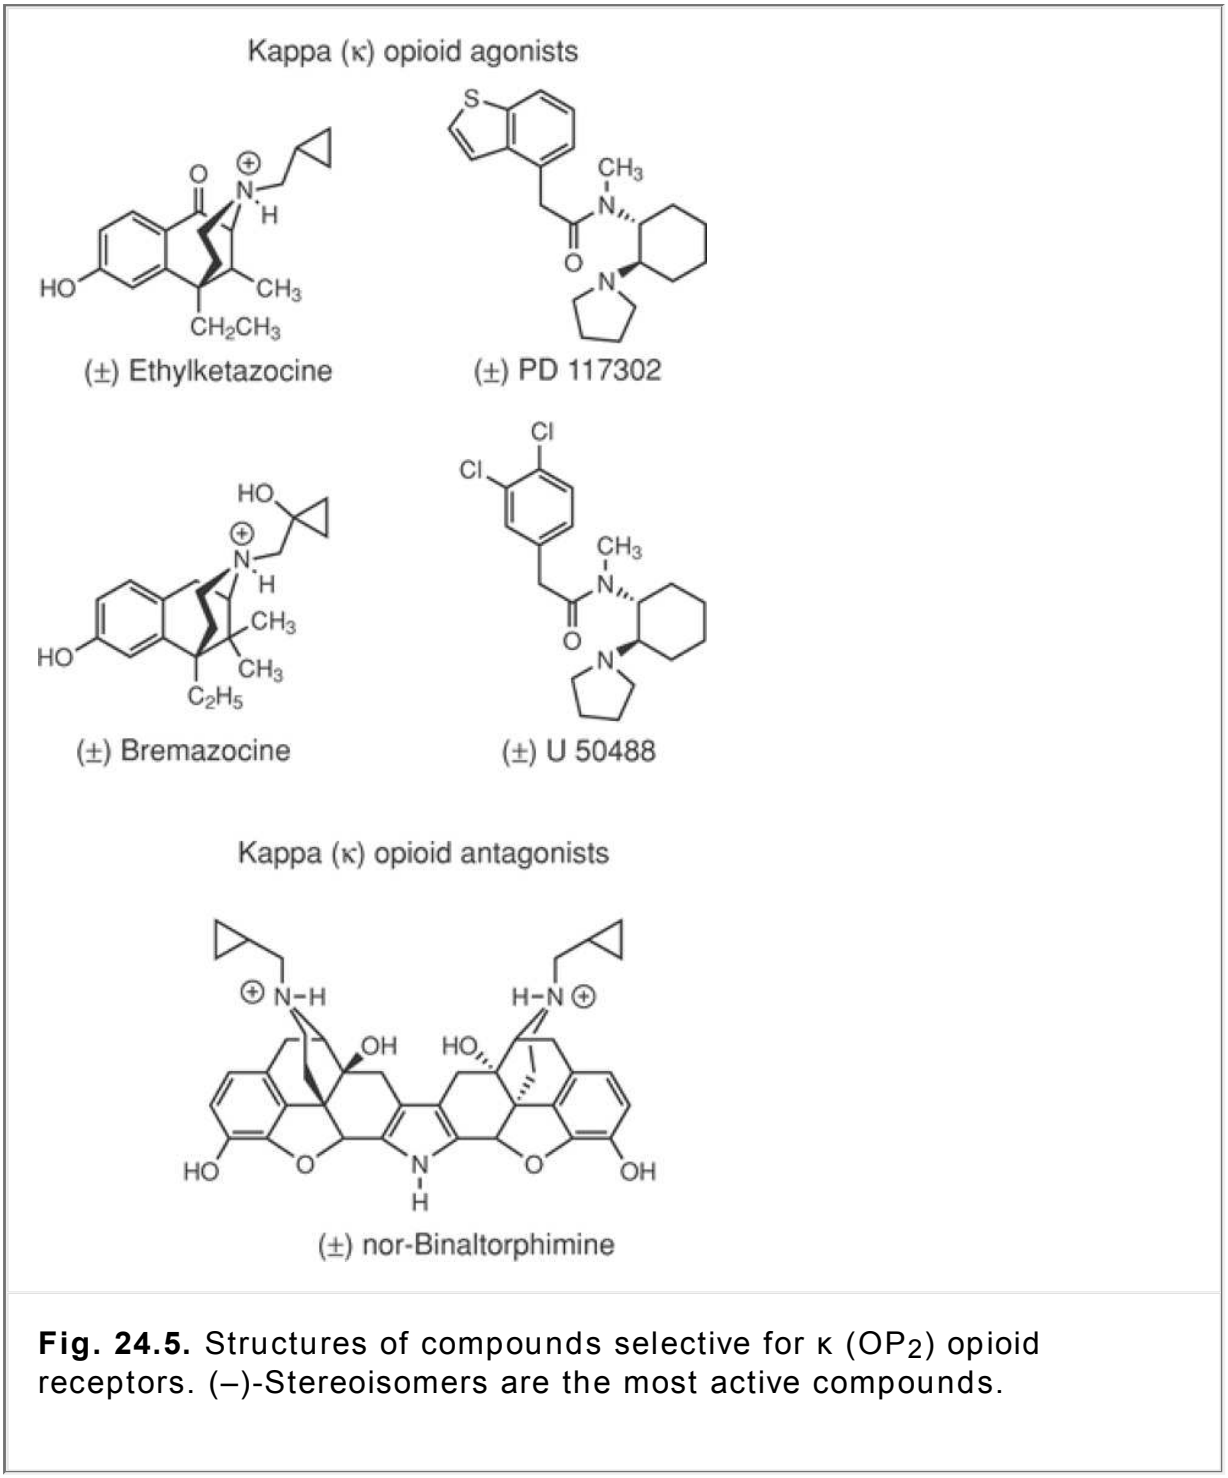

Fig. 24.5. Structures of compounds selective for κ (OP_2) opioid receptors. (–)-Stereoisomers are the most active compounds.

Naltrindol and naltriben are highly selective nonpeptide antagonist for δ receptors (46,47). Naltrindol penetrates the CNS and displays antagonist activity that is selective for δ receptors in in vitro and in vivo systems. Peptidyl antagonists TIPP and TIPP-ψ are selective for δ receptors

(48,49); however, their usefulness for in vivo studies and as clinical agents is limited by their poor pharmacokinetic properties. The δ opioid receptor antagonists have shown clinical potential as immunosuppressants and in treatment of cocaine abuse.

Receptor Affinity Labeling Agents

A number of opioid receptor selective affinity labeling agents (i.e., compounds that form an irreversible covalent bond with the receptor protein) have been developed (Fig. 24.7). These compounds have been important

in the characterization and isolation of the opioid receptor types. Each of the affinity-labeling agents contains a pharmacophore that allows initial reversible binding to the receptor. Once reversibly bound to the receptor, an affinity labeling agent must have an electrophilic group positioned so that it can react with a nucleophilic group on the receptor protein. The receptor selectivity of these agents is dependent on 1) the receptor type selectivity of the pharmacophore, 2) the location of the electrophile within the pharmacophore structure so that when bound to the receptor it is positioned near a nucleophile, and 3) the relative reactivities of the electrophilic and nucleophilic groups.

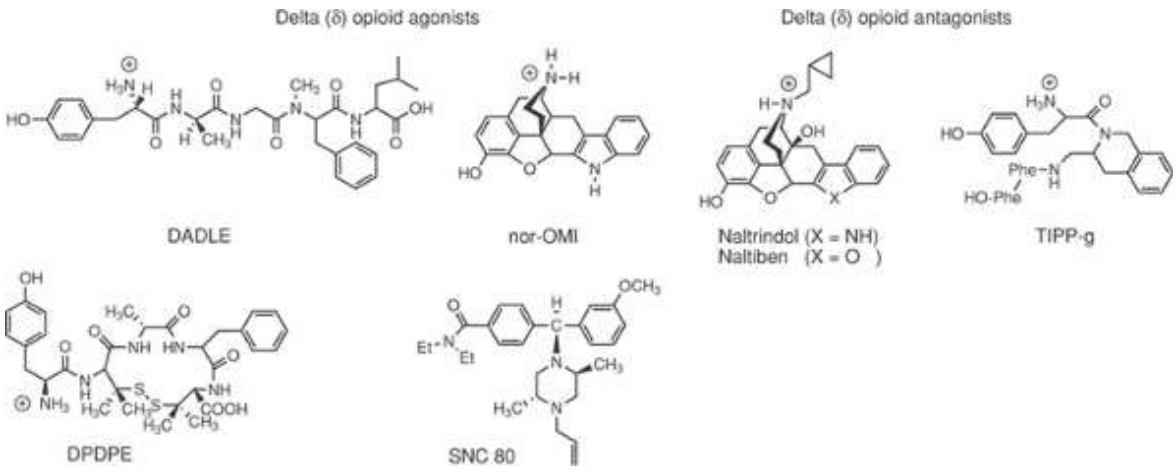

Fig. 24.6. Structures of compounds selective for δ (OP_1) opioid receptors.

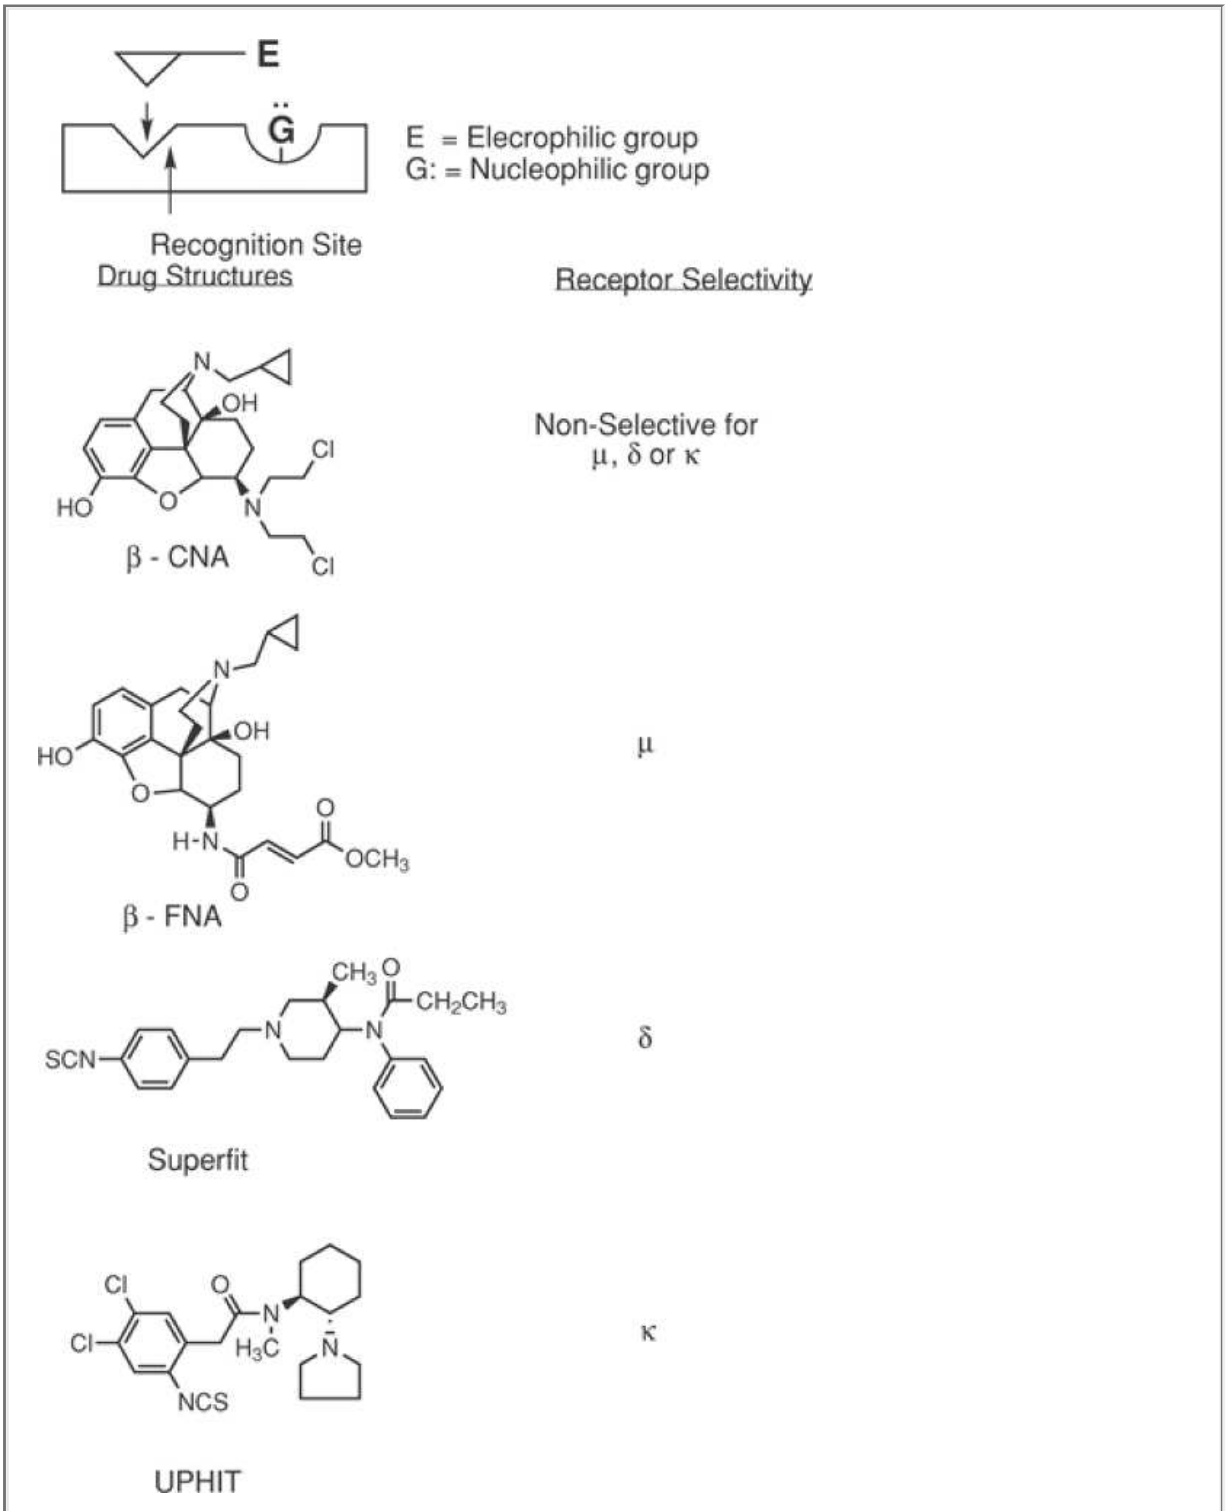

Fig. 24.7. A representation of the concept of affinity labeling of receptors and affinity labeling agents for opioid receptors.

Examples of important affinity labeling agents are β-CNA, which because of its highly reactive 2-chloroethylamine electrophilic group irreversibility binds to all three opioid receptor types (50). The structurally related compound β-FNA has a less reactive fumaramide electrophilic group and reacts irreversibly with only μ receptors (51). Derivatives of the fentanyl series, FIT and

SUPERFIT, bind μ and δ receptors, but only the δ receptor is bound irreversibly (52,53). Apparently, when these agents are bound to μ receptors, the electrophilic isothiocyanate group is not oriented in proper juxtaposition to a receptor nucleophile for covalent bond formation to occur. Incorporation of the electrophilic isothiocyanate into the structure of the highly κ receptor–selective arylacetamides has provided affinity labeling agents (UPHIT and DIPPA) for κ receptors (54,55).

Neurobiology of Drug Abuse and Addiction

The factors that drive some individuals to abuse drugs, with resultant tolerance and psychological and physical dependence, remains unknown. It has been proposed that a deficiency exists in the opioid-mediated self-reward system of individuals who have a predisposition to abuse addictive drugs (56). In the United States, the use of highly addictive drugs, such as heroin and cocaine, is treated as a crime rather than as a medical problem. New insights regarding the neurobiology of drug addiction is now providing an understanding of why individuals abuse drugs and how drug abuse and addiction can be avoided and treated.

Self-Reward Response

It is now evident that all forms of drug addiction are driven by the stimulation of the brain's self-reward system (57), which originates in the ventral tegmental nucleus (VTN) and extends to the nucleus accumbens (NAC) area of the midbrain (Fig. 24.8). Self-reward is initiated by the release of dopamine (DA) from the mesocorticolimbic DA neurons originating in the VTN and stimulating D_1 and D_2 receptors in the NAC. Cocaine acts by inhibiting the reuptake of DA at nerve terminals, thus increasing the intensity and duration of the reward response. Amphetamine, methamphetamine, and similar indirect acting adrenergic stimulants cause inhibition of DA reuptake, DA release, and inhibition of monoamine oxidase–mediated mediated of DA at this site. The μ opioid agonists work upstream in the reward neuronal system by exerting an inhibitory action on GABAergic neurons, thus removing the inhibitory GABAergic tonus on DA neurons and initiating the self-reward response. The κ opioid agonists work at a site more downstream in the system and cause the opposite effect of the μ agonists. The κ neurons synapse directly onto the DA nerve terminal in the NAC and exert an inhibitory effect (negative tonus) on DA release. Thus, a μ agonist will cause a self-reward and euphoric stimulus, and a κ agonist will cause an aversive and dysphoric stimulus. Alcohol (ethanol) also causes a stimulation of the self-reward system, partially by acting on the μ opioid neurons to facilitate the release of endogenous opioids

(58). Nicotine, acting through nicotinic cholinergic receptors, also has been shown to stimulate the DA self-reward system (59).

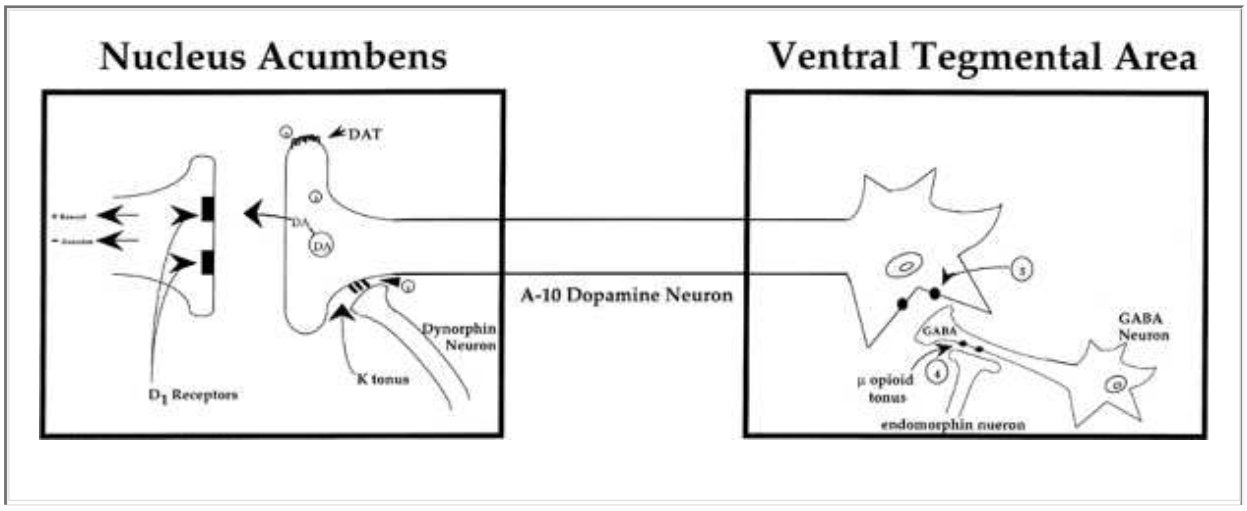

Fig. 24.8. The neurochemical basis of drug abuse and addiction. The diagram is a representation of the brain's self-reward system. According to this theory, any agent that promotes stimulation of type-1 dopamine (D_1) receptors in the nucleus accumbens (NCA) potentiates self-reward and has the potential to be abused. Major drugs of abuse exert their actions at various sites within the self-reward system to increase dopamine (DA) in the NCA and stimulate D_1 receptors. Site 1: Cocaine blocks DA reuptake by the DA transporter (DAT) and greatly enhances DA action at D_1. Site 2: Amphetamine, methamphetamine, and related drugs cause DA release with the resultant stimulation of D_1. Site 3: Opioid κ agonists exert an inhibitory effect on DA neuronal firing, resulting in a decrease in DA release and aversion in animals. Site 4: Opioid μ agonists, such as morphine and heroin, exert an inhibitory action on γ-aminobutyric acid (GABA) interneurons in the VAT, thus removing the GABAergic inhibition on DA neuronal firing. Site 5: GABA agonists, such as gabapentin, enhance DA neuronal firing and DA release, and these agents may be useful in treating or preventing drug abuse and addiction. Other abused agents, such as nicotine and cannabis, also cause an increase in DA release in the NAC, but their exact neuronal connections to the self-reward system is not yet understood.

Thus, the common driving pathway in drug addiction is the euphoria experienced when a drug is taken and the self-reward system is activated by DA release. The self-reward response tends to be self-limiting, because feedback (adaptive) mechanisms in the nerve cells attenuate the reward delivered after prolonged or repeated activation of the system. Agents that slowly distribute to the brain have minor abuse potential, because the adaptive mechanisms in the self-reward neuronal system are able to respond quickly enough to attenuate the euphoric response. Highly abused substances tend to have high potency, full efficacy, and a fast onset of action so that the reward signal is initiated and fully activated before the adaptive process can take effect. Factors that contribute to fast onset of action are high lipophilicity of the drug and a dosing method that allows rapid distribution to the brain. Most abused drugs are highly lipophilic so that they rapidly cross the blood-brain barrier. The dosage routes preferred by drug addicts (smoking and intravenous injection) meet the criteria for fast distribution to the brain. Of course, agents that are rapidly distributed to and absorbed by the brain also are rapidly redistributed from the brain to other body tissues. Because of the redistribution phenomenon, the intense euphoric rush experienced by the addict is short-lived and must be frequently reinduced. Repeated exposure of the reward system to the drugs activates the adaptive mechanisms, which results in desensitization (tolerance) of the system to the abused substance. The addict must take a larger dose of the drug to get the euphoric high that she or he seeks, which results in increased tolerance and propagation of the addiction cycle.

Opioid Tolerance and Withdrawal

Tolerance to and withdrawal from the opioids is explained by the cellular adaptation that occurs on repeated activation of μ opioid receptors (60). When an agonist binds to the μ receptor, $G_{i/o}$ second messenger proteins are activated, and inhibition of adenylate cyclase occurs. Continual activation of the receptors results in an upregulation of adenylate cyclase to compensate for the decrease in cellular concentrations of cAMP. In addition, cellular mechanisms are activated that result in a decrease in the synthesis of $G_{i/o}$ protein subunits and an internalization of the μ

receptor protein. Together, these adaptations cause a decrease in the magnitude of the opioid response to a given dose of agonist and explain the development of tolerance in the system and the need for ever-higher doses to get the same degree of euphoric response.

When the nerve cells are pushed into a highly tolerant state, they have a great capacity to make cAMP because of the upregulation in adenylate cyclase; however, the capacity is held in check by inhibitory effect of the opioids on

adenylate cyclase. On cessation of dosing the opioid (~4–6 hours with heroin), the inhibitory effect on the upregulated adenylate cyclase system is removed, and the cells overproduce cAMP. The increase in cellular cAMP induces a number of abnormal and unpleasant effects that are recognized collectively as opioid withdrawal symptoms. The acute phase of withdrawal lasts for days (i.e., the time required for cAMP levels and receptor mechanisms to return to a normal state). The long-term effect of drug addiction is a learned drug-craving behavior, which can last for a lifetime and is thought to be responsible for the high incidence of stress-induced relapses into drug abuse.

Interestingly, not all μ opioid agonists have the same capacity to initiate receptor internalization and downregulation, which are typical occurrences in the development of tolerance. Morphine has a high capacity to induce tolerance, whereas methadone has a much lower tolerance capacity. Clinical studies are in progress to see if coadministration of morphine and methadone will result in lower tolerance development (61).

Rehabilitation of Opioid Addiction

Therapeutic programs that employ drugs in the rehabilitation of drug addicts have been in use for some time. The best-known treatment is the use of methadone maintenance in the rehabilitation of the opioid addict. In a well-run program, daily treatment with oral methadone maintains the addicted (tolerant) state while allowing minimal euphoric/aversive mood swings, attenuates drug craving, decreases the spread of HIV (by decreasing needle sharing), and minimizes the social destructive behavior (e.g., prostitution and theft) of the addicted patient (62). Other agents, such as the μ agonist L-α-acetylmethadol (levomethadyl) and the partial μ agonist buprenorphine, can be substituted for methadone and offer the advantage of dosing every third day (63,64). The biggest problem with addiction treatment programs is their failure to alleviate the drug-craving behavior of the recovering addict, and she or he resumes the habit of drug abuse. Evidence suggests that treatment of a detoxified opioid addict (i.e., an individual who has been weaned from opioid dependence through a methadone or other treatment program) with a long-acting opioid antagonist, such as naltrexone, can not only pharmacologically block readdiction but also curb the addict's drug-craving urge (65). Interestingly, naltrexone treatment has been shown to inhibit alcohol craving in recovering alcoholics (66). Naltrexone and buprenorphine have shown promise in treatment of cocaine abuse (67,68).

A number of possible neurobiological mechanisms have been identified by which drug intervention might prevent drug abuse or aid in the recovery of the addict (Fig. 24.8). The use of μ opioid agonists, partial agonists, and antagonists has been described in the preceding paragraph. Additional opioid-related mechanisms may be effective in the prevention of drug abuse and addiction. When a δ opioid agonist is given in combination with a μ opioid agonist, analgesia is enhanced, and there is minimal induction of tolerance and physical dependence (69). It also has been shown that administration of a μ agonist along with a δ antagonist to rodents resulted in analgesia without inducing tolerance and physical dependence (70). α-Adrenergic agonists are known to interact with many of the same neuronal systems as the opioids. The centrally acting μ-agonist clonidine works through the same $G_{i/o}$ second messenger system as the opioids, and it is used clinically to inhibit withdrawal symptoms in patients addicted to opioids. Testing of the long-acting indirect GABAergic agent vigabatrin (a suicide inhibitor of GABA aminotransferase) has been proposed for the treatment of drug addiction (71). One additional area of promise is the proposal that a high-affinity, slow-onset inhibitor of the DA transporter will be effective for the

treatment of cocaine abuse (72).

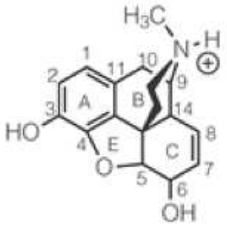
Structure–Activity Relationships of μ Receptor Agonists

Morphine

Morphine is the prototype opioid (Table 24.2). It is selective for μ opioid receptors. The structure of morphine is composed of five fused rings, and the molecule has five chiral centers with absolute stereochemistry 5(*R*), 6(*S*), 9(*R*), 13(*S*) and 14(*R*). The naturally occurring isomer of morphine is levo-[(–)] rotatory. (+)-Morphine has been synthesized, and it is devoid of analgesic and other opioid activities (73).

It is important to remember that a minor change in the structure of morphine (or any other opioid) will likely cause a different change in the affinity and intrinsic activity of the new compound at each of the opioid receptor types. Thus, the opioid receptor selectivity profile of the new compound may be different than the structure from which it was made or modeled (i.e., a selective μ agonist may shift to become a selective κ agonist, etc.). In addition, the new compound will have different physicochemical properties than its parent. The different physicochemical properties (e.g., solubility, partition

coefficient, and pK_a) will result in different pharmacokinetic characteristics for the new drug and can affect its in vivo activity profile. For example, a new drug (Drug A) that is more lipophilic than its parent may distribute better to the brain and appear to be more active, whereas in actuality, it may have lower affinity or intrinsic activity for the receptor. The greater concentration of Drug A reaching the brain is able to overcome its decreased agonist effect at the receptor. The SARs discussed in the following paragraphs describe the relative therapeutic potencies of the compounds and are a combination of pharmacokinetic and receptor binding properties of the drugs.



(-)-Morphine

3-H for -OH	10× Decrease
6-OH to 6-keto	Decrease activity or increase w/7,8-dihydro
6-OH to 6-H	Increase activity
7,8-dihydro	Increase activity
14 b-OH	Increase activity
3-OCH_3 for OH	Decrease activity
CH_3CO-ester at 3	Decrease activity
CH_3CO-ester at 6	Increase activity
NCH_2CH_2Ph for NCH_3	Increase activity (10×)
$NCH_2CH{=}CH_2$ for NCH_3	Becomes a μ antagonist

Table 24.2 Structure, Numbering and Selected SAR for (-)-Morphine)

The A ring and the basic nitrogen, which exists predominantly in the protonated (ionized) form at physiological pH, are the two most common structural features found in compounds displaying opioid analgesic activity. The aromatic A ring and the cationic nitrogen may be connected either by an ethyl linkage (9,10-positions of the B ring) or a propyl linkage (either edge of the piperidine ring that forms the D ring). The A ring and the basic nitrogen are necessary components in every potent μ agonist known. These two structural features alone are not sufficient for μ opioid activity, however, and additional pharmacophoric groups are required. In compounds having rigid structures (i.e., fused A, B, and D rings), the 3-hydroxy group and a tertiary nitrogen either greatly enhance or

are essential for activity. A summary of other important SAR features for morphine is given in Table 24.2.

Nitrogen Atom

The substituent on the nitrogen of morphine and morphine-like structures is critical to the degree and type of activity displayed by an agent. A tertiary amine usually is necessary for good opioid activity. The size of the N-substituent can dictate the compound's potency and its agonist versus antagonist properties. Generally, N-methyl substitution results in a compound with good agonist properties. Increasing the size of the N-substituent to three to five carbons (especially where unsaturation or small carbocyclic rings are included) results in compounds that are antagonists at some or all opioid receptor types. Larger substituents on nitrogen return agonist properties to the opioid. An N-phenylethyl–substituted opioid usually is on the order of 10-fold more potent as a μ agonist than the corresponding N-methyl analogue.

Ideal Opioid

Thousands of derivatives of morphine and other μ agonists have been prepared and tested (74,75). The objective of most of the synthetic efforts has been to find an analgesic with improved pharmacological properties over known μ agonists. Specifically, one would like to have an orally active drug that retains the strong analgesic properties of morphine yet lacks its ability to cause tolerance, physical dependence, respiratory depression, emesis, and constipation. The success of this search has been limited. Many compounds that are more potent than morphine have been discovered. Also, compounds with pharmacodynamic properties different from those of morphine have been discovered, and some of these compounds are preferred to morphine for selected medical uses. The ideal analgesic drug, however, is yet to be discovered. Research to find new centrally acting analgesics has turned away from classic μ agonists and now is focused on agents that act through other types or subtypes of opioid receptors or through nonopioid neurotransmitter systems.

3-Phenolic Hydroxy Group

The SARs of compounds structurally related to morphine are outlined in Table 24.2. A number of the structural variations on morphine have yielded compounds that are available as drugs in the United States. The most important of these agents, in terms of prescription volume, is the alkaloid codeine. Codeine, the 3-methoxy derivative of morphine, is a relatively weak μ agonist, but it undergoes slow metabolic O-demethylation to morphine, which accounts for much of its action. Codeine also is a potent antitussive agent and is used extensively for this purpose.

Heroin

The 3,6-diacetyl derivative of morphine is commonly known as heroin. It was synthesized from morphine in 1874 and was introduced to the market in 1898 by the Friedrich Bayer Co. in Germany. The 1906 Squibb's *Materia Medica* listed 10-mg tablets of heroin at $1.20 per 1,000. At the time of its introduction, heroin was described as “preferable to morphine because it does not disturb digestion or produce habit readily.” Heroin itself has relatively low affinity for μ opioid receptors; however, its high lipophilicity compared to morphine results in enhanced penetration of the blood-brain barrier. Once in the body (including the brain), serum and tissue esterases hydrolyze the 3-acetyl group to produce 6-acetylmorphine. This latter compound has μ agonist activity in excess of morphine. The combination of rapid penetration by heroin into the brain after intravenous dose and rapid conversion to a potent μ agonist provides a “euphoric rush” that makes this compound a popular drug of abuse. Repeated use of heroin results in the development of tolerance, physical dependence, and acquisition of a drug habit that often is destructive to the user and society. In addition, the use of unclean or shared hypodermic needles for self-administering heroin often results in the transmission of the HIV, hepatitis, and other infectious diseases.

C Ring

Changes in the C-ring chemistry of morphine or codeine can lead to compounds with increased activity. Hydromorphone is the 7,8-dihydro-6-keto derivative of morphine,

P.663

and it is 8 to 10 times more potent than morphine on a weight basis. Hydrocodone, the 3-methoxy derivative of hydromorphone, is considerably more active than codeine.

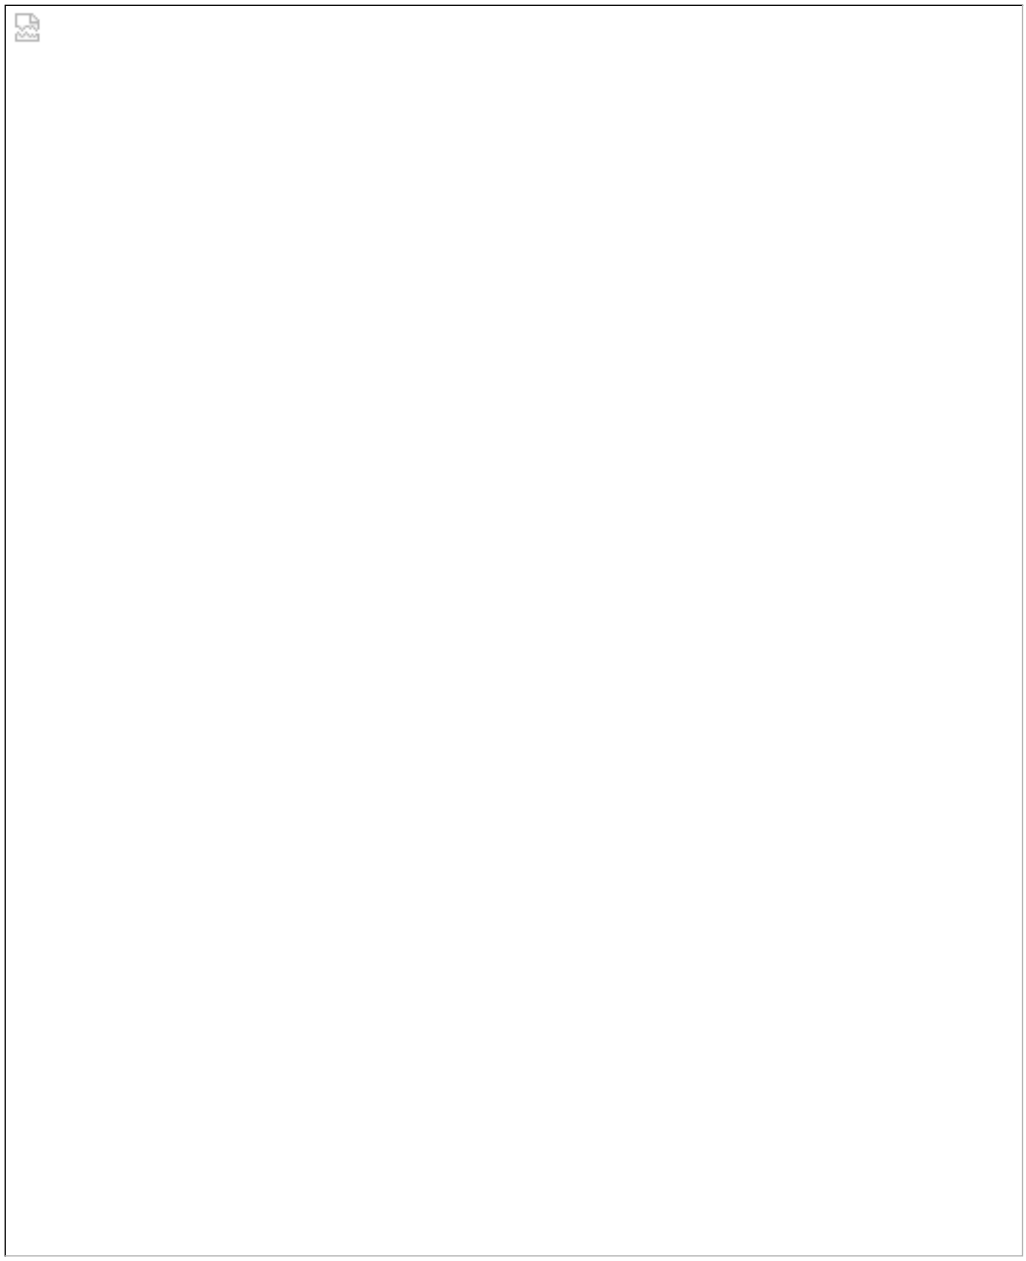


Fig. 24.9. Diverse structural families that yield potent opioid agonists.

14α-Hydroxy-6-Keto Derivatives

The opium alkaloid thebaine can be synthetically converted to 14α-hydroxy-6-keto derivatives of

morphine. The 14α-hydroxy group generally enhances μ agonist properties and decreases antitussive activity, but activity varies with the overall substitution on the structure. Oxycodone, the 3-methoxy-N-methyl derivative, is about as potent as morphine when given parenterally, but its oral to parenteral dose ratio is better than that for morphine. Oxymorphone is the 3-hydroxy-N-methyl derivative, and it is 10 times as potent as morphine on a weight basis. Substitution of an N-cyclobutylmethyl for N-methyl and reduction of the 6-keto group to 6α-OH of oxymorphone gives nalbuphine, which acts through κ receptors and has approximately half the analgesic potency of morphine. Nalbuphine is an antagonist at μ receptors. Interestingly, N-allyl- (naloxone) and N-cyclopropylmethyl- (naltrexone) noroxymorphone are "pure" opioid antagonists. Naloxone and naltrexone are slightly μ receptor selective and are antagonists at all opioid receptor types.

Figure 24.9 contains some of the diverse chemical structures that produce μ agonist activity. The structures shown in the figure illustrate that the morphine structure may be built up or broken down to yield compounds that produce potent agonist activity. Reaction of thebaine with dienophiles (i.e., Diels-Alder reactions) results in 6, 14-endo-ethenotetrahydrothebaine derivatives, which are commonly called oripavines (76). Some of the oripavine derivatives are extremely potent μ agonists. Etorphine and buprenorphine are the best known of these derivatives. Etorphine is approximately 1,000 times more potent than morphine as a μ agonist. Etorphine has a low therapeutic index in humans, and its respiratory depressant action is difficult to reverse with naloxone or naltrexone. Thus, the compound is not useful in medical practice. Etorphine (M-99) is available for use in veterinary medicine for the immobilization of large animals. The oripavine structure–based antagonist diprenorphine is used to reverse the tranquilizing effect of etorphine. Buprenorphine, a marketed oripavine derivative, is a

partial agonist at μ receptors, with a potency of 20 to 30 times that of morphine. The compound's uses and properties are described in the section on clinically available agents.

3,4-Epoxide Bridge and the Morphinans

Removal of 3,4-epoxide bridge in the morphine structure results in compounds that are referred to as morphinans. One cannot remove the epoxide ring from the morphine structure by simple synthetic means. Rather, the morphinans are prepared by total synthesis using a procedure described by Grewe (77). The synthetic procedure yields compounds as racemic mixtures and only the levo-(–)-isomers possess opioid activity. The dextro isomers have useful antitussive activity. The two morphinan derivatives that are marketed in the United States are levorphanol and butorphanol. Levorphanol is approximately eight times more potent than morphine as an analgesic in humans. Levorphanol's increased activity results from an increase in affinity for μ opioid receptors and its greater lipophilicity, which allows higher peak concentrations to reach the brain. Butorphanol is a μ antagonist and a κ agonist. The mechanism of action of the mixed agonist/antagonists is described in more detail later in this chapter.

Benzomorphans

Synthetic compounds that lack both the epoxide ring and the C ring of morphine retain opioid activity. Compounds having only the A, B, and D rings are named chemically as derivatives of 6,7-benzomorphan (Fig. 24.9) or, using a different nomenclature system, of 2,6-methano-3-benzazocine. They are commonly referred to simply as benzomorphans. The only agent from this structural class that is marketed in the United States is pentazocine, which has an agonist action on κ opioid receptors—an effect that produces analgesia. Pentazocine is a weak antagonist at μ receptors. The dysphoric side effects that are produced by higher doses of pentazocine result from actions at κ opioid receptors and also at σ (PCP) receptors. The benzomorphan-derivative phenazocine (N-phenylethyl) is approximately 10 times as potent as morphine as a μ agonist and is marketed in Europe.

Aminotetralins represent A- and B-ring analogues of morphine. A number of active compounds in

this class have been described, but only dezocine, a mixed agonist/antagonist, has been marketed.

4-Phenylpiperidines

Analgesic compounds in the 4-phenylpiperidine class may be viewed as A- and D-ring analogues of morphine (Fig. 24.9). The opioid activity of these agents was discovered serendipitously. The first of these agents, meperidine, was synthesized in 1937 by Eislab (78), who was attempting to prepare antispasmodic agents. The compound produced an S-shaped tail (Straub tail) in cats, an effect that had been recognized as a response caused by morphine and its derivatives. Meperidine proved to be a typical μ agonist, with approximately one-fourth the potency of morphine on a weight basis. It is particularly useful in certain medical procedures because of its short duration of action because of esterases hydrolysis to a zwitterionic metabolite. Reversed esters of meperidine have greater potency, and several of these derivatives have been marketed. The 3-methyl reversed ester derivatives of meperidine, α- and β-prodine, were available in the United States but have been removed from the market because of their low prescription volume and their potential to undergo elimination reactions to compounds that resemble the neurotoxic agent MPTP (see Chapter 25). Trimeperidine or μ-promedol, the 1,2,5-trimethyl reserved ester of meperidine, is used in Russia as an analgesic.

Anilidopiperidines

Structural modification of the 4-phenylpiperidines has led to discovery of the 4-anilidopiperidine, or the fentanyl, group of analgesics (Fig. 24.9). Fentanyl and its derivatives are μ agonists, and they produce typical morphine-like analgesia and side effects. Structural variations of fentanyl that have yielded active compounds are substitution of an isosteric ring for the phenyl group, addition of a small oxygen containing group at the 4-position of the piperidine ring, and introduction of a methyl group onto the 3-position of the piperidine ring. Newer drugs that illustrate some of these structural changes are alfentanil and sufentanil. Both of these drugs have higher safety margins than other μ agonists. For unknown reasons, the compounds produce analgesia at much lower doses than is necessary to cause respiratory depression.

Diphenylheptanone

In the period just before or during the Second World War, German scientists synthesized another series of open-chain compounds as potential antispasmodics. In a manner analogous to that of meperidine, animal testing showed some of the compounds to possess analgesic activity. Methadone was the major drug to come from this series of compounds (Fig. 24.9). Methadone is especially useful for its oral activity and its long duration of action. These properties make methadone useful in maintenance therapy for opioid addicts and for pain suppression in the terminally ill (i.e., hospice programs). Methadone is marketed in the United States as a racemic mixture, but the (–)-isomer possesses almost all of the analgesic activity. Many variations on the methadone structure have been made, but little success in finding more useful drugs in class has been achieved. Reduction of the keto and acetylation of the resulting hydroxyl group gives the acetylmethadols (see below). Variations of the methadone structure have led to the discovery of the useful antidiarrheal opioids diphenoxylate and loperamide.

Propoxyphene is an open-chain compound that was discovered by structural variation of methadone. Propoxyphene is a weak μ opioid agonist having only one-fifteenth the activity of morphine. The (+)-isomer produces all of the opioid activity.

μ Antagonists

The SAR for μ antagonists is relatively simple if one focuses just on marketed compounds. All of the marketed, rigid-structured opioid analogues that have the 3-phenolic group and an N-allyl,

N-cyclopropylmethyl (N-CPM), or N-cyclobutylmethyl (N-CBM) substituent replacing the N-methyl are μ antagonists (Fig. 24.5). Compounds behaving as μ antagonists may retain agonist activity at other opioid receptor types. The only exception to this rule is buprenorphine, which has an N-CPM substituent and is a potent partial agonist (or partial antagonist) at μ receptors. Only two compounds are pure antagonists (i.e., act as antagonists at all opioid receptors). These compounds are the N-allyl (naloxone) and N-CPM (naltrexone) derivatives of noroxymorphone. The 14α-hydroxyl group is believed to be important for the pure antagonistic properties of these compounds. It is not understood how the simple change of an N-methyl to an N-allyl group can change an opioid from a potent agonist into a potent antagonist. The answer may lie in the ability of opioid receptor protein to effectively couple with signal transduction proteins (G proteins) when bound by an agonist but not to couple with the G proteins when bound by an antagonist. This explanation infers that an opioid having an N-substituent of three to four carbons in size induces a conformational change in the receptor or blocks essential receptor areas that prevent the interaction of the receptor and the signal transduction proteins.

Those interested in an in-depth understanding of the SAR for μ receptor antagonists should be aware that properly substituted N-methyl-4-phenylpiperidines, N-methyl-6,7-benzomorphans, and even nonphenolic opioid derivatives that have good antagonist activity are known.

Structure–Activity Relationships of κ Receptor Agonists

The SAR for marketed κ agonists is somewhat related to that of μ antagonists (Fig. 24.5). All of the marketed κ agonists have structures related to the rigid opioids and N-allyl, N-CPM or N-CBM substitutions. The compounds are all μ receptor antagonists and κ receptor agonists. The κ agonist activity is enhanced if there is an oxygen group placed at the 8-position (e.g., ethylketazocine) or into the N-substituent (e.g., bremazocine). The oxygen group in a N-furanylmethyl substituent also enhances κ activity.

Potent and selective κ agonists that lack antagonistic properties at any of the opioid receptors are found in a number of *trans*-1-arylacetamido-2-aminocyclohexane derivatives. There are not enough compounds reported in this class to develop strong trends in SARs. The relative mode of receptor binding for the morphine-related verses the arylacetamide κ agonists is not known. Evidence exists for the selective binding of the arylacetamides to κ_1 and of the benzomorphan compounds (e.g., bremazocine) to κ_2 and κ_3 opioid receptor subtypes.

Structure–Activity Relationships of δ Receptor Agonists

Structure–activity relationships for δ receptor agonists are the least developed among the opioid compounds. Peptides with high selectivity for δ receptors are known. The SARs for some of these peptides are discussed in the following paragraphs. Nonpeptide δ selective agonists (Fig. 24.6) have been discovered, and SARs are being developed (79). Several selective δ agonists entered clinical trials but were withdrawn because of the potential convulsive (80) action of the agents.

Structure–Activity Relationships of Opioid Peptides

Thousands of derivatives related to the endogenous opioid peptides have been prepared since the discovery of the enkephalins in 1975 (81) (Fig. 24.1). A thorough discussion of the SAR of these peptides would be a major task; however, some major trends have emerged and easily can be discussed. Some selected general SAR points for peptide opioids are:

1. All of the endogenous opioid peptides, except for the endomorphans, have Leu- or Met-enkephalin as their first five amino acid residues.
2. The tyrosine at the first amino acid residue position of all the endogenous opioid peptides is essential for activity. Removal of the phenolic hydroxyl group or the basic nitrogen (amino

terminus group) will abolish activity. The Tyr^1 free amino group may be alkylated (methyl or allyl groups to give agonists and antagonists), but it must retain its basic character. The structural resemblance between morphine and the Tyr^1 group of opioid peptides is especially obvious.

3. In addition to the phenol and amine groups of Tyr^1, the next most important moiety in the enkephalin structure is the phenyl group of Phe^4. Removal of this group or changing its distance from Tyr^1 results in full or substantial loss in activity.
4. The enkephalins have several low-energy conformations, and different conformations likely are bound at different opioid receptor types and subtypes.
5. The replacement of the natural L-amino acids with unnatural D-amino acids can make the peptides resistant to the actions of several peptidases that generally rapidly degrade the natural endorphins. The use of a D-Ala in place of Gly^2 has been

especially useful for protecting the peptides from the action of nonselective aminopeptidases. The placement of bulky groups into the structure (e.g., the addition of N-Me to Phe^4) also will slow the action of peptidases. When evaluating new peptides for opioid activity, it often is difficult to tell if changes are caused by metabolic stability or receptor affinity.

6. Conversion of the terminal carboxyl group into an alcohol or an amide will protect the compound from carboxy peptidases.
7. Any introduction of unnatural D- or L-amino acids or bulky groups into the enkephalin structure will affect its conformational stability. The resultant peptides will have an increase or decrease in affinity for each of the opioid receptor types. The right combination of increases and/or decreases in receptor affinity will result in selectivity for a receptor type.
8. Structural changes that highly restrict the conformational mobility of the peptides (e.g., substitution of proline for Gly^2 or cyclization of the peptide) have been especially useful for the discovery of receptor-selective opioid peptides.

For examples of the above SARs, see the structures of the peptides given in Figures 24.4, 24.5, and 24.6.

Enkephalin Peptides

The effect of lengthening the amino acid chain of the enkephalin peptides deserves special consideration. As previously noted, the endogenous opioids found in mammals most often have Leu- or Met-enkephalin at their amino terminus end. Lengthening the carboxyl terminus can give the peptide greater affinity or selectivity for an opioid receptor type. This effect can be illustrated by the dynorphins, for which incorporation of the basic amino acids (especially Arg^7) into the C-terminus chain results in a marked increase in affinity for κ receptors. The message-address analogy has been used to describe this effect. The first four amino acids [Tyr-Gly-Gly-Phe] are essential for peptide ligands to bind to and to activate all opioid receptor types. The N-terminus amino acids can then be referred to as carrying the “message” to the receptors. Adding additional amino acids to the C-terminus can “address” the message to a specific receptor type. The additional peptide chain may be affecting the address (selectivity) by providing new and favorable binding interactions to one of the receptor types. Alternatively, the additional peptide could be inducing a conformational change in the message portion of the peptide that favors interaction with one of the receptor types.

Metabolism of The Opioids

Knowledge of the metabolism of the opioid drugs is essential to the understanding of the uses of these agents. The poor oral versus parenteral dose ratio (~6:1) of morphine is caused by extensive first-pass metabolic conjugation of morphine at the phenolic (3-OH) position (Fig. 24.10). The metabolism occurs predominantly in the liver and requires the action of sulfotransferase or glucuronyltransferase enzymes. The conjugates have low activity and poor distribution properties. The 3-glucuronide does undergo enterohepatic cycling, which explains the need for high initial oral doses of morphine, followed by lower maintenance doses. Glucuronidation of morphine at the 6-OH position results in the formation of an active metabolite. Morphine is also N-demethylated to give normorphine, a compound that has decreased opioid activity and decreased bioavailability to the CNS. Normorphine undergoes N- and O-conjugations and excretion. Geriatric patients metabolize morphine at a slower rate than normal adult patients; thus, they are likely to show greater sensitivity to the drug and require lower doses.

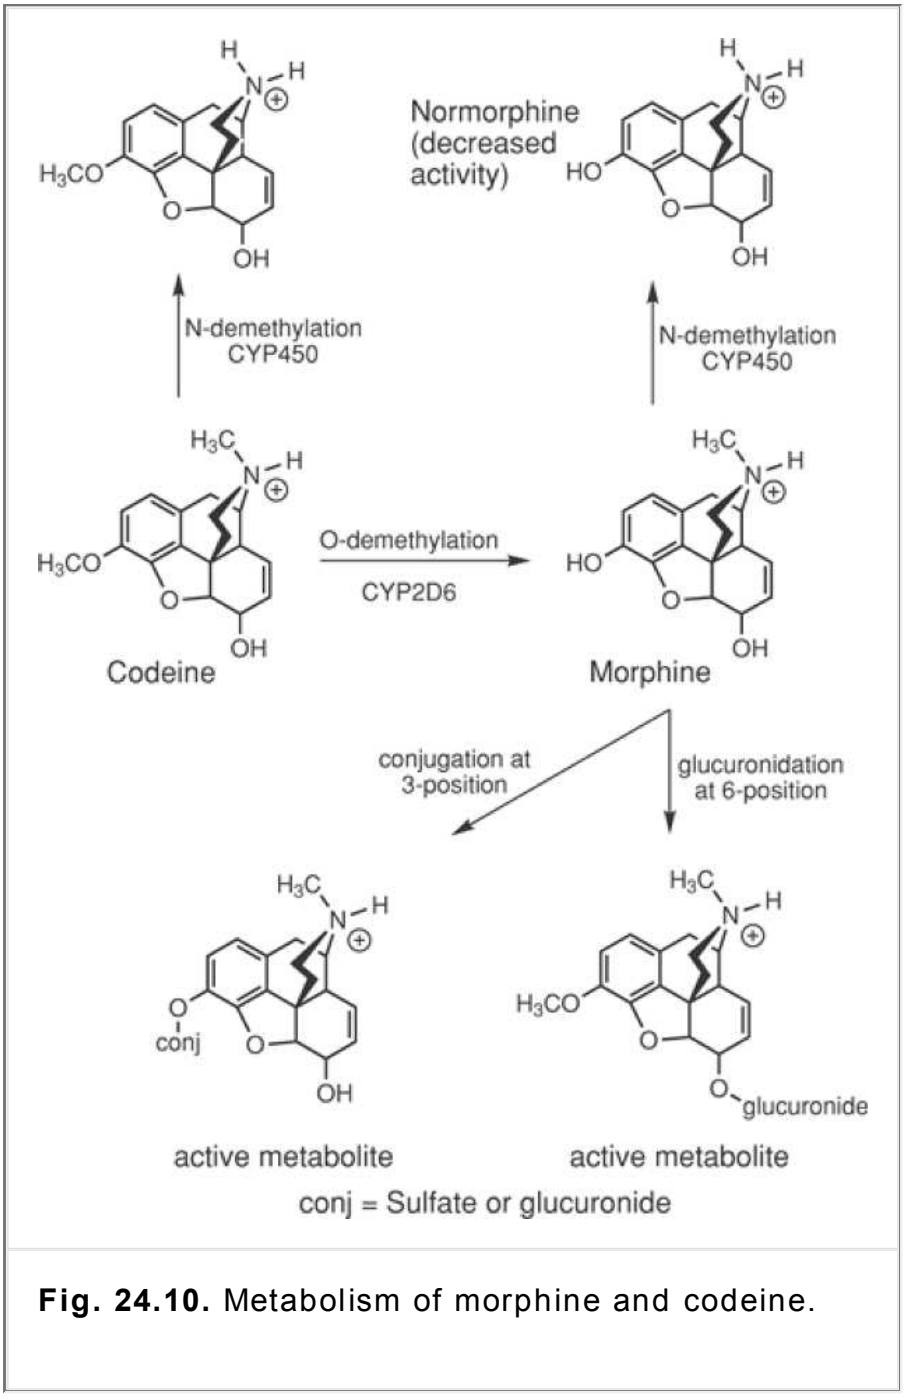

Fig. 24.10. Metabolism of morphine and codeine.

In human subjects, approximately 10% of an oral dose of codeine is O-demethylated by CYP2D6 to

produce morphine. The morphine produced as a metabolite of codeine is essential for the analgesic effect. A significant portion of the American population (8–10%) lacks CYP2D6, and these individuals do not experience analgesia

when dosed with codeine (82). The antitussive activity of codeine is produced by the unmetabolized drug at nonopioid receptors and is not affected by the lack of CYP2D6. The bioactivation of codeine (versus the bioinactivation of morphine) results in an oral:parenteral dose ratio for codeine of 1.5:1; however, codeine is seldom given parenterally because of its strong effect to release histamine from mast cells.

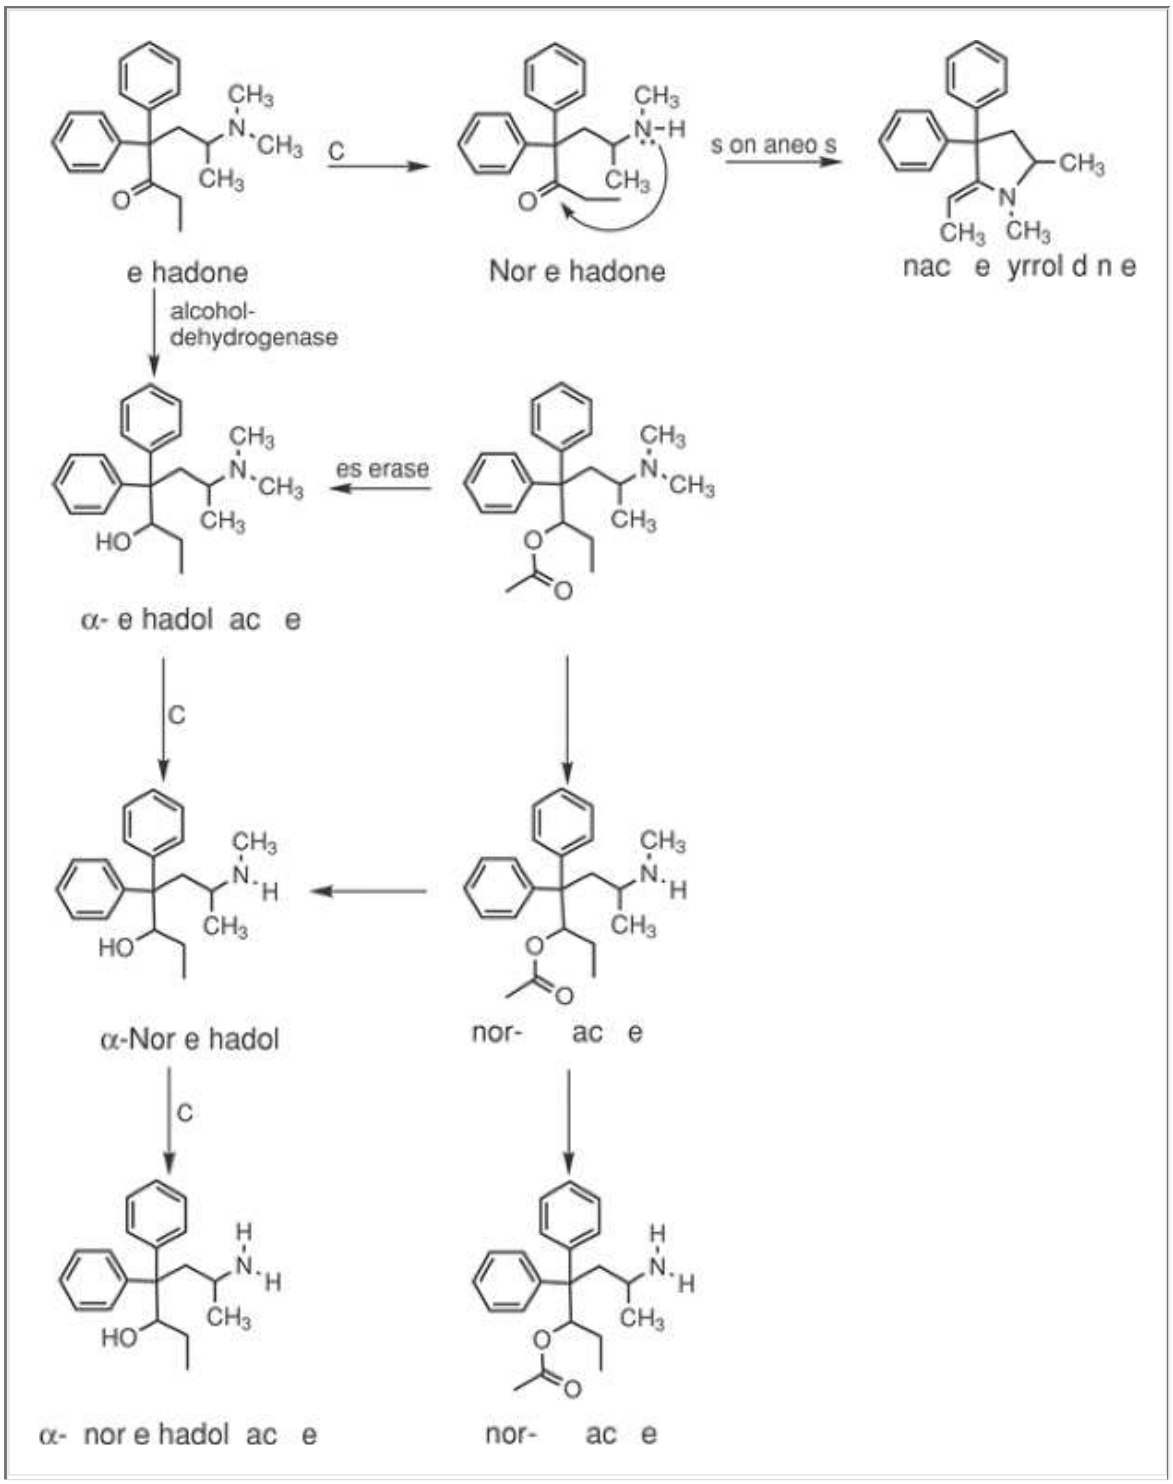

Fig. 24.11. Metabolism of methadone and levomethadyl (LAAM).

Other rigid-structured opioid analogues undergo routes of metabolism similar to that of morphine. The amount of first-pass 3-O-conjugation varies from compound to compound; thus, the relative oral:parenteral dosages of the agents will vary. In general, compounds that are more potent and lipophilic than morphine (e.g., levorphanol) tend to have better oral activity. Compounds with N-alkyl groups larger than methyl get N-dealkylated as a major route of inactivation.

The short duration of action of meperidine is the result of rapid metabolism. Plasma esterases cleave the ester bond to leave the inactive zwitterionic 4-carboxylate derivative. Meperidine also undergoes N-demethylation to give normeperidine. Normeperidine has little analgesic activity, but it contributes significantly to the toxicity of meperidine.

The metabolism of methadone, as outlined in Figure 24.11, is important to its action. The major route of inactivation results from N-demethylation and cyclization of the secondary amine into an inactive pyrrole derivative. If the keto group is reduced by alcohol dehydrogenase to give methadol, the demethylation product can no longer cyclize to the pyrrole derivatives. Methadol is less active than methadone as an analgesic, but the N-demethylation products of methadol, normethadol and dinormethadol, are active analgesics with increased half-lives compared to that of methadone. The buildup of these metabolites is responsible for the long duration of action and the mild, prolonged withdrawal symptoms associated with methadone.

Levo-α-acetylmethadol (LAAM, levomethadyl acetate) is longer acting than methadone. Its slow onset of action

after oral dose (and the isolation of at least three active metabolites) suggests that LAAM itself is a pro-drug. The relative contributions of LAAM and its active metabolites to the analgesic and addition maintenance properties in humans have not been determined. It is clear that a 75- to 100-mg oral dose of this agent will suppress withdrawal symptoms in opioid addicts for 3 to 4 days.

μ Opioid Receptor Models

A number of models have been proposed to represent the bonding interactions of agonists at μ opioid receptors. These models are “reflections” of complementary bonding interactions of μ agonists to the receptor as revealed from SAR studies. Beckett and Casy (83) published the first such receptor drawing in 1954. They studied the configurations and conformations of the μ agonists known at that time and proposed that all opioids could bind to the template (receptor model) shown in Figure 24.12. The model presumed that nonrigid opioids (e.g., meperidine and methadone) took a shape like that of morphine when binding to the receptor. It soon became apparent that the most stable conformations of meperidine and methadone were not able to be superimposed on the structure of morphine. New compounds that could not assume the shape of morphine also were being discovered, and it became apparent that the Beckett and Casy model could not explain the activity of all μ agonists.

In the mid-1960s, Portoghese (84) attempted to correlate the structures and analgesic activities of rigid and nonrigid opioids that contained the same series of N-substituents. He argued that if all opioids bound the receptor in the same conformation, then a substituent at a like position on any of the compounds should fall on the same surface area of the receptor. One would expect the same structural modification on any opioid structure to give the same type and degree of bonding interaction and, thus, the same contribution to analgesic activity. Portoghese found that parallel changes of the N-substituent on rigid (morphine, morphinan, or benzomorphan) analgesic parent structures gave parallel changes in activity. This finding supported the notion that rigid-structured opioid compounds bound to the receptor for analgesia in the same manner. When the same test

was applied to nonrigid (meperidine-like) opioid structures, however, varying the N-substituent did not produce an activity change that paralleled that seen for the rigid-structured series. Apparently, the N-substituents in the rigid and nonrigid opioid series were falling on different surfaces of a receptor and, thus, making different contributions to analgesic activity. Portoghese concluded that the rigid and nonrigid series of compounds either were binding to different receptors or were interacting with the same receptor by different binding modes. He introduced the bimodal receptor binding model (Fig. 24.13) as one possible explanation of the results. Later, it was discovered that the activity of the rigid opioid compounds (Series 1) was enhanced by a 3-OH substituent on the aromatic ring, whereas a like substituent in some nonrigid opioids (Series 2) caused a loss of activity. Again, like substituents produced nonparallel changes in activity, indicating that the aromatic rings in the two series were not binding to the same receptor site. To provide an explanation for these results, the bimodal binding model was modified to incorporate the structure of the enkephalin (Fig. 24.14) (85). The rigid-structured opioids that benefit from the inclusion of a phenolic

hydroxyl group were proposed to bind the μ receptor in a manner equivalent to the tyrosine (Tyr^1 or T-subsite) of enkephalin. The nonrigid-structure opioids, which lose activity on introduction of a phenolic hydroxyl group into their structure, were proposed to interact with the receptor in a manner equivalent to the phenylalanine (Phe^4 or P-subsite) of enkephalin. The free amino group of Tyr^1 occupies the anionic binding site of the receptor that is the common binding point of both opioid series. This model closely resembles original bimodal binding proposal.

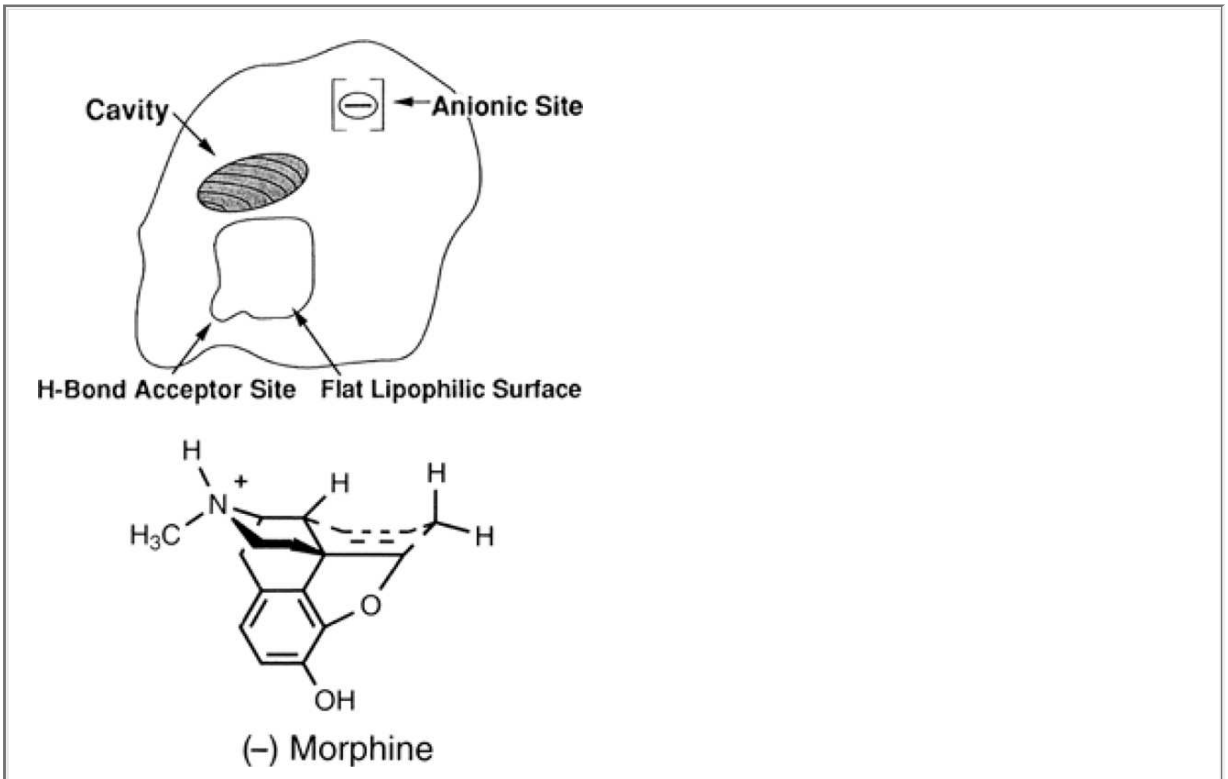

Fig. 24.12. A representation of the original model for the opioid receptor as proposed by Beckett and Casy (83). The morphine structure would have to rotate 180° about a vertical axis before it could bind to the receptor site. The model is only good for μ-selective agents.

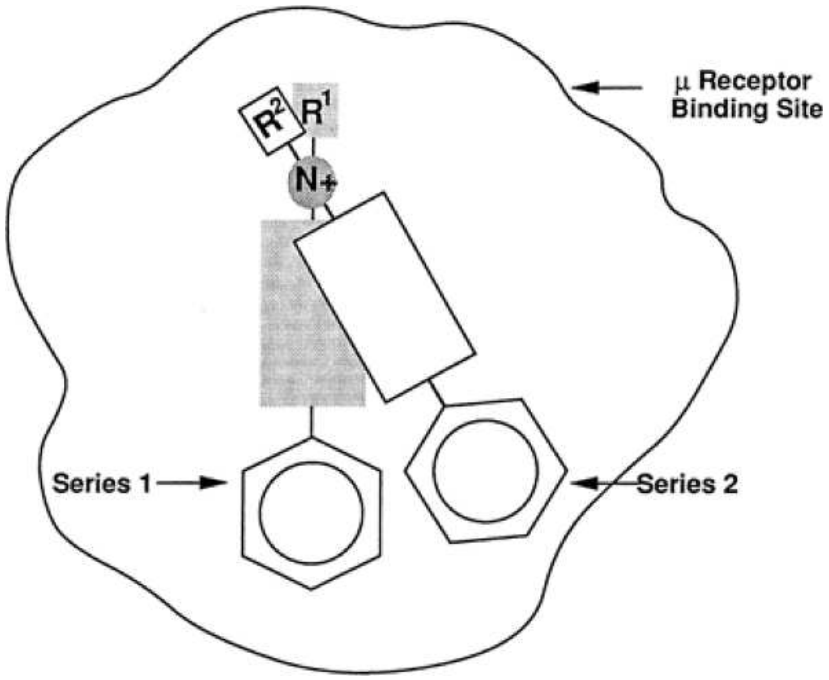

Fig. 24.13. A representation of the bimodal binding model of the μ opioid receptor as proposed by Portoghese (84). Different opioid series bind to different surface areas of the same receptor protein.

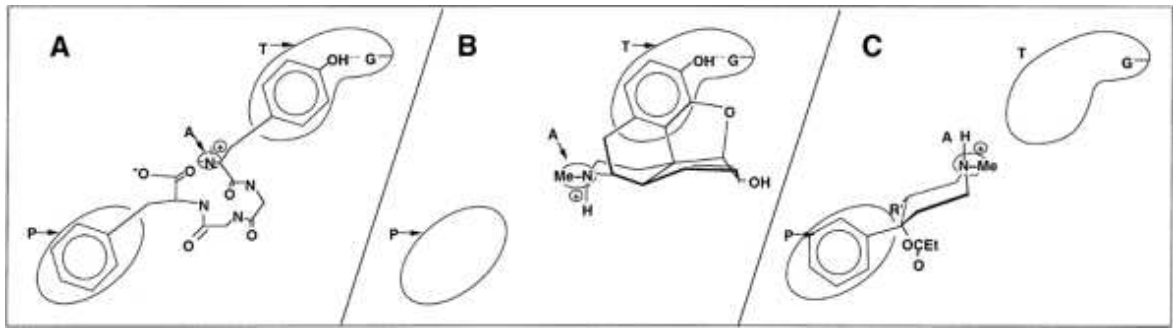

Fig. 24.14. A representation of the enkephalin binding site of μ opioid receptors (85). (A) An enkephalin bound to the receptor. (B) Morphine binding the receptor by utilizing the T-subsite (i.e., the tyrosine-binding site). (C) A meperidine-type opioid binding the receptor by utilizing the P-subsite (i.e., the phenylalanine-binding site).

Models that attempt to explain the ability of Na^+ to decrease the binding affinity of agonists, but not antagonists, for the opioid receptor have been made (86). Sodium ions also protect the receptor

from alkylation by nonselective alkylating agents.

The Beckett and Casy model was extended to explain the increased potency of the oripavine analogues, such as etorphine (Fig. 24.15) (76). The affinity of the oripavines for the μ opioid receptor can be much greater than that seen for morphine. It is likely that the increased receptor affinity comes from auxiliary drug–receptor bonding interactions similar to those depicted in the receptor model.

Martin (87) has proposed a receptor model for κ opioid receptors. Martin's model considers just the binding of rigid morphine-related opioid structures. The relationship of how rigid morphine-related agents interact with the κ receptor compared to the arylacetamide κ agonist derivatives has not been well studied.

Models for the δ opioid receptors have not been proposed.

Specific Drugs

μ Agonists

Structures of specific drugs and compounds are given in Table 24.3.

(–)-Morphine Sulfate

Morphine sulfate is the analgesic used most often for severe, acute, and chronic pain. Morphine is a μ agonist and is a Schedule II drug. It is available in intramuscular, subcutaneous, oral, rectal, epidural, and intrathecal dosage forms. The epidural and intrathecal preparations are formulated without a preservative. Morphine is three- to six times more potent when given intramuscularly than when given orally. The difference in activity results from extensive first-pass 3-O-glucuronidation of morphine—an inactive metabolite. The half-life of intramuscularly dosed (10 mg) morphine is approximately 3 hours. The dose of morphine, by any dosage route, must be reduced in patients with renal failure and in geriatric and pediatric patients. The enhanced effects of morphine in renal failure is believed to be caused by a buildup of the active 6-glucuronide metabolite, which depends on renal function for elimination.

The analgesic effect of orally dosed morphine can equal that obtained by parenteral administration, if proper doses are given. When given orally, the initial

dose of morphine is usually 60 mg, followed by maintenance doses of 20 to 30 mg every 4 hours. Addiction to clinically used morphine by the oral route generally is not a problem.

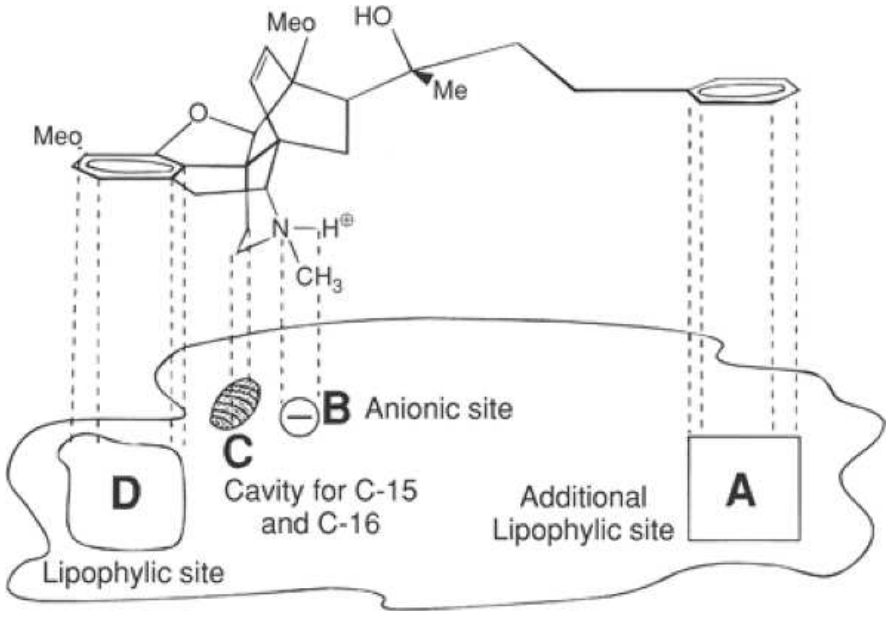

Fig. 24.15. A representation of the binding of an oripavine-type analgesic to the μ opioid receptor (76). The hydroxyl and phenyl groups in the side chain are believed to form additional bonding interactions with the receptor compared to the Beckett and Casy receptor model.

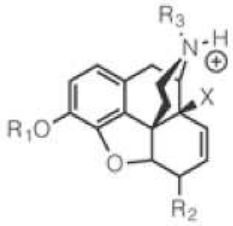


Generic nam e	R_1	R_2	R_3	X	Other
(-)-Morphine	H	OH	$-CH_3$	H	None
(-)-Codeine	CH_3	OH	$-CH_3$	H	None
(-)-Hydromorphone	H	Keto	$-CH_3$	H	No 7,8-double bond
(-)-Oxymorphone	H	Keto	$-CH_3$	OH	No 7,8-double bond
(-)-Hydrocodone	CH_3	Keto	$-CH_3$	H	No 7,8-double bond
(-)-Oxycodone	CH_3	Keto	$-CH_3$	OH	No 7,8-double bond
(-)-Nalbuphine	H	OH	$-H_2C-cBu$	H	No 7,8-double bond
(-)-Naloxone	H	Keto	$-CH_2-CH=CH_2$	OH	No 7,8-double bond
(-)-Naltrexone	H	Keto	$-H_2C-cPr$	OH	No 7,8-double bond

Table 24.3. Marketed Drugs that are Derivatives of Morphine

Overdoses of morphine, as well as all μ agonists in this section, can be effectively reversed with naloxone.

(–)-Codeine Phosphate

Codeine is used extensively to treat moderate to mild pain. Codeine is a weak μ agonist, but approximately 10% of an oral dose (30–60 mg) is metabolized to morphine (see the section on metabolism in this chapter), which contributes significantly to its analgesic effect. The plasma half-life of codeine after oral dose is 3.5 hours. The dose of codeine needed to produce analgesia after parenteral dose causes releases of histamine sufficient to produce hypotension, pruritus, and other allergic responses. Thus, administration of codeine by parenteral route is not recommended.

(–)-Hydromorphone Hydrochloride (Dilaudid)

Hydromorphone is a potent μ agonist (eight times greater than morphine) that is used to treat severe pain. It is available in intramuscular, intravenous, subcutaneous, oral, and rectal dosage forms. Like all strong μ agonists, hydromorphone is addicting and is a Schedule II drug. Hydromorphone has an oral:parenteral potency ratio of 5:1. The plasma half-lives after parenteral and oral dosage are 2.5 and 4 hours, respectively.

(–)-Oxymorphone Hydrochloride (Numorphan)

Oxymorphone is a potent μ agonist (10 times greater than morphine) that is used to treat severe pain. It is used by intramuscular, subcutaneous, intravenous, and rectal routes of administration. The intramuscular dose of oxymorphone (1 mg) has a half-life of 3 to 4 hours. It is a Schedule II drug. Oxymorphone, because of its 14-hydroxy group, has low antitussive activity.

(–)-Levorphanol Bitartrate (Levo-Dromoran)

Levorphanol is a potent μ agonist (approximately sixfold greater than morphine), and its uses, side effects, and physical dependence liability are like those of oxymorphone or hydromorphone. Levorphanol is available in oral, subcutaneous, and intravenous dosage forms. The oral dose of levorphanol is approximately twice the parenteral dose. This drug is unique among the μ agonists in that its analgesic duration of action is 4 to 6 hours, whereas its clearance half-life is 11.4 hours. Thus, effective analgesic doses of this agent can lead to a buildup of the drug in the body and result in excessive sedation.

(–)-Hydrocodone Bitartrate (Lortab, Vicodin in Combinations with Acetaminophen)

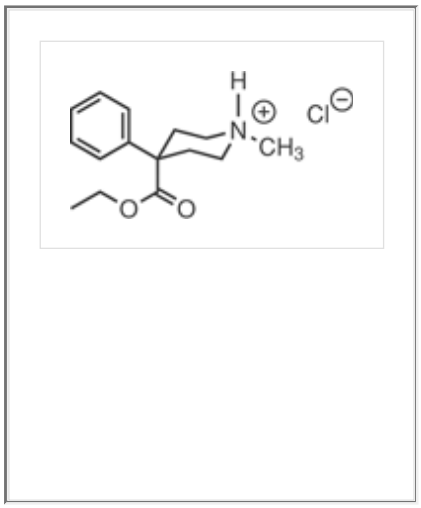
Hydrocodone is a Schedule III drug that is used to treat moderate pain. It is used mostly by the oral route (5-mg tablets and solutions) in combination with acetaminophen. The compound has good oral bioavailability and is metabolized in a manner similar to codeine.

(–)-Oxycodone Hydrochloride (Roxicodone, Oxycontin Sustained Release; and Percocet, Percodan, Tylox; in Combinations)

Oxycodone is about equipotent with morphine, but because of the 3-OCH group, it has a much lower oral:parenteral dose ratio. Thus, oxycodone is used orally to treat severe to moderate pain. It is a Schedule II drug as a single agent and when combined in strong analgesic mixtures. Oxycodone has a plasma half-life of approximately 4 hours and requires dosing every 4 to 6 hours.

Metabolism of this agent is comparable to that of codeine.

Meperidine Hydrochloride (Demerol)



Meperidine is a μ agonist with approximately one-tenth the potency of morphine after intramuscular dose. Meperidine produces the analgesia, respiratory depression, and euphoria caused by other μ opioid agonists, but it causes less constipation and does not inhibit cough. When given orally, meperidine has 40 to 60% bioavailability because of significant first-pass metabolism. Because of the limited bioavailability, it is one-third as potent after an oral dose compared to a parenteral dose.

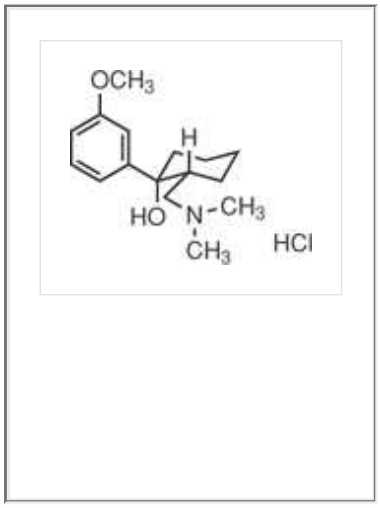
Meperidine has received extensive use in obstetrics because of its rapid onset and short duration of action. When it is given intravenously in small (25-mg) doses during delivery, the respiratory depression in the newborn child is minimized. Meperidine is used as an analgesic

in a variety of nonobstetric anesthetic procedures. Meperidine is extensively metabolized in the liver, with only 5% of the drug being excreted unchanged. Prolonged dosage of meperidine may cause an accumulation of the metabolite normeperidine (see the section on metabolism in this chapter). Normeperidine has only weak analgesic activity, but it causes CNS excitation and can initiate grand mal seizures. It is recommended that meperidine be discontinued in any patient who exhibits signs of CNS excitation.

Meperidine has a strong adverse reaction when given to patients receiving a monoamine oxidase inhibitor. This drug interaction has been seen recently in patients with Parkinson's disease taking the monoamine oxidase–selective inhibitor selegiline (Eldepryl).

The elimination half-life of meperidine is 3 to 4 hours, and it can double in patients with liver disease. Acidification of the urine will cause enhanced clearance of meperidine, but there is a lesser effect on the clearance of the toxic metabolite normeperidine.

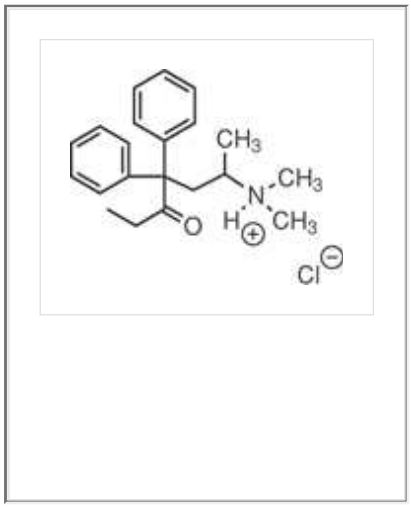
(±)Tramadol HCl (Ultram)



The analgesic activity of tramadol is attributed to a synergistic effect caused by the opioid activity of the (+)-isomer and the neurotransmitter reuptake blocking effect of the (–)-isomer. The (+)-isomer possesses weak μ opioid agonist activity equivalent to approximately 1/3,800 that of morphine. The O-desmethyl metabolite (CYP2D6) of (±)-tramadol has improved μ opioid activity equivalent to 1/35 that of morphine. Affinity for both δ and κ receptors is improved. Despite its higher opioid potency, the contribution of O-desmethlytramedol to the overall analgesic effect has been questioned but not well studied. Individuals who lack CYP2D6 or are taking a CYP2D6 inhibitor have a reduced effect to tramadol (88). The fact that naloxone causes a decrease in the analgesic potency of tramadol argues strongly for an opioid component to the analgesic activity. (–)-Tramadol possesses only 1/20 the opioid activity of its (+)-isomer, but it has good activities for inhibition of norepinephrine (K_i = 0.78 μM) and serotonin (K_i = 0.99 μM) reuptake. Tramadol's neurotransmitter reuptake activity is approximately 1/20 that of imipramine, a tricyclic antidepressant agent that is used widely in pain management. Although none of the individual pharmacological activities of tramadol is impressive, they interact to give a synergistic analgesic effect that is clinically useful.

Tramadol has been used in Europe since the 1980s and was introduced to the U.S. market in 1995. The drug is nonaddicting and, thus, is not a scheduled agent. In addition, tramadol does not cause respiratory depression or constipation.

(±)-Methadone Hydrochloride (Dolophine Hydrochloride)



Methadone is a synthetic agent with about the same μ opioid potency as morphine. The drug is used as a racemic mixture in the United States, but nearly all of the activity is caused by the

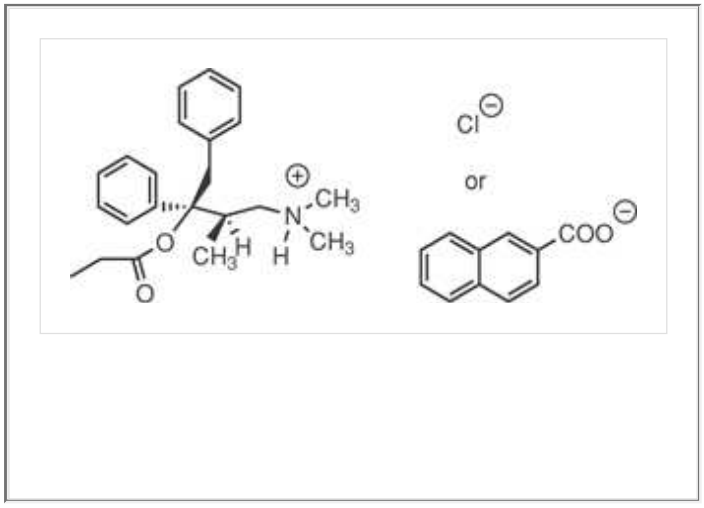
R-(–)-isomer. Methadone's usefulness is a result of its greater oral potency and longer duration compared to most other μ agonists. When given orally, a 20-mg dose given every 8 to 12 hours can provide effective analgesia. Methadone is an excellent analgesic for use in patients with cancer, and it often is used in hospice programs. Oral doses of 40 mg are commonly used for 24-hour suppression of withdrawal symptoms (addiction maintenance) in opioid addicts. When given parenterally in doses of 2.5 to 10 mg, methadone (Schedule II drug) has all the effects of morphine and other μ agonists.

The metabolism of methadone is extremely important in determining its long duration of action (see the section on metabolism in this chapter). The elimination of methadone is dependent on liver function and urinary pH. The typical half-life is 19 hours. When urinary pH is raised from normal values of 5.2 to 7.8, the half-life becomes 42 hours. At the higher pH, a lower percentage of methadone exists in the ionized form, and there is more renal reabsorption of the drug. The metabolism of methadone by liver enzymes is extensive, and there are at least two active metabolites. CYP3A4 is the major enzyme catalyzing methadone metabolism. Enzyme inducers (e.g., phenytoin and rifampin) can lead to the initiation of opioid withdrawal symptoms in patients using methadone for maintenance of addiction. Toxic concentrations of methadone can accumulate in patients with liver disease, in geriatric patients with a decreased oxidative metabolism capacity, or in patients taking an inhibitor of CYP3A4 (e.g., nifedipine, diazepam, and fluvoxamine).

Methadone is a good drug for maintenance of addiction, but it is not ideal. Methadone requires once-a-day dosing, usually at a clinic, to suppress withdrawal symptoms. Once-a-day dosing is expensive and, sometimes, logistically difficult to achieve. Levomethadyl acetate is available and is used in some treatment programs to overcome the problems of methadone. Levomethadyl acetate is more potent than methadone, and it has a longer duration of action. A single oral dose of this agent can suppress abstinence withdrawal for up to 3 days. Both

methadone and levomethadyl are associated with rare induction of cardiac arrhythmias through increases in the QT interval.

Propoxyphene Hydrochloride or Napsylate (Darvon, Dolene, Darvon-N & Generics)

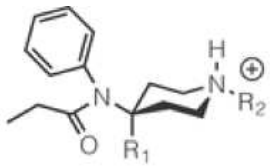


Propoxyphene is a weak μ agonist that is used as a single agent and in mixtures with nonsteroidal anti-inflammatory agents to treat mild or moderate pain. The active (+)-isomer has (2*S*,3*R*) absolute configuration. Propoxyphene is only available in oral dosage forms. Propoxyphene has approximately one-twelfth the potency of morphine, and most studies show it to be equally or less effective than aspirin as an analgesic. Doses of propoxyphene that approach the analgesic efficacy of morphine are toxic. Propoxyphene's popularity results from the fact that physicians prescribe it

for its lower abuse potential (Schedule IV) compared to that of codeine.

Fentanyl Citrate (Sublimaze; Also in Combination with Droperidol)

The structure of fentanyl and related compounds are given in Table 24.4. Fentanyl is a μ agonist with approximately 80 times greater potency than morphine. Fentanyl has been used in combination with nitrous oxide for "balanced" anesthesia and in combination with droperidol for "neurolepalgesia." The advantages of fentanyl over morphine for anesthetic procedures are its shorter duration of action (1–2 hours) and the fact that it does not cause histamine release on intravenous injection.



Generic name	Trade name	R_1	R_2
Fentanyl	Sublimaze Duragesic	H	$-CH_2CH_2-C_6H_5$
Sufentanil	Sufenta	$-CH_2OCH_3$	$-CH_2CH_2-C_4H_3S$
Alfentanil	Alfenta	$-CH_2OCH_3$	$-CH_2CH_2-N(C(=O)N(Et)N{=}N)$
Remifentanil	Ultiva	$-C(=O)OCH_3$	$-H_2C-CH_2-C(=O)-OCH_3$

Table 24.4. Analogues Related to Fentanyl [4-(phenylpropionamido) piperidines]

A fentanyl patch is available for the treatment of severe chronic pain. This dosage form delivers fentanyl transdermally and provides effective analgesia for periods of up to 72 hours. In 1999, fentanyl also became available in a lollipop dose form for absorption from the oral cavity.

Fentanyl's short duration of action after parenteral dose is caused by redistribution rather than by metabolism or excretion. Repeated doses of fentanyl can result in accumulation and toxicities. Elderly patients usually are more sensitive to fentanyl and require lower doses.

Opioids have a wide spectrum of P-glycoprotein (P-gp) activity, acting as both substrates and inhibitors, which might contribute to their varying CNS-related effects. Although fentanyl, sufentanil, and alfentanil did not behave as P-gp substrates, they inhibited the in vitro P-gp–mediated efflux of drugs known to be P-gp transported, such as digoxin, increasing their blood levels and the potential for important drug interactions by inhibition of P-gp efflux transporter.

Sufentanil Citrate (Sufenta)

Addition of the 4-methoxymethyl group and bioisosteric replacement of the phenyl with a

2-thiophenyl on the fentanyl structure results in a 10-fold increase in μ opioid activity (Table 24.4). The resultant compound, sufentanil, is 600 to 800 times more potent than morphine. Despite its greater sedative and analgesic potency, sufentanil produces less respiratory depression at effective anesthetic doses. Sufentanil is available in an intravenous dosage form, and it is used for anesthetic procedures. It has a faster onset and shorter duration of action than fentanyl. The short duration is caused by redistribution from brain tissues after intravenous dosage.

Alftentanil Hydrochloride (Alfenta)

Substitution of tetrazol-5-one for the thiophene ring in sufentanil results in a decrease in potency (~25 times that of morphine) and a decrease in the pK_a of the resultant compound, alfentanil (Table 24.4). The lower pK_a of alfentanil results in a lower percentage of the drug existing in the ionized form at physiological pH. Being more un-ionized, alfentanil penetrates the blood-brain barrier faster than other fentanyl derivatives and has a faster onset and shorter duration of action. Alfentanil is 99% metabolized in the liver and has a half-life of only 1.3 hours. Alfentanil is available as an intravenous dosage form for use in ultrashort anesthetic procedures.

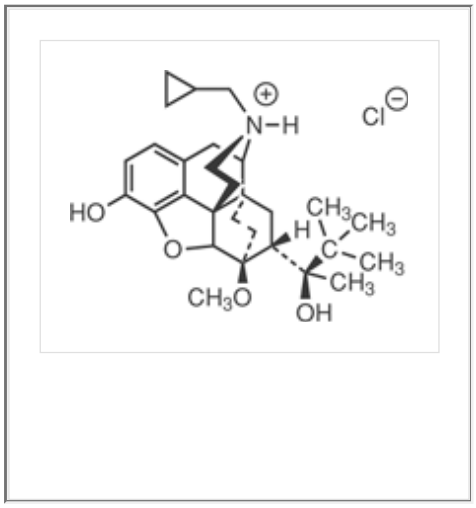
Remifentanil HCl (Ultiva)

Remifentanil is much like alfentanil in its pharmacodynamic effects. It is a selective μ opioid agonist with 15 to 20 times greater potency than alfentanil (Table 24.4). Remifentanil has an onset of action of 1 to 3 minutes when given intravenously. Its unique property is its rapid

offset of action, which is independent of the duration of administration of the compound. Thus, it is very useful for titration of antinociceptive effect, followed by a rapid and predictable recovery time of 3 to 5 minutes. The short duration of action is a result of the ester group, which has been rationally designed into the substituent on the piperidine nitrogen. This ester group is rapidly hydrolyzed to the inactive carboxylic acid by serum and tissue esterases, making the drug's duration of action essentially independent of the liver or renal function of the patient. Remifentanil is used extensively for analgesia associated with general anesthesia procedures. It often is used in combination with injectable general anesthetic agents, such as midazolam or propofol.

Mixed Agonist/Antagonists

(–)-Buprenorphine Hydrochloride (Buprenex)



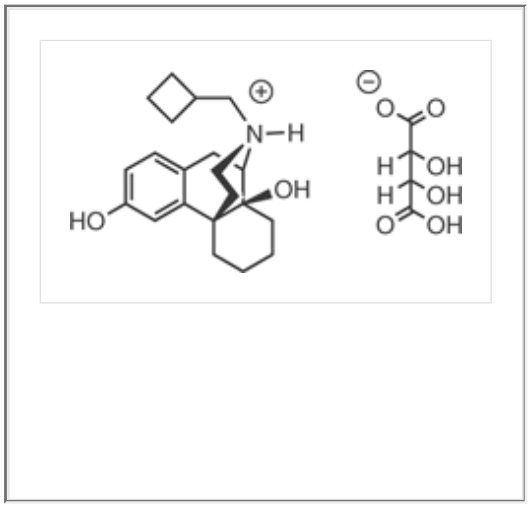
Buprenorphine is 20 to 50 times more potent than morphine in producing an ED50 analgesic effect in animal studies; however, it cannot produce an ED100 (compared to morphine) in these tests. Thus, buprenorphine is a potent partial agonist at μ opioid receptors. It also is a partial agonist at κ

receptors but more of an antagonist at δ receptors. Buprenorphine, at 0.4 mg intramuscular dose, will produce the same degree of analgesia as 10 mg of morphine. Because of its partial agonist properties, it has a lower ceiling on its analgesic action but also produces less severe respiratory depression. It is incapable of producing tolerance and addiction comparable to full μ agonists. In fact, buprenorphine's partial agonist action, very high affinity for opioid receptors, and high lipophilicity combine to give buprenorphine a tolerance, addiction, and withdrawal profile that is unique among the opioids. When given by itself to opioid-naive patients, little tolerance or addictive potential (Schedule 5) is observed. A mild withdrawal can occur some 2 weeks after the last dose of buprenorphine. Buprenorphine will precipitate withdrawal symptoms in highly addicted individuals, but it will suppress symptoms in individuals who are undergoing withdrawal from opioids. It effectively blocks the effect of high doses of heroin. Because of these properties, buprenorphine has been approved for office-based use in treating opioid dependence (64). It also has been reported to suppress cocaine use and addiction.

Buprenorphine undergoes extensive first-pass 3-O-glucuronidation, which negates its usefulness after oral dose. It is available in parenteral and sublingual dosage forms. The typical dose is 0.3 to 0.6 mg three times per day by intramuscular injection for analgesia or 8 mg/day as a sublingual tablet for opioid-dependence maintenance. The duration of analgesic effect is 4 to 6 hours. After parenteral dose, approximately 70% of the drug is excreted in the feces, and the remainder appears as N-dealkylated and conjugated metabolites in the urine.

Naloxone is not an effective antagonist to buprenorphine because of the latter's high binding affinity to opioid receptors.

(–)-Butorphanol Tartrate (Stadol)



Butorphanol is a strong agonist at κ opioid receptors, and through this interaction, it is five times more potent than morphine as an analgesic. The κ agonists have a lower ceiling analgesic effect than full μ agonists; thus, they are not as effective in treating severe pain. Butorphanol is an antagonist at μ opioid receptors with approximately one-sixth the potency of naloxone. If given to a person addicted to a μ agonist, butorphanol will induce an immediate onset of abstinence syndrome.

Butorphanol has a different spectrum of side effects than μ opioid analgesics. Respiratory depression occurs. There is a lower ceiling on this effect, however, and it is not generally lethal, as is the case with high doses of μ agonists. Major side effects after normal analgesic doses are sedation, nausea, and sweating, as well as dysphoric (hallucinogenic) effects at higher doses. Butorphanol causes an increase in pulmonary arterial pressure and pulmonary vascular resistance. There is an overall increased workload on the heart, and it should not be used in patients with congestive heart failure or to treat pain from acute myocardial infarction. Butorphanol has low

abuse potential and is not a scheduled drug.

Because of first-pass metabolism, butorphanol is not used in an oral dose form. Given parenterally, it has a plasma half-life and duration of analgesic effectiveness of 3 to 4 hours. The outpatient use of butorphanol has been greatly increased by the introduction of a metered inhalant dosage form of the drug. The major metabolite of butorphanol is the inactive *trans*-3-hydroxycyclobutyl product, which is excreted primarily in the urine.

Nalbuphine Hydrochloride (Nubain)

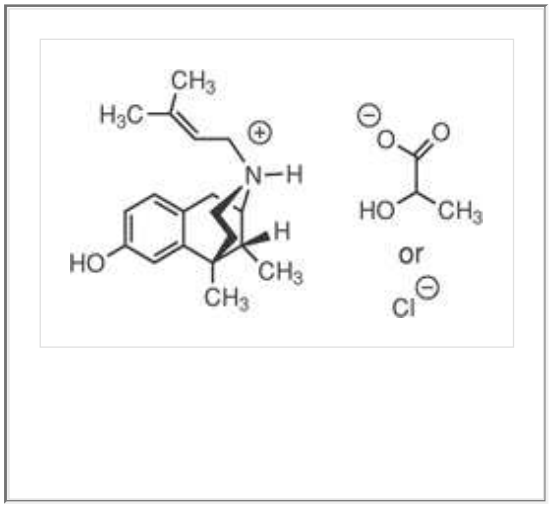
Nalbuphine (Table 24.3) is an antagonist at μ receptors and an agonist at κ receptors. As an antagonist, it has approximately one-fourth the potency of naloxone, and it produces withdrawal when given to addicts. On a weight basis, the analgesic potency of nalbuphine

approaches that of morphine. An intramuscular injection of 10 mg will give about the same degree and duration of analgesia as an equivalent dose of morphine.

Side effects of nalbuphine are like those of other κ. Dysphoria is not as common as with pentazocine. Sedation is the most common side effect. Nalbuphine does not have the adverse cardiovascular properties found with pentazocine and butorphanol. Nalbuphine has low abuse potential and is not listed under the Controlled Substances Act.

Nalbuphine is only available for parenteral dosage. Its elimination half-life is 2 to 3 hours. Metabolism of nalbuphine is by conjugation of the 3-OH group, and greater than 90% of the drug is excreted as conjugates in the feces.

(–)-Pentazocine Hydrochloride and Lactate (Talwin Nx and Talwin)



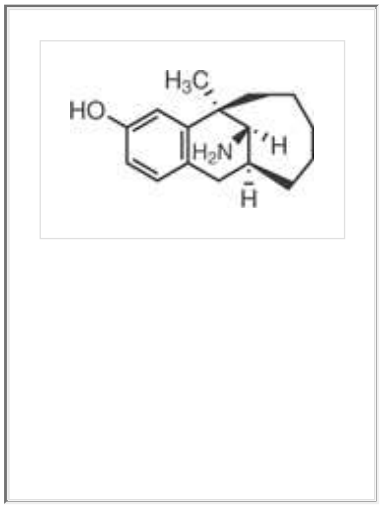
Pentazocine is a weak antagonist (one-thirtieth the potency of naloxone) at μ receptors and an agonist at κ receptors. Pentazocine is one-sixth as potent as an analgesic compared to morphine after parenteral doses. Pentazocine also is dosed orally and has an oral:parenteral dose ratio of approximately 2:1. It is used to treat moderate pain. The μ antagonist properties of pentazocine are sufficient to produce abstinence signs in opioid addicts.

The side effects of pentazocine are like other κ agonists. It has a greater tendency to produce dysphoric episodes, and it causes an increase in blood pressure and heart rate similar to butorphanol. Pentazocine is a Schedule IV drug. The major abuse of pentazocine has been its injection along with the antihistaminic drug tripelennamine (the “T's and blues”). Inclusion of the antihistaminic drug reportedly causes an increase in the euphoric, while decreasing the dysphoric, effects of the pentazocine. The manufacturers of pentazocine have attempted to thwart this use by

including naloxone in the oral dose formulation of pentazocine. When taken orally, as intended, the naloxone has no bioavailability, and the pentazocine is able to act as normal. When the tablet is dissolved and injected, the naloxone will effectively block the opioid actions of the pentazocine.

The elimination half-life of pentazocine is approximately 4 hours after parenteral dosage and 3 hours after oral dosage. Bioavailability after oral dose is only 20 to 50% because of first-pass metabolism. Pentazocine is metabolized extensively in the liver and is excreted via the urinary tract. The major metabolites are 3-O-conjugates and hydroxylation of the terminal methyl groups of the N-substituent. All metabolites are inactive.

Dezocine (Dulgan)



Dezocine is classified as a mixed agonist/antagonist. The SAR of dezocine is unique among the opioids. It is a primary amine, whereas all other nonpeptide opioids are tertiary amines. Its exact receptor selectivity profile has not been reported; however, its pharmacology is most similar to that of buprenorphine. It seems to be a partial agonist at μ receptors, to have little effect at κ receptors, and to exert some agonist effect at δ receptors. On a weight basis, it is about equipotent with morphine, and like morphine, it is useful for the treatment of moderate to severe pain. It is available for intramuscular and intravenous dose. The drug is indicated for postoperative and cancer-induced pain.

Dezocine has a half-life of 2.6 to 2.8 hours in healthy patients and 4.2 hours in patients with liver cirrhosis. The onset of action of dezocine is faster (30 minutes) than equivalent analgesic doses of morphine, and its duration of action is longer (4–6 hours). Dezocine is extensively metabolized by glucuronidation of the phenolic hydroxyl group and by N-oxidation. Metabolites are inactive and excreted mostly via the renal tract.

Dezocine causes respiratory depression, but like buprenorphine, there is a ceiling to this effect. Presumably, there also is a ceiling to the analgesic effect of dezocine, but this point is not well documented. Dezocine has lower affinity for μ receptors than buprenorphine, allowing its respiratory depressant effect to be readily reversed by naloxone.

The major side effects of dezocine are dizziness, vomiting, euphoria, dysphoria, nervousness, headache, pruritus, and sweating. Normal volunteers and recovered addicts report the subjective effects of single doses of dezocine to be like morphine. Because of the partial agonist mechanism of dezocine, one would not expect it to have a high abuse potential.

Opioids Used as Antidiarrheal Agents

Structure modification of 4-phenylpiperidines has led to the discovery of opioid analogues that are

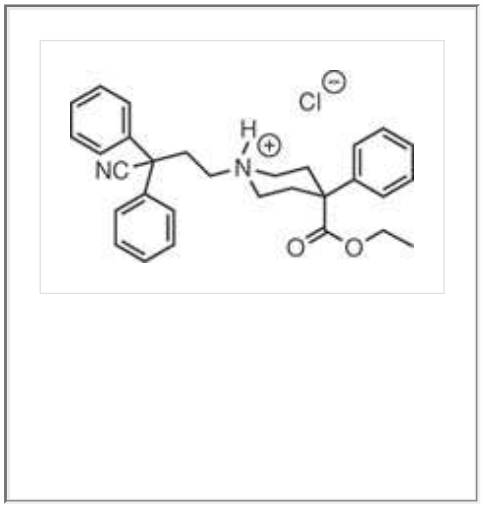
used extensively as antidiarrheal agents. Opioid agonists that act on μ and δ receptors have a strong inhibitory action on the peristaltic reflex on the intestine. This action occurs because endogenous opioid tracts innervate the intestinal wall, where they synapse onto cholinergic neurons. When opioids are released onto cholinergic neurons, they inhibit the release of acetylcholine and, thus, inhibit peristalsis. Any μ agonist used in medicine causes constipation as a side effect. Most μ agonists are not used as

antidiarrheal agents because of their potential for abuse and addiction.

Opium tincture and camphorated opium tincture (Paregoric) have long been used as effective antidiarrheal agents. The bad taste of these liquid preparations and their abuse potential (Schedule II and III, respectively) serve to limit their use and to favor newer agents. Codeine sulfate or phosphate salt, as a single agent, is sometimes used for the short-term treatment of mild diarrhea.

Synthetic agents that are structural combinations of meperidine and methadone are used extensively as antidiarrheal agents. Structures and uses of these agents are given below.

Diphenoxylate HCl with Atropine Sulfate (Lomotil)

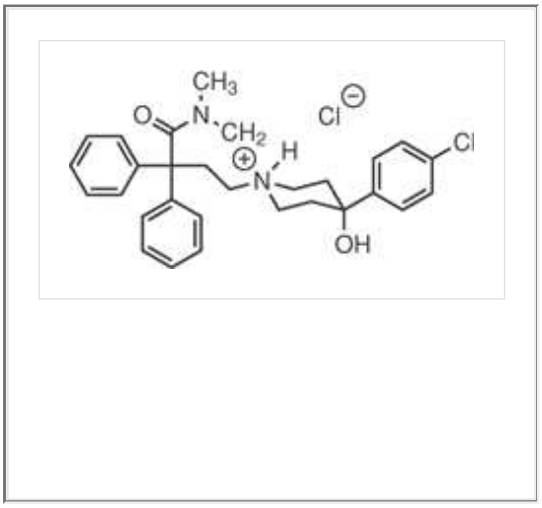


Diphenoxylate HCl (2.5 mg) and atropine (0.025 mg) are combined in tablets or 5 mL liquid and are used effectively as symptomatic treatment for diarrhea. The typical dose is two tablets or 10 mL every 3 to 4 hours. The combination with atropine enhances the block of acetylcholine-stimulated peristalsis, and the adverse effects of atropine helps to limit the abuse of the opioid. The combination is Schedule V under the Controlled Substances Act. Diphenoxylate itself has low μ opioid agonist activity. It is metabolized rapidly by ester hydrolysis to the zwitterionic free carboxylate (difenoxin), which is five times more potent after oral dosing. The zwitterionic properties of difenoxin probably limits its penetration into the CNS and explains the low abuse potential of this agent. High doses of diphenoxylate (40–60 mg) will cause euphoria and addiction.

Difenoxin HCl with Atropine Sulfate (Motofen)

Difenoxin, the active metabolite of diphenoxylate (as described above), also is used as an antidiarrheal agent. Tablets contain 1 mg of difenoxin and 0.025 mg of atropine sulfate. Dosage, uses, and effectiveness are similar to those of diphenoxylate.

Loperamide HCL (Imodium)

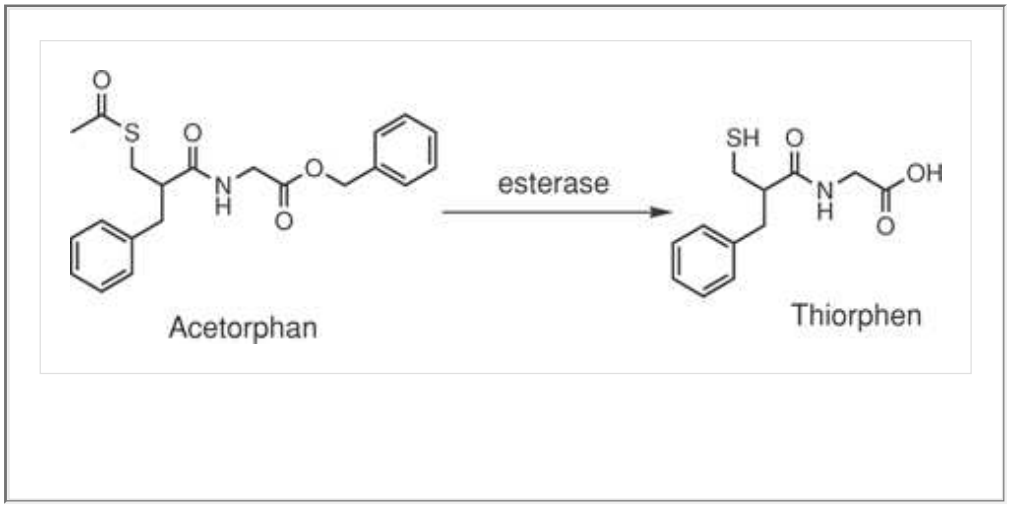


Loperamide is a safe and effective opioid-derived antidiarrheal agent, and it is not listed under the Controlled Substances Act. This medication is now available as a nonprescription item in the United States. It is used extensively for traveler's diarrhea. It exerts its antidiarrheal effects through interaction with μ-opiate receptors in the intestine to reduce peristalsis. Loperamide is marketed as capsules (2 mg) and liquid (1 mg/5 mL) preparations. The recommended dose is 4 mg initially and an additional 2 mg following each diarrheal stool. The dose should not exceed 16 mg/day. It is too lipophilic to dissolve in water for an intravenous dosage form, a property that limits its abuse potential. The compound is highly lipophilic and undergoes slow dissolution, thus limiting the bioavailability of the agent to approximately 40% of the dose. Its low oral bioavailability also can be attributed to first-pass metabolism by both CYP2C8 and CYP3A4 to its primary N-demethyl metabolite. Peak plasma levels are reached in approximately 5 hours, with an elimination half-life of approximately 11 hours. Approximately 1% of the dose is excreted into the urine unchanged. Loperamide also is a potent inhibitor of intestinal CYP3A4, increasing the intestinal absorption of other CYP3A4 substrates. The clinically significant drug interactions of loperamide with coadministered CYP3A4 and CYP2C8 substrates or inhibitors would be limited, however, because of its two metabolic pathways.

The efflux transporter P-gp is a major determinant of the pharmacokinetics and pharmacodynamics of loperamide, a potent opiate. The main reason that loperamide does not produce opioid CNS effects at usual doses in patients is a combination of slow dissolution, first-pass metabolism, and P-gp–mediated efflux, which prevents brain absorption, perhaps contributing to its low addiction potential. Loperamide produced no respiratory depression when administered alone, but when administered with a P-gp inhibitor, respiratory depression occurred, which could not be explained by increased plasma loperamide concentrations. This effect demonstrates the potential for important drug interactions by inhibition of P-gp efflux transporter. The lack of respiratory depression produced by loperamide, which allows it to be safely used therapeutically, can be reversed by a drug causing P-gp inhibition, resulting in serious toxic and abuse potential.

Enkephalinase Inhibitors as Antidiarrheal Agents

Although not available in the United States, inhibitors of enkephalinase, the major enzyme for the inactivation of endogenous opioid peptides, are available in Europe and much of the world for the treatment of diarrhea. Acetorphan (racecadotril), a pro-drug of thiorphan, is a good example of a clinically useful enkephalinase inhibitor used to treat diarrhea. The free thio group of thiorphan binds tightly to the zinc ion in the active site of the enzyme and inhibits its proteolytic action. Orally dosed acetorphan causes its antidiarrheal effect by inhibition of intestinal secretions and has a complementary effect when used in combination with loperamide, which exerts its effects by decreasing gastrointestinal transit time.



Opioid Agents Used as Cough Suppressants (Antitussives)

Many of the rigid-structured opioids have cough suppressant activity. This action is not a true opioid effect in that it is not always antagonized by opioid antagonists, the (+)-isomers are equally effective with the analgesic (–)-isomers as cough suppressants, and the SARs for opioid analgesia and cough suppression do not parallel each other. The 3-methoxy derivatives of morphine (codeine and hydrocodone) are nearly as effective antitussive agents as free phenolic agents. The better oral activity and decreased abuse potential of the methoxy derivatives make them preferred as antitussive agents. Incorporation of the 14α-hydroxyl into the structure (oxycodone) greatly decreases antitussive activity. If no cough suppression is desired in a patient being treated for pain, meperidine is the preferred agent.

Codeine is used extensively as a cough suppressant. It is available as a single agent or as mixtures in a variety of tablet and liquid cough suppressant formulations. As a simple agent, codeine is Schedule II, and in mixtures, it is Schedule V under the Controlled Substances Act. When used properly as a cough suppressant, codeine has little abuse potential; however, cough formulas of codeine often are abused.

Hydrocodone bitartrate is approximately threefold more effective on a weight basis as an oral antitussive medication compared to codeine. Hydrocodone also has greater analgesic activity and abuse potential than codeine. Hydrocodone is only available as a Schedule III prescription agent in combination formulations for cough suppression.

Dextromethorphan HBr is the (+)-isomer of the 3-methoxy form of the synthetic opioid levorphanol. It lacks the analgesic, respiratory depressant, and abuse potential of μ opioid agonists but retains the centrally acting antitussive action. Dextromethorphan is not an opioid and is not listed in the Controlled Substances Act. Its effectiveness as an antitussive is less than that of codeine. Dextromethorphan is available in a number of nonprescription cough formulations.

Case Study

Victoria F. Roche

S. William Zito

SJ is a 75-year-old native Hawaiian woman with debilitating degenerative arthritis of the spine. She has been stabilized on 50 μg/hour transdermal patches of fentanyl for 2 years, and these patches have allowed her to resume normal activities of daily living, including playing bridge with friends, visiting grandchildren, walking, and gardening. Her quality of life was good until last month, when she began having significant bouts of breakthrough pain that compromised both her abilities and her spirit. She sought help from her physician

to achieve better pain control, and he prescribed compound 1, administered intranasally. SJ has just presented the prescription at your pharmacy.

On checking SJ's patient profile, you find that she is a poor CYP2C9 metabolizer who is on low-dose, delayed-release sodium valproate for the treatment of complex partial seizure disorder. Her seizures are being well-controlled on this medication. You evaluate the physician's therapeutic recommendation against the other analgesics you have available in your pharmacy and prepare to make a therapeutic decision on SJ's behalf.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 25

Drugs Used to Treat Neuromuscular Disorders: Antiparkinsonian and Spasmolytic Agents

Raymond G. Booth

Overview of Neuromuscular Disorders

Neuromuscular disorders covered in this chapter include the neurodegenerative movement disorder, Parkinson's disease, and various spasticity disorders. Parkinson's disease is characterized by debilitating tremor, rigidity, and bradykinesia. The neuropathology (but not the etiology) of Parkinson's disease, with resulting dopamine neurotransmitter deficit, has been well defined for decades; however, pharmacotherapy of the disorder remains far from satisfactory. The development of prophylactic and, perhaps, curative pharmacotherapy of Parkinson's disease requires advances in our understanding of the causes and pathogenesis of the disease, and this chapter reviews some current research in these areas in addition to available drugs.

Spasticity disorders covered here generally are characterized by an increase in tonic stretch reflexes and flexor muscle spasms together with muscle weakness. Muscle spasticity may accompany a number of different disorders but mostly is associated with cerebral palsy, multiple sclerosis, spinal cord injury, and stroke. These disorders do not share a similar pathophysiology with neurodegenerative diseases, such as parkinsonism. Accordingly, drugs used to treat spastic neuromuscular disorders have mechanisms of action that differ from those used to treat Parkinson's disease. Nevertheless, most drugs described in this chapter to treat neurodegenerative or spastic neuromuscular disorders have in common the ability to reduce muscle tone by virtue of their action on the central nervous system (CNS).

Parkinson's Disease

Clinical Features and Neuropathology

Parkinson's disease, first described by James Parkinson in 1817, affects approximately 0.3% of the general population and 1 to 2% of individuals who are 65 years or older. The average onset age is approximately 60 years, and the disorder presents clinically as a classic triad of signs: resting tremor, rigidity, and bradykinesia. Dementia also is a common feature of Parkinson's disease and occurs 6.6-fold more frequently in elderly patients with the disease than in elderly patients without the disease. Along with this morbidity, mortality is two- to five-fold higher among patients with Parkinson's disease than in age-matched controls, greatly reducing life expectancy among affected individuals (1).

Neuropathologically, Parkinson's disease is a slowly progressive, neurodegenerative disorder of the extrapyramidal dopaminergic nigrostriatal pathway (Fig. 25.1). The disease is characterized by the destruction of dopaminergic cells in the pars compacta region of the substantia nigra in the midbrain, leading to a deficiency of dopamine in the nerve terminals of the striatum in the forebrain (2). Degenerative changes in the pigmented nuclei of the noradrenergic locus ceruleus region also are typical, as is the appearance of intraneuronal inclusions called Lewy bodies. Neurochemically, the striatal dopamine deficiency accounts for the major motor symptoms of the disease, but loss of noradrenergic nerve terminals with concomitant reductions in norepinephrine may account for several of the nonmotor features seen in Parkinson's disease, including fatigue and abnormalities of blood pressure regulation. The mainstay of pharmacological treatment (3),

developed in the mid-1960s, continues to be replacement therapy with the α-amino acid L-dihydroxyphenylalanine (L-dopa), the biochemical precursor to the catecholamine neurotransmitters dopamine and norepinephrine (Fig. 25.2).

Pathophysiology

Parkinson's disease primarily affects the part of the brain known as the basal ganglia, which consists of five interconnected, subcortical nuclei that span the telencephalon

(forebrain), diencephalon, and mesencephalon (midbrain). These nuclei include the striatum (caudate and putamen), globus pallidus, subthalamic nucleus, substantia nigra pars compacta, and substantia nigra pars reticulata. The neuroanatomical connections of the basal ganglia, cerebral cortex, and motor neurons of the spinal cord are complex, and current understanding is incomplete. However, recent models of basal ganglia function (Fig. 25.3) have helped to understand pharmacological management of Parkinson's disease (4).

Clinical Significance

The identification and description of Parkinson's disease in the early 1800s started us down a road to understanding and discovery that would be revolutionized almost 140 years later. This revolution centered on elucidating the nigrostriatal pathway and its important role in facilitating motor function and movement. Through better characterization of the structure and function of this anatomy and an understanding of the interrelationship of GABAergic, glutamatergic, dopaminergic, and cholinergic pathways, progress has been—and continues to be—made in relation to pharmacotherapy. In addition, understanding the contributions of genetics and environment to the development of diseases affecting motor function may ultimately lead to preventative therapies and, perhaps, cures. While reading this chapter, pay particular attention to the chemistry of agents that are used to treat movement disorders and how they affect the neuropharmacology of critical pathways. Applying this same knowledge to other agents with opposing pharmacology will help to reveal their potential to cause movement disorders. Ultimately, better clinical application will occur through a thorough comprehension of neuropharmacology as it relates to motor function and movement as well as the chemical nature and pharmacology of agents that affect it.

David Hayes, Pharm.D.

Clinical Assistant Professor

Department of Clinical Sciences and Administration

University of Houston College of Pharmacy

In normal striatum, dopamine, which is released from nerve terminals of dopaminergic cells originating in the substantia nigra, modulates the activity of inhibitory γ-aminobutyric acid (GABA) neurons. In turn, striatal GABAergic neurons, through a series of complex “direct” and “indirect” neuronal pathways, modulate neuronal outflow to the thalamus, which provides excitatory (glutamatergic) input to the motor cortex. In the direct pathway are two sequential inhibitory GABAergic links that provide input directly to the thalamus. The first set of striatal GABAergic neurons in the direct pathway contains a predominance of excitatory dopamine D_1-type receptors. Thus, the net effect of dopamine D_1-mediated stimulation of striatal GABA neurons in the direct pathway is increased excitatory outflow from the thalamus to the motor cortex (Fig. 25.3). The indirect pathway uses two sequential GABAergic links, like the direct pathway, that are followed

by an excitatory glutamatergic link and another inhibitory GABAergic input to the thalamus. The first set of striatal GABAergic neurons in the indirect pathway contains a predominance of inhibitory D_2-type receptors; thus, the net effect of dopamine D_2-mediated modulation of striatal GABAergic neurons in the indirect pathway is to reduce excitatory outflow from the thalamus to the motor cortex (Fig. 25.3). In the normal condition, the direct pathway is dominant, but in Parkinson's disease, the reduced levels of striatal dopamine negates this preference, and the indirect pathway becomes more apparent, with a net effect of decreased excitatory input to the motor cortex (Fig. 25.3).

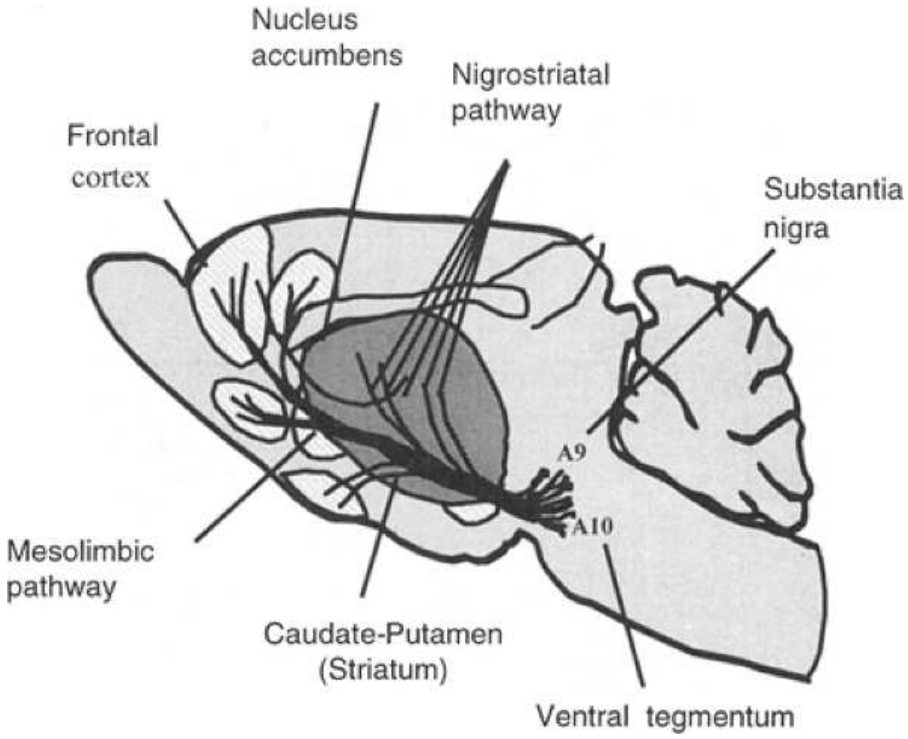

Fig. 25.1. Some dopaminergic pathways in the brain. The nigrostriated pathway (A9 cell bodies in substantia nigra; nerve terminals in striatum) is degenerated in Parkinson's disease.

Etiology

Although the neuropathology is well defined, the cause of Parkinson's disease is unknown. The development of effective pharmacotherapeutic and prophylactic therapy will require advances in our understanding of the etiology of the disease. Currently, there are several, sometimes convergent theories regarding the cause of

Parkinson's disease: “proteolytic stress,” which recently has been characterized in connection with rare Parkinson's disease genetic mutations as well as environmental and/or endogenous neurotoxicants, mitochondrial dysfunction, and oxidative metabolism—any and all of which may lead to “oxidative stress.” This section describes these and some alternative proposals regarding the etiology of Parkinson's disease.

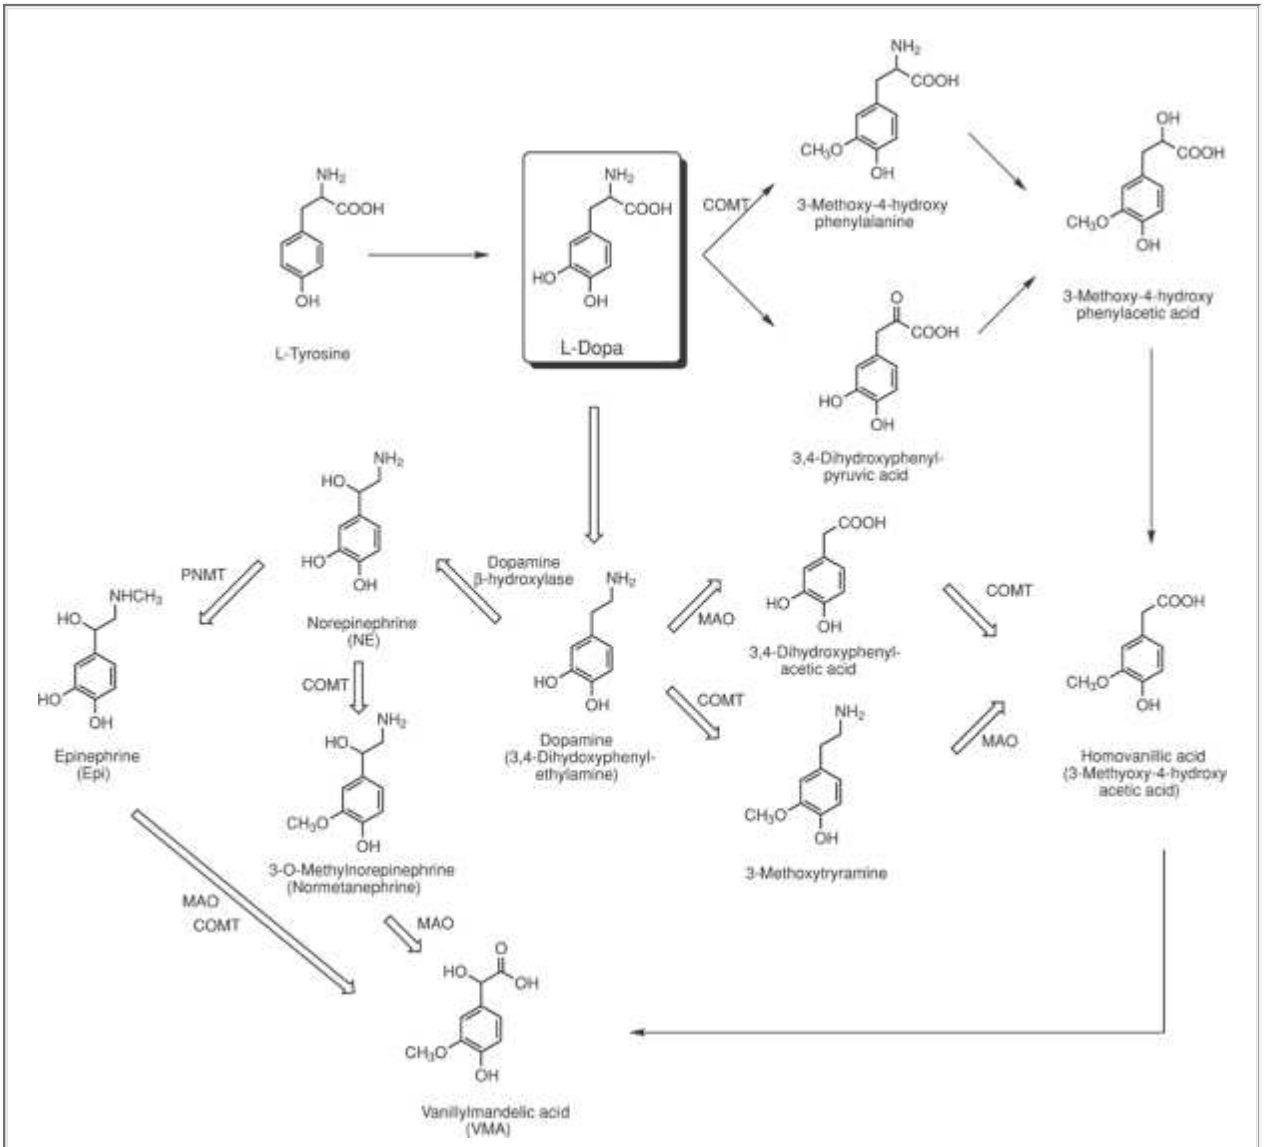

Fig. 25.2. Important pathways in the biosynthesis and metabolism of levodopa. Major pathways are shown by heavy arrows. COMT, catechol-O-methyltransferase; MAO, monoamine oxidase, PNMT, phenylethanolamine N-methyltransferase.

Several neurodegenerative disorders (including the movement disorder Huntington's disease) are genetically determined; thus, researchers have investigated a possible genetic influence in Parkinson's disease. Epidemiological studies have found that apart from age, a family history of Parkinson's disease is the strongest predictor of an increased risk of the disorder (5,6); however, the role of shared environmental exposure in families must be considered. One familial form of the disease is characterized by mutations in the α-synuclein gene, originally reported in a single large Italian family, three smaller Greek families, and a German family (7,8). α-Synuclein is a highly conserved, abundant, 140-amino-acid protein that is expressed mainly in presynaptic nerve terminals in the brain; however, its function is unclear (9). Aggregation of α-synuclein protein leads to pathological inclusions (synucleinopathy)

that characterize many neurodegenerative disorders, including Parkinson's disease (10).

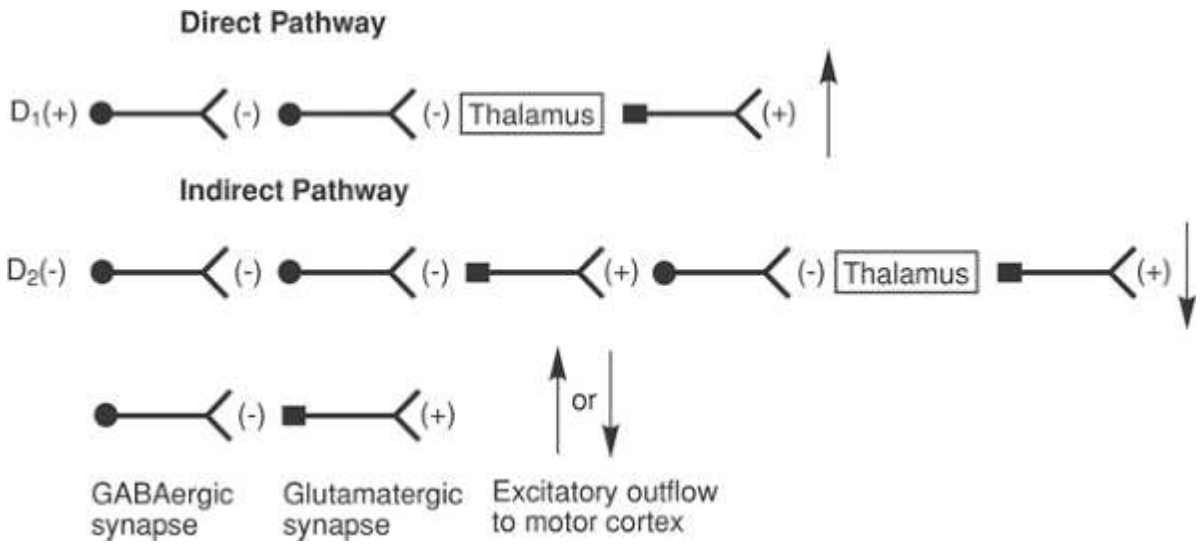

Fig. 25.3. Striatal dopaminergic stimulation of the direct and indirect pathways modulates the thalamus excitatory outflow to the motor cortex.

Mutations in four other genes, parkin, DJ-1, PINK1, and LRRK2 codes for dardarin protein, are unequivocally associated with the development of familial Parkinson's disease (11), and a number of other mutations also are implicated. It is proposed that such mutations may lead to excessive production of damaged proteins and/or dysfunction of protein clearance mechanisms in the brain (12). In normal physiological conditions, damaged proteins usually are degraded and cleared by the ubiquitin–proteasome system (UPS). Increased production of damaged proteins and/or decreased UPS-mediated degradation and clearance of proteins may lead to protein aggregation and proteolytic stress. Proteolytic stress affects a variety of cellular structures and processes, and it can lead to cell death (13,14). In cases of familial Parkinson's disease associated with LRRK2/dardarin mutations, protein accumulation and Lewy body formation have been documented in postmortem analysis (15), but such data currently are unavailable for the parkin (a UPS enzyme), DJ-1, and PINK-1 mutations. Meanwhile, several studies have failed to detect mutations in the α-synuclein gene in a large sampling of families (16,17), and studies using both identical and heterozygous twins, which provide a rigorous genetic analysis, have failed to reveal a genetic component of Parkinson's disease (18). Thus, although compelling evidence exists for apparently rare cases of genetically linked Parkinson's disease, primarily involving early onset of the disorder, the majority of cases are not associated with known genetic mutations and are considered to be sporadic (19). It should be noted, however, that synucleinopathy has been detected in sporadic cases of Parkinson's disease (20), suggesting that hypotheses involving protein aggregation may be relevant to the etiology of the more common forms of the disease. Moreover, although Parkinson's disease associated with genetic mutation is rare (<10% of cases), the study of these cases has facilitated understanding of the molecular pathways that lead to neurodegeneration, especially involving dopaminergic neurons.

In contrast to Parkinson's disease forms that are associated with genetic mutations, little evidence suggests that the disorder is autoimmune-related (21). Likewise, although a form of parkinsonism associated with influenza virus–induced encephalitis did occur in a 1918 epidemic, recent studies indicate no evidence for a communicable infectious etiology (22). Strong evidence, however, suggests that some cases of Parkinson's disease may be caused by environmental toxicants. For instance, manganese miners in South America have a high risk of developing the

disease (23), and in the major agricultural region of the Quebec province of Canada, a remarkably high correlation between the incidence of Parkinson's disease and the sale of pesticides is documented (24). An interesting link to the environment and/or endogenous milieu is that the incidence of Parkinson's disease is lower in cigarette smokers than in nonsmokers (25). It has been proposed that something in cigarette smoke may protect against a toxicant (environmental or endogenous) relevant to parkinsonian neuropathology. For example, the carbon monoxide in cigarette smoke may detoxify free radicals from environmental or endogenous sources. It also has been suggested that compounds in cigarette smoke, or the metabolites of these compounds, may inhibit monoamine oxidase (MAO)-B activity (26), the main enzyme responsible for metabolism of monoamine neurotransmitters, such as dopamine.

In fact, dopamine itself has been implicated in the disease process through production of chemically reactive oxidation products, suggesting that endogenously formed substances may be etiologic factors in Parkinson's disease (27). For example, the MAO-catalyzed oxidation of the monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) generates hydrogen peroxide (see Equation 1 in Fig. 25.4), which can undergo a redox reaction with superoxide in the Haber-Weiss reaction (28) to form the extremely cytotoxic hydroxy radical (see Equation 2 in Fig. 25.4). Moreover, the auto-oxidation of dopamine to the corresponding electrophilic semiquinone and quinone (Fig. 25.4) species has received attention, because these oxidation

products also are cytotoxic (29). Manganese ion can catalyze oxidation of dopamine, and the resulting semiquinone and quinone species have been implicated in manganese neurotoxicity (30). The auto-oxidation of dopamine also leads to the formation of the polymeric black pigment neuromelanin (29). The physiologic role of neuromelanin is poorly understood. The pigment is increasingly deposited in catecholaminergic neurons with advancing age, however, and it has been suggested that its accumulation in nigral neuronal cells eventually causes cell death (2).

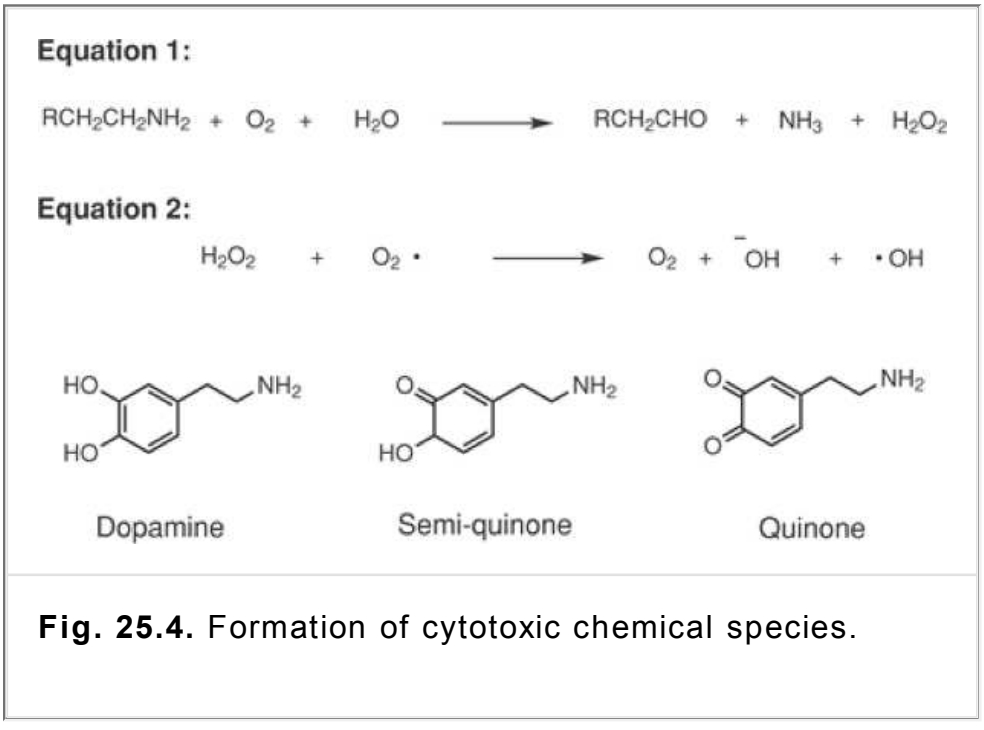

Fig. 25.4. Formation of cytotoxic chemical species.

It has been postulated that Parkinson's disease might be the consequence of normal aging superimposed on a lesion in the substantia nigra that occurred earlier in life (31). Dopamine neurons degenerate with advancing age, and in normal adults, dopamine levels in striatum decline by approximately 13% per decade (32). Parkinsonian symptoms usually become apparent when striatal dopamine levels decline by approximately 80% (33). Conceivably, the symptoms of

parkinsonism could be produced by two processes, a specific disease-related insult combined with pathological changes resulting from normal aging. This two-pronged pathophysiology may explain why Parkinson's disease is a progressive disorder of late onset. The discovery of the potent and selective dopaminergic neurotoxicant N-methyl-4-phenyl-1, 2,3,6-tetrahydropyridine (MPTP) has greatly aided scientists conducting studies to determine the etiology of Parkinson's disease.

Parkinsonism Caused by MPTP

The cyclic tertiary amine MPTP (Fig. 25.5) induces a form of parkinsonism in humans and monkeys similar in neuropathology and motor abnormalities to idiopathic Parkinson's disease (34,35,36). The role of MPTP in parkinsonian disorders was revealed by a serendipitous series of events. In 1977, a 23-year-old college student suddenly developed parkinsonian symptoms, with severe rigidity, bradykinesia, and mutism. The abrupt and early onset of symptoms was so atypical that the patient initially was thought to have catatonic schizophrenia. The subsequent diagnosis of parkinsonism was substantiated by a therapeutic response to L-dopa, whereupon the patient was referred to the National Institute of Mental Health in Bethesda, Maryland. The patient admitted having synthesized and used several illicit drugs, after which the psychiatrist who had elicited the patient's history visited his home and collected glassware that had been used for chemical syntheses. Chemical analysis revealed several pyridines, including MPTP, formed as by-products in synthesizing the reverse ester of the narcotic analgesic meperidine known as N-methyl-4-propionoxy-4-phenylpiperidine (MPPP), “designer heroin,” or “synthetic heroin.” This substance also is an analogue of another narcotic analgesic, α-prodine (Fig. 25.6). It was initially unclear, however, whether MPTP or other constituents of the injected mixture accounted for the neurotoxicity.

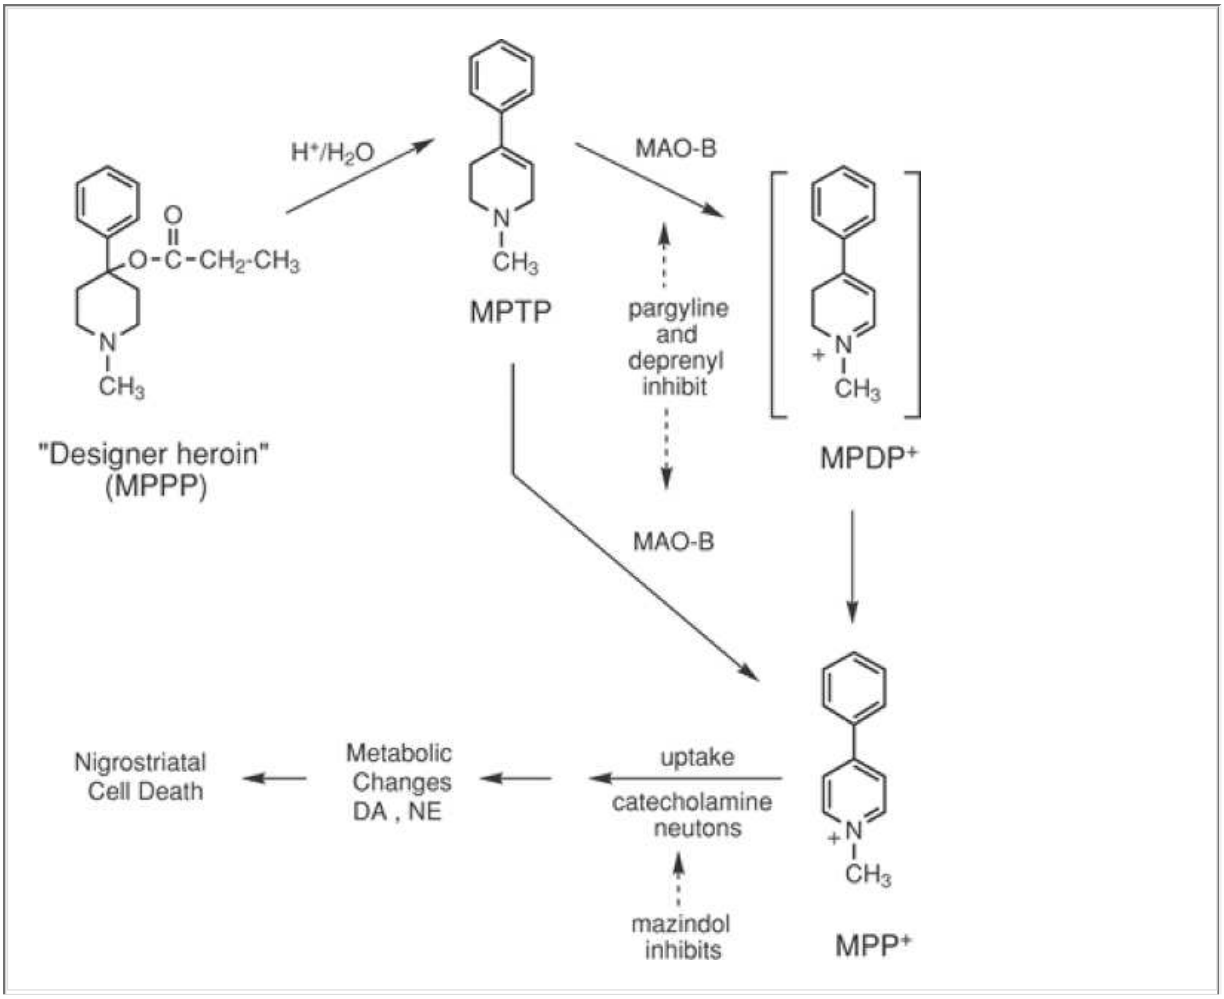

Fig. 25.5. Chemical conversion of MPPP and probable mechanism of MPTP neurotoxicity.

After the patient returned home, he continued to abuse drugs and died of an overdose; autopsy revealed degeneration of the substantia nigra—the hallmark

neuropathological feature of Parkinson's disease. Subsequently, other patients were identified with virtually identical parkinsonian symptoms who had also been receiving intravenous injections of MPPP preparations containing varying amounts of MPTP. In several patients, MPTP was the principal or sole constituent injected, providing the first definitive evidence that MPTP is a parkinsonism-producing neurotoxicant. Both the clinical and neuropathological features of MPTP-induced parkinsonism resemble idiopathic Parkinson's disease more closely than any previous animal or human disorder elicited by toxins, metals, viruses, or other means. Accordingly, understanding the molecular pathophysiology of MPTP neurotoxicity has shed light on the neurodegenerative mechanisms in idiopathic parkinsonism.

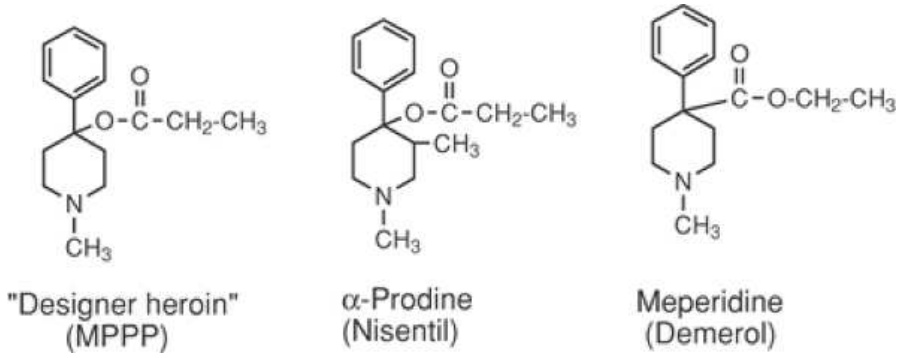

Fig. 25.6. Phenylpiperidine synthetic analgesics.

Mechanisms of Neuronal Cell Death in MPTP-Induced Parkisonism

Consideration of the chemical structure of MPTP would suggest that the compound is relatively chemically inert, because no highly reactive functional group is present. Almost immediately, it was recognized that MPTP might undergo some type of metabolic activation to a more reactive metabolite. Researchers soon discovered that brain MAO-B catalyzes the two-electron oxidation of MPTP at the allylic α-carbon to give the unstable intermediate product 1-methyl-4-phenyl-2,3-dihydropyridinium ($MPDP^+$), which subsequently undergoes a further two-electron oxidation to the stable 1-methyl-4-phenylpyridinium species (MPP^+) via auto-oxidation, disproportionation, and enzyme-catalyzed mechanisms (Fig. 25.5) (37,38,39). Inhibitors of MAO-B subsequently were shown to prevent MPTP-induced parkinsonism in primates (40), and it currently is accepted that MPP is the major metabolite of MPTP responsible for the destruction of dopamine neurons, although a role for the unstable dihydropyridinium species $MPDP^+$ has not been ruled out.

The relationship of MAO and MPTP has neurobiological relevance beyond MPTP neurotoxicity. Monoamine oxidase catalyzes the α-carbon oxidation of the monoamine neurotransmitters (e.g., dopamine, norepinephrine, and serotonin) (Fig. 25.2). Oxidation of a heterocyclic tertiary amine (i.e., MPTP) by MAO is unprecedented and suggests a novel physiologic role for this enzyme. For example, MAO could be important in regulating the oxidation state of pyridine systems, such as those involving nucleic acids and NADH (41), which may be involved in the neurotoxicity of MPTP (vide infra). Interestingly, biochemical and epidemiologic evidence suggests that cigarette smokers have depressed MAO-B activity (42) and a lower incidence of Parkinson's disease (43). Nicotine is not a particularly potent inhibitor of MAO, and in fact, nicotine increases the neurotoxicity of MPTP (44). Other components of cigarette smoke, however, do inhibit MAO, and cigarette smoke protects against MPTP-induced depletion of striatal dopamine in mice (45).

Although extensive metabolic, biochemical, and toxicological investigations have established that the nigrostriatal neurodegenerative properties of MPTP are mediated by the MAO-B derived metabolite, MPP^+, this bioactivation reaction must proceed outside of the target nigrostriatal dopamine neurons, because they apparently do not contain MAO-B (46). It is thought that MPTP is oxidized to MPDP in MAO-B–rich glial cells near striatal nerve terminals and nigral cell bodies; the conjugate base MPDP presumably diffuses out of glial cells and is subsequently oxidized to the MPP^+ metabolite. The MPP^+ is sequestered into striatal dopaminergic nerve terminals via the dopamine neurotransporter, which accepts MPP^+ as a substrate (Fig. 25.5) (47). Intraneuronally, MPP^+ is concentrated into mitochondria, where it selectively inhibits complex I of the electron-transport chain, inhibiting NADH oxidation and, eventually, depleting the nigrostriatal neuronal cell of adenosine triphosphate (48,49). Thus, the current hypothesis regarding the mechanism of nigrostriatal cell death induced by MPTP (via MPP^+) is energy failure at the level of the mitochondrial respiratory chain (50,51).

Several sequential factors may account for the selective damage of nigrostriatal dopamine neurons by MPTP (Fig. 25.5). First, MPTP binds selectively to MAO-B, which is highly concentrated in glial cells in human substantia nigra and corpus striatum. Then, the MPP^+ produced from MPTP is selectively accumulated by dopamine neurotransporters into nigral dopamine cells and striatal dopamine nerve terminals. Finally, within nigral cell bodies, MPP^+ binds to neuromelanin and may be gradually released in a depot-like fashion, maintaining a toxic intracellular concentration of MPP^+ that inhibits mitochondrial respiration.

The serendipitous discovery and subsequent scientific investigation of the mechanism of parkinsonism produced by MPTP refocused study of the etiology and pathogenesis of idiopathic Parkinson's disease. For example, evidence suggests that a defect of mitochondrial respiratory chain function may occur in idiopathic Parkinson's disease (52,53). Specifically, it has been documented that there is a 30 to 40% reduction in mitochondrial complex I activity in the substantia nigra of patients with Parkinson's disease (52,53). In general, mitochondrial dysfunction and disorders of oxidative metabolism (oxidative stress), which can include a genetic component (11), now are considered to be critical components of most theories of nigral cell degeneration in Parkinson's disease. Discovery of the selective ability of MPTP to induce nigral cell death has stimulated broad interest in identifying potential environmental or endogenous compounds that may be causative agents in Parkinson's disease.

Pharmacotherapy of Parkinson's Disease

So far, clinical studies to evaluate the effectiveness of coadministration of an MAO-B inhibitor plus the antioxidant

vitamin E to slow the progression of neurodegeneration in Parkinson's disease have not yielded encouraging results (54,55,56). Thus, currently available pharmacotherapy continues to be

symptomatic, involving replacement of the dopamine deficiency in striatum by one or more of the following means: 1) augmentation of the synthesis of brain dopamine, 2) stimulation of dopamine release from presynaptic sites, 3) direct stimulation of dopamine receptors, 4) decreasing reuptake of dopamine at presynaptic sites, or 5) decreasing dopamine catabolism.

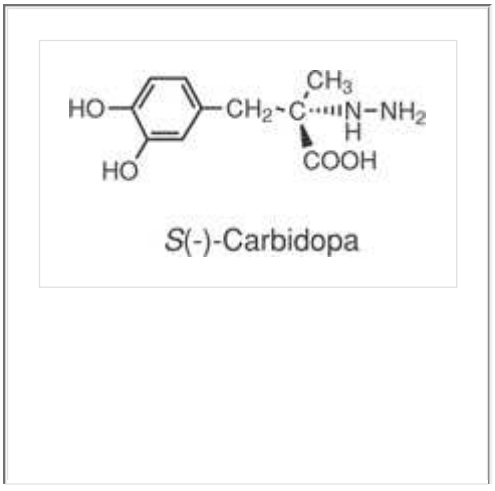
Levodopa Therapy

About 40 years after its introduction, levodopa remains the most effective pharmacotherapy in Parkinson's disease (57). Despite controversy regarding long-term efficacy, side effects, and even potential neurotoxicity, most patients derive a substantial benefit from levodopa over the entire course of their illness. Moreover, levodopa increases life expectancy among patients with Parkinson's disease, and survival is significantly reduced if the initiation of levodopa therapy is delayed (58).

The seminal report by Cotzias et al. (59) in 1967, describing dramatic symptomatic improvement of parkinsonian patients given high oral doses of racemic dopa, was followed by more clinical trials that confirmed the efficacy and safety of the levo isomer. The effectiveness of levodopa requires penetration of the drug into the CNS and its subsequent enzymatic decarboxylation to dopamine. Dopamine does not cross the blood-brain barrier, because it exists primarily in its protonated form under physiologic conditions (pK_a = 10.6 [NH_2]) (60). The precursor amino acid levodopa, however, is less basic (pK_a = 8.72 [NH_2]) and, thus, can penetrate the CNS.

Biosynthesis and metabolism

Levodopa is an intermediary metabolite in the biosynthesis of catecholamines, formed from L-tyrosine in a rate-limiting hydroxylation step by tyrosine hydroxylase (Fig. 25.2). Levodopa subsequently is decarboxylated by the cytoplasmic enzyme L-aromatic amino acid decarboxylase (dopa decarboxylase) to form dopamine. The effects observed following systemic administration of levodopa have been attributed to its catabolites, dopamine, norepinephrine, and epinephrine, acting at various sites in the periphery and in the brain. The principal metabolic pathways for levodopa are shown in Figure 25.2. A small amount is methylated to 3-O-methyldopa, which accumulates in the CNS because of its long half-life. Most levodopa, however, is decarboxylated to dopamine, small amounts of which are metabolized to norepinephrine and epinephrine. The activity of dopa decarboxylase, however, is greater in the liver, heart, lungs, and kidneys than in the brain (61). Therefore, ingested levodopa is converted to dopamine in the periphery in preference to the brain. It is thought that in humans, levodopa thus enters the brain only when administered in doses high enough to overcome losses caused by peripheral metabolism (3–6 g daily). Inhibition of peripheral decarboxylase activity, by coadministration of a peripheral decarboxylase inhibitor such as carbidopa, can markedly increase the proportion of levodopa that crosses the blood-brain barrier (Fig. 25.7).



The greater amount of dopamine that is formed in the brain after orally administered levodopa/carbidopa presumably provides symptomatic relief of parkinsonian symptoms, such as rigidity and bradykinesia. Parkinsonian patients not previously treated with levodopa usually are started on a combination therapy with Sinemet, which is available in a fixed ratio of 1 part carbidopa and 10 parts levodopa. Once formed from levodopa, metabolism of dopamine then proceeds relatively rapidly to the principal excretion products 3,4-dihydroxyphenylacetic acid and 3-methoxy-4-hydroxyphenylacetic acid (homovanillic acid) (Fig. 25.2).

Pyridoxine (a coenzyme for dopa decarboxylase) can reverse the therapeutic effects of levodopa by increasing decarboxylase activity, which results in more levodopa being converted to dopamine in the periphery and, consequently, less being available for penetration into the CNS. When peripheral dopa decarboxylation is blocked with carbidopa, however, the pyridoxine effect on peripheral levodopa metabolism is negligible (Fig. 25.7).

Side effects

One of the most common side effects of levodopa therapy is gastric upset with nausea and vomiting. This appears to be the result of direct gastrointestinal irritation as well as stimulation by dopamine of the chemoreceptor trigger zone in the area postrema of the brainstem that activates the emetic center of the medulla. The blood-brain barrier is poorly developed in the area postrema, and the chemoreceptor trigger zone is accessible to emetic substances in the circulation. One of the advantages of combining levodopa with a peripheral decarboxylase inhibitor, such as carbidopa, is that a 75 to 80% reduction of the dosage of levodopa is permitted; thus, some side effects may be avoided or lessened in severity. Administration of carbidopa with levodopa results in a significant decrease in the incidence and severity of nausea and vomiting associated with levodopa alone. Other side effects of levodopa involve activation of peripheral adrenergic and dopaminergic receptors by dopamine (Fig. 25.7). For example, dopamine stimulation of peripheral α-adrenergic receptors causes vasoconstriction, and stimulation of β-adrenergic receptors enhances heart rate. Either of these may lead to increased blood pressure, and stimulation of peripheral dopamine receptors causes renal and mesenteric vasodilation. These cardiovascular side effects of levodopa (via dopamine) also can be diminished by coadministration of carbidopa to allow a lower dose of levodopa.

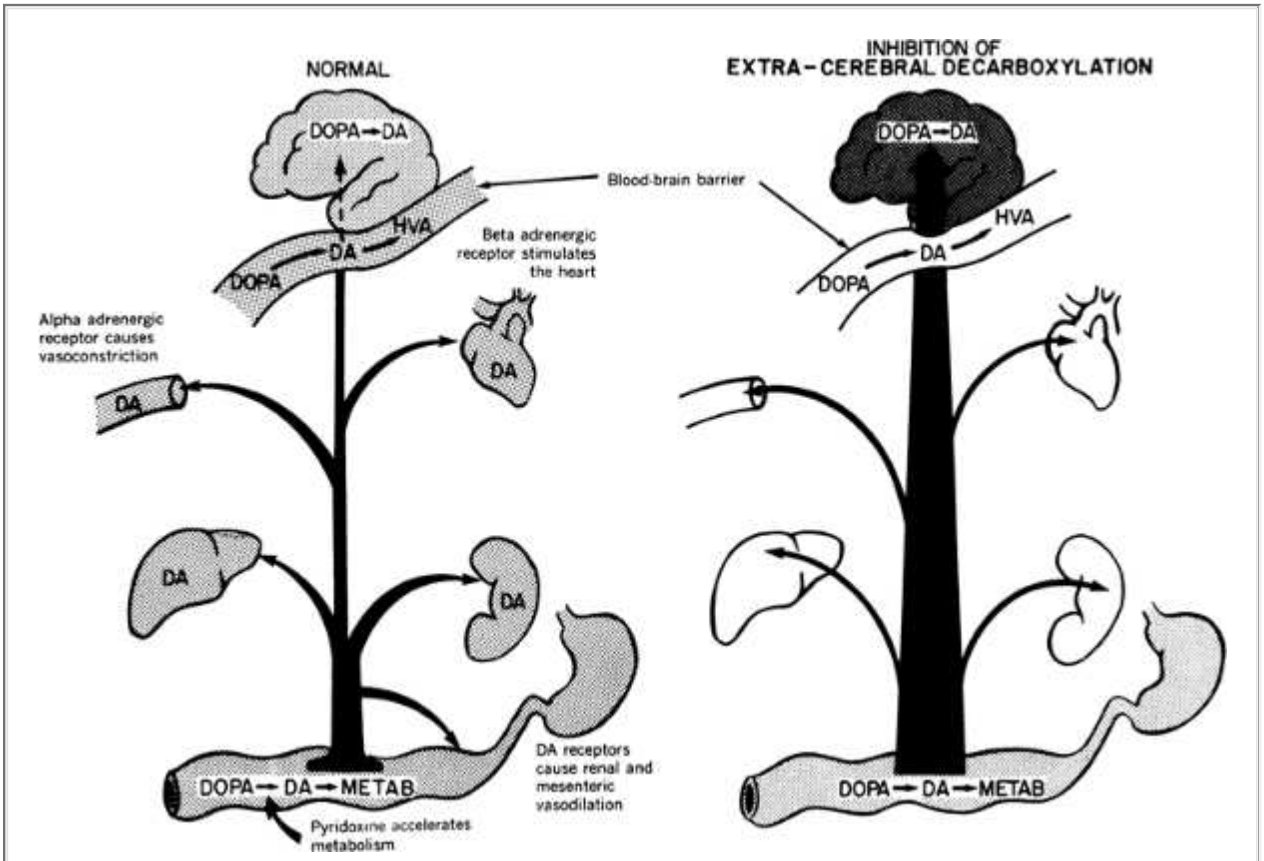


Fig. 25.7. Diagrammatic representation of the peripheral decarboxylation of levodopa to form dopamine (DA) and the mode of action of extracerebral decarboxylase on levodopa metabolism and distribution in vivo. The concurrent administration of levodopa and a decarboxylase inhibitor decreases the amount of levodopa required to elicit a therapeutic response in parkinsonism. HVA, homovanillic acid.

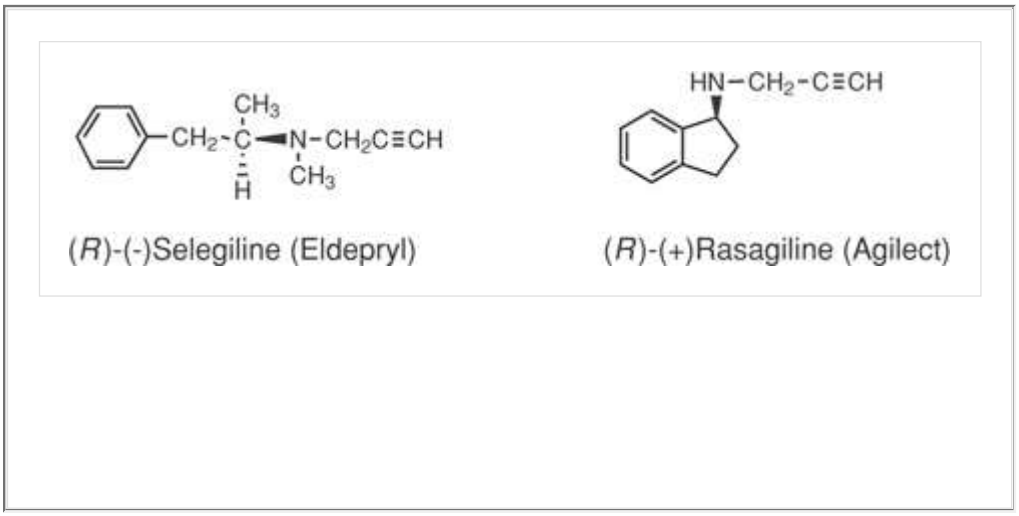
After approximately 5 years of levodopa therapy, 50% of patients develop motor fluctuations; the proportion of patients affected increases to 70% after 15 years of therapy (62). Motor complications include “off” periods of immobility or greater severity of other parkinsonian symptoms and various abnormal involuntary movements. This phenomenon may be caused by progression of the disease, with resulting striatal nerve terminal degeneration and decreased synthesis and storage of dopamine generated from endogenous or exogenous levodopa. In addition to these presynaptic changes, changes in postsynpatic D_1-type and D_2-type receptor systems in the striatum also may occur.

Psychiatric disturbances, such as visual hallucinations, mania, hypersexuality, and paranoid psychosis, also are complications of levodopa therapy. It generally is believed that these psychiatric disturbances result from dopamine (produced from levodopa) stimulation of dopamine receptors outside the motor striatum (i.e., in the mesolimbic dopaminergic system).

MAO-B Inhibitors



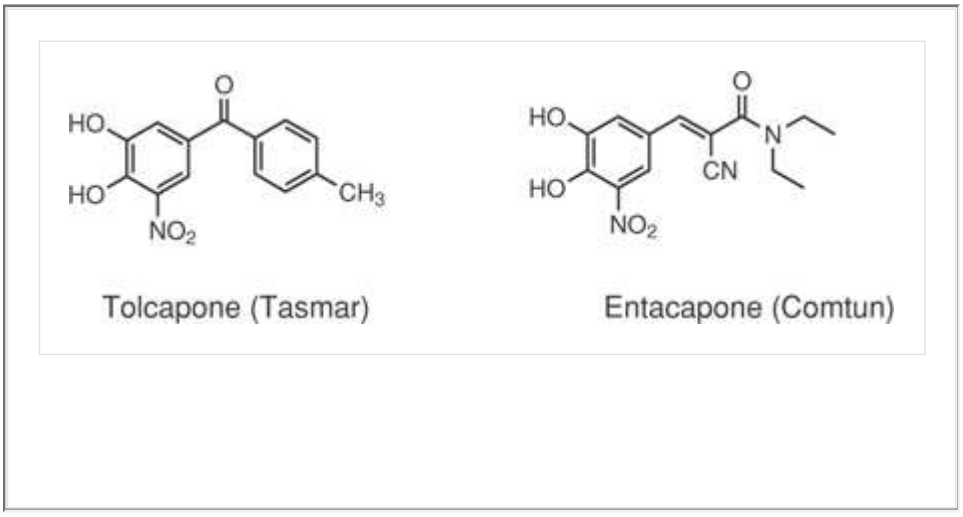
(*R*)-(-)Selegiline (Eldepryl) (*R*)-(+)Rasagiline (Agilect)

Selegiline and rasagiline

Selegiline and rasagiline are propargylamine-type selective inhibitors of MAO-B, which inactivates dopamine in the brain. The MAO-B inhibitors extend the duration of response to levodopa by reducing metabolism of dopamine; thus, the dose of levodopa can be reduced without loss of therapeutic benefit (3). It has been proposed that MAO-B inhibitors may prevent formation of neurotoxic oxidation products of dopamine and slow neurodegeneration in Parkinson's disease; however, data from recent clinical studies do not support this attractive "neuroprotective" hypothesis (54,55). Nevertheless, MAO-B inhibitors have a beneficial effect on motor fluctuations because of their levodopa-sparing effect (56).

Selegiline and rasagiline undergo extensive hepatic metabolism. Selegiline is N-dealkylated via CYP2B6 and CYP2C19 to (–)-methamphetamine and, subsequently, to (–)-amphetamine, which has vasoactive activity similar to (+)-amphetamine (63). The amphetamine metabolites of selegiline may contribute to its other pharmacological property of dopamine and norepinephrine reuptake inhibition, thus potentiating the pharmacological effects of levodopa (50). The amphetamine metabolites of selegiline have been associated with cardiovascular (orthostatic hypotension) and psychiatric (hallucinations) side effects. Rasagiline is N-dealkylated primarily by CYP1A2 to (*R*)-1-aminoindan, which does not have vasoactive activity (63).

Catechol-O-Methyltransferase Inhibitors



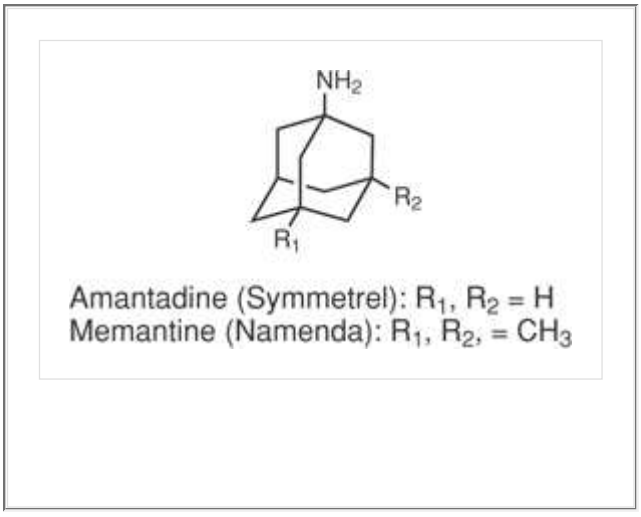
Tolcapone (Tasmar) Entacapone (Comtun)

Tolcapone and entacopone

Tolcapone and entacopone are reversible inhibitors of catechol-O-methyltransferase (COMT), which normally transfers a methyl group from the metabolic intermediate S-adenosyl-L-methionine to the 3-phenolic moiety of dopamine, resulting in inactivation of the neurotransmitter (Fig. 25.2). Therefore, because tolcapone and entacopone block the activity of COMT, they prolong the activity of dopamine. Because COMT also inactivates levodopa, COMT inhibitors prolong the action of levodopa. (Fig. 25.2).

Examination of the chemical structures of tolcapone and entacapone reveal obvious similarities, and the molecular mechanisms by which these drugs interact with human COMT are proposed to be similar (64). Although the mechanisms of action and pharmacotherapeutic effects are similar for tolcapone and entacapone, they differ with respect to pharmacokinetic properties and adverse effects. Tolcapone has a relatively longer duration of action (8–12 hours) and acts both in the brain and periphery, whereas entacapone has a shorter duration of action (2 hours) and acts mostly in the periphery to inhibit COMT. Some common adverse effects of these agents are predictable and attributable to increased brain dopamine (e.g., nausea, vivid dreams, confusion, and hallucinations). A potentially fatal adverse effect, however, occurs only with tolcapone—after marketing, three fatal cases of fulminant hepatic failure were observed, leading to its restriction to only those patients who have not responded to other therapies and who have appropriate monitoring for hepatic toxicity. The unforeseen hepatotoxicity associated with tolcapone has left entacapone as the only COMT inhibitor in wide clinical use (65). The mechanism by which liver damage is induced exclusively by tolcapone is believed to involve uncoupling of mitochondria oxidative phosphorylation, significantly reducing cellular generation of adenosine triphosphate (66,67). Additionally, it recently was shown that tolcapone (but not entacapone) induces cytotoxic pro-oxidant radical formation in hepatocytes (68). Finally, both COMT inhibitors may cause severe diarrhea and produce increased dyskinesias that may require a reduction in the dose of levodopa (69).

Dopamine Release and Dopamine Reuptake Inhibitor agents



Amantadine and memantine

Amantadine demonstrates clinically significant antiparkinsonian effects during the initial stages of the disease. Relief of symptoms generally is attributed to its activity to promote dopamine release from intraneuronal storage sites and to prevent dopamine reuptake (70). Both amantadine and its dimethyl derivative memantine (approved for Alzheimer's disease) are glutamic acid (N-methyl-D-aspartate [NMDA]) receptor antagonists that may be neuroprotective by preventing excessive

influx of calcium into neuronal cells that may lead to excitotoxicity (70).

Amantadine is a primary amine, with a pK_a of 10.8, and most of the drug is in the protonated form at physiologic pH. Nevertheless, the drug may enter the brain because of its cage-like structure that not only increases its lipophilicity but also precludes its catabolism by oxidative enzymes; metabolism studies have shown that amantadine is excreted in the urine unchanged.

Dopamine Receptor Agonists

Mechanism of action

The nigrostriatal neurodegeneration that proceeds over the course of Parkinson's disease limits the number of striatal nerve terminals that are available to decarboxylate levodopa to dopamine. Drugs that act directly to stimulate dopamine receptors, however, do not require functioning dopaminergic nerve terminals and can be useful in the management of late-stage disease problems during levodopa therapy. Dopamine receptor agonists currently available are nonselective and without balanced activity at D_1-type and D_2-type receptors–clinically used agents are full or partial agonists primarily at D_2-type receptors. Use of dopamine agonist monotherapy (i.e., without levodopa) has been suggested as initial therapy for Parkinson's disease based on the hypothesis that oxidative metabolites of dopamine (formed from exogenous and endogenous levodopa) may be neurotoxic. At present, however, no substantial evidence supports an indirect neuroprotective effect of dopamine receptor agonists. Meanwhile, dopamine receptor agonists have a longer duration of action (8–24 hours) compared to levodopa (6–8 hours) and may be less likely than levodopa to induce on/off effects and dyskinesias. In fact, the dopamine receptor agonists pramipexole and ropinirole (Fig. 25.8) do produce reduced motor fluctuations compared to levodopa; however, they also produce increased incidence of other adverse effects (71,72), such as nausea and vomiting (presumably from activation of the chemoreceptor trigger zone), sedation, and hallucinations and other psychiatric disturbances that are particularly troublesome for elderly patients. Thus, the dopamine agonists usually are given in combination with a reduced dose of levodopa/carbidopa, but monotherapy may be used for younger patients better able to tolerate side effects (3).

Bromocriptine

Bromocriptine (Fig. 25.8) is an ergot peptide derivative that is a partial agonist at D_1-type and a full agonist at D_2-type postsynaptic dopamine receptors

(73), usually given in combination with levodopa therapy. It was the first direct dopamine receptor agonist used in treatment of Parkinson's disease after its development as an inhibitor of prolactin release (via activation of anterior pituitary D_2 receptors). At low doses (typically 1–5 mg/day), bromocriptine is an effective prolactin inhibitor, and at higher doses (typically 10–20 mg/day), the antiparkinsonism and mood-elevating effects of bromocriptine become apparent. Bromocriptine is absorbed after oral administration, but approximately 90% of a dose undergoes extensive first-pass hepatic metabolism, with the remainder hydrolyzed in the liver to inactive metabolites that are eliminated mostly in the bile. The half-life is relatively short (~3 hours).

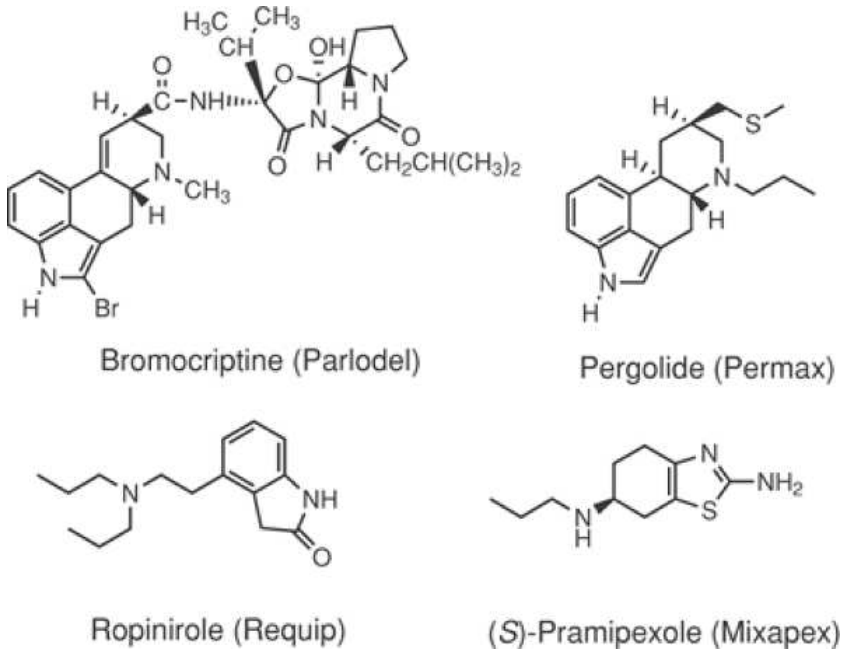


Fig. 25.8. Structures of the dopamine agonists bromocriptine, pergolide, ropinirole, and pramipexole.

Pergolide

Pergolide (Fig. 25.8) is a nonpeptide ergot derivative with higher potency and efficacy as a D_1 agonist and equivalent D_2 agonist activity when compared to bromocriptine (73). For Parkinson's disease, as well as for inhibition of lactation, pergolide is more potent than bromocriptine and may be effective in patients who have become tolerant to bromocriptine. After oral administration, pergolide undergoes hepatic metabolism to 10 metabolites, some of which are pharmacologically active. Elimination of the drug is primarily renal, with a half-life is approximately 27 hours.

Ropinirole and pramipexole

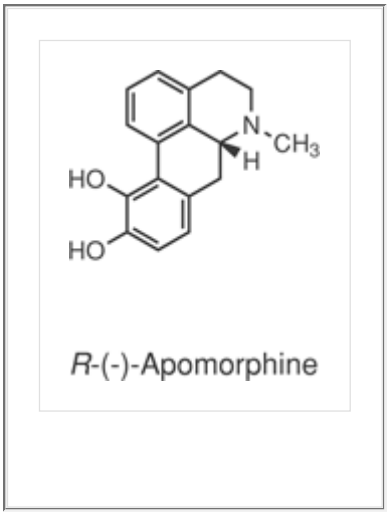
Ropinirole and pramipexole (Fig. 25.8) are nonergot compounds that are full agonists selective for dopamine D_2 and D_3 receptors, in contrast to ergot derivatives that also have activity at D_1-type and other nondopaminergic neurotransmitter receptors. Both ropinirole and pramipexole are indicated for treatment of early Parkinson's disease, either as monotherapy and as combination therapy with levodopa. A slower decline of dopaminergic neuronal function is noted for pramipexole monotherapy compared to initial treatment with levodopa (74). Ropinirole also is approved to treat restless leg syndrome, and although the mechanism is not clear, neuropharmacological studies suggest that dopaminergic neurotransmission is involved. Ropinrole is orally active and metabolized principally via CYP1A2 to form hydroxylated and N-dealkylated inactive products, with an elimination half-life of approximately 6 hours. Pramipexole is orally absorbed and primarily eliminated via the kidneys unchanged, with an elimination half-life of approximately 8–12 hours.

Structure–activity relationships of dopamine receptor agonists

As described in Chapter 22, molecular cloning technology has been used to identify five genes

that code for dopamine receptor proteins: two D_1-type receptors (D_1 and D_5), and three D_2-type receptors (D_2, D_3, and D_4). Whereas antipsychotic drug design (see Chapter 22) is directed toward discovery of molecules that act as antagonists at, especially, dopamine D_2-type receptors (albeit, an important role for the D_1 family has not been ruled out), the dopamine deficiency that characterizes Parkinson's disease naturally directs research toward discovery of ligands that act as agonists at dopamine receptors. Currently, however, no validated three-dimensional orientation of the amino acid residues at the ligand binding site has been reported for D_1-type or D_2-type receptors. Thus, development of selective agonists and antagonists for dopamine receptors still is guided by quantitative structure–activity relationships based on probe molecules.

The side chain of dopamine possesses unlimited flexibility and unrestricted rotation about the β-carbon–phenyl bond; thus, little information can be obtained concerning the conformational requirements for activation of dopamine receptors using the endogenous ligand. Accordingly, various compounds in which the catechol ring and the amino-ethyl moiety of dopamine are held in rigid conformation have been synthesized to probe the molecular determinants for binding and activation of dopamine receptors. One such compound is the aporphine alkaloid apomorphine (Fig. 25.9), which is obtained by the acid-catalyzed rearrangement of morphine. Apomorphine directly stimulates central dopamine receptors to produce effects similar to those of dopamine, including emetic and antiparkinson actions, which provide its pharmacotherapeutic usefulness.



R-(-)-Apomorphine

Although the pK_a of apomorphine is approximately nine (mostly protonated at physiologic pH), the molecule

apparently is lipophilic enough to pass across the blood-brain barrier, whereas dopamine (pK_a = 10.6) cannot. In the brain, (*R*)-(–)-apomorphine is a potent D_1 and D_2 agonist and produces an antiparkinsonian effect equivalent to that of levodopa. Interestingly, *S*-(+)-apomorphine is a postsynaptic D_2-type antagonist and a presynaptic D_2-type autoreceptor agonist that decreases dopamine synthesis (theoretically, such neurobiochemical activity would be desirable in an antipsychotic drug) (75). Unfortunately, apomorphine is difficult to administer because of first-pass enterohepatic metabolism and potent emetic effects. Apomorphine can be administered by subcutaneous injection and is approved to treat late-stage Parkinson's disease (76).

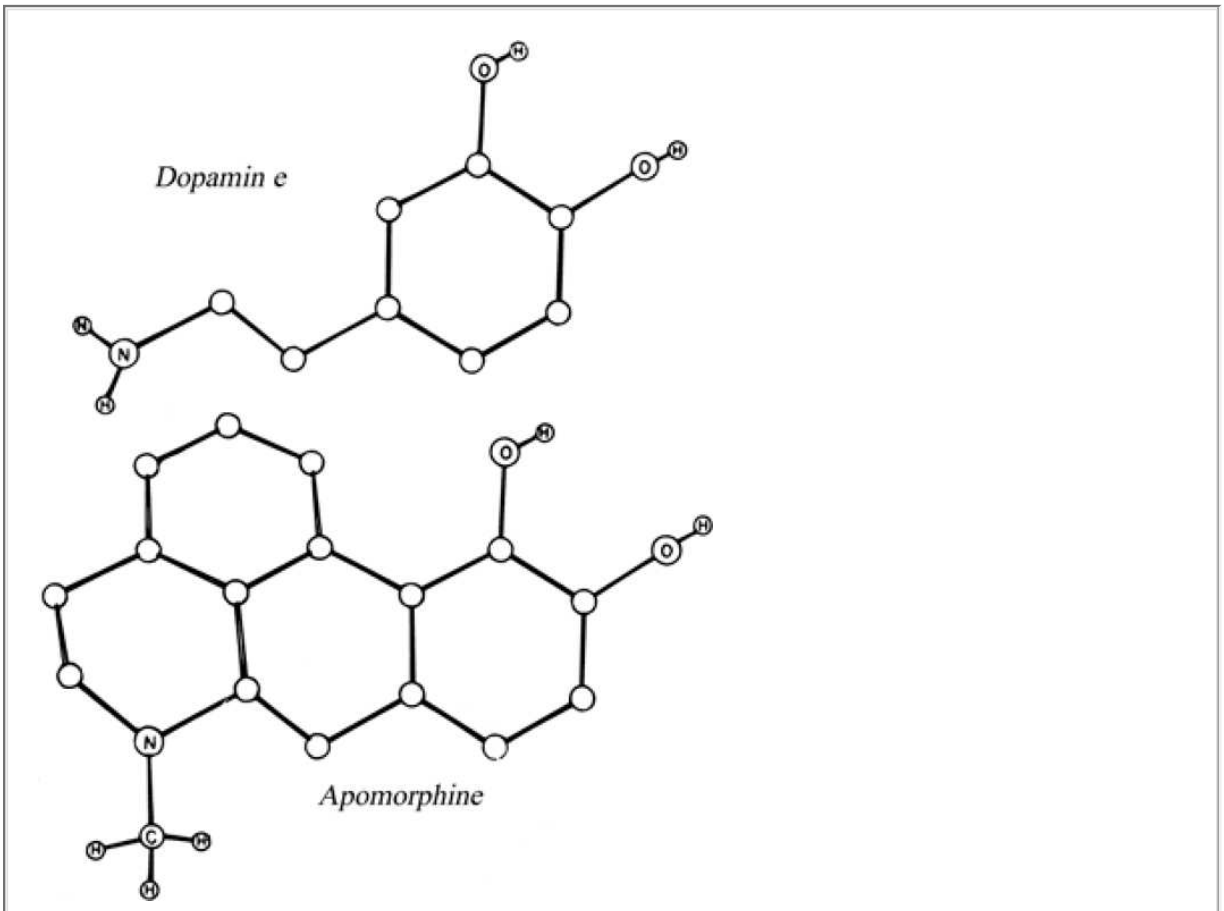


Fig. 25.9. Model of apomorphine molecule as determined by the x-ray crystal data of Giesecke (77) showing the structural relationship to dopamine in the *trans* α-rotameric conformation.

To help characterize the structure and function of dopamine receptors at the molecular level, the *x-ray crystal structure of apomorphine (77) was compared to a structural model of dopamine (*Fig. 25.9*). It is obvious that apomorphine contains molecular features in common with the structure of dopamine in the trans α-rotamer conformation (*Figs. 25.9 *and* 25.10*). Isoapomorphine, which embeds the structure of dopamine in the trans β-rotameric conformation (*Fig. 25.10*), is less active than apomorphine as a dopamine agonist. The 1,2-dihydroxyaporphine analogue, which mimics the cis α-rotamer conformation of dopamine, is inactive (*78*). In other studies, the semirigid aminotetralin 2-amino-6,7-dihydroxy-1,2,3,4-tetrahydronaphthalene (A-6,7-DTN), which has a trans β-rotamer conformation between the benzene ring and the amino side chain (*Fig. 25.10*), was found to be a more potent dopamine agonist than 2-amino-5,6-dihydroxy-1,2,3,4-tetrahydronaphthalene (A-5,6-DTN), which has a trans α-rotamer conformation (*Fig. 20.10*) (*79*). Thus, results of experiments using these rigid dopamine-mimetic compounds suggest that the preferred conformation of dopamine is the extended trans conformation (α- or β-rotamer). Results from other experimental and molecular modeling/computational chemistry studies indicate that ligand activity at D_1 vs. D_2 receptors is critically dependent on the position of a ligand protonated nitrogen moiety that can form a high-affinity ionic bond with an anionic aspartic acid residue in the third transmembrane α-helix of the receptor (*80*).*

Adjunct Therapy—Anticholinergic and Antihistamine Drugs

Cholinergic interneurons in the striatum exert mainly excitatory effects on GABAergic output from the striatum. Historically, it had been observed that drugs which increase cholinergic neurotransmission (e.g., the cholinesterase inhibitor physostigmine and the cholinergic agonist carbachol) aggravate parkinsonism in humans. Accordingly, before the discovery of levodopa, drug therapy for parkinsonism depended primarily on the limited efficacy of the natural belladonna alkaloids (e.g., atropine), which are cholinergic muscarinic receptor antagonists. With newer synthetic alkaloids (Table 25.1), attempts were made to increase central anticholinergic effects as well as to reduce undesirable peripheral effects, such as dry mouth, blurred vision, constipation, urinary retention, and tachycardia. Unfortunately, the CNS side effects of these agents also are very troublesome and include delusions, hallucinations, somnolence, ataxia, and dysarthria. In general, anticholinergic drugs rarely produce more than 20% improvement, and despite continued use, the symptoms of the disease continue to progress. The most important present usage of the anticholinergic agents is as adjunct therapy with L-dopa. The antihistamines, particularly those with central anticholinergic effects, generally are better tolerated in the elderly and may produce slightly greater relief from tremor, but this therapy is rarely used today.

Spasticity Disorders

Clinical Evaluation

Spasticity is characterized by skeletal muscle spasms and an increase in tonic stretch reflexes, sometimes with accompanying muscle weakness. Spasticity often is associated with cerebral palsy, multiple sclerosis, spinal cord injury, or stroke. The mechanisms that underlie clinical spasticity appear to involve damage to descending pathways in the spinal cord that results in hyperexcitability of α motor neurons. In addition to lack of accurate experimental models, a limiting factor in characterizing the pathophysiology of spasticity and effectiveness of antispasmodic drugs continues to be lack of quantitative methodology for assessment of the spasmodic condition

(87,88). Simple tests of muscle tone or reflex latency have not been fruitful; however, global clinical assessments, such as the number of painful spasms per day, have been more useful. Even the combined subjective impressions of improvement by the patient, family, and physician, however, may not establish that a particular drug is efficacious. Furthermore, spasm frequently coexists with pain and spasmolytic drug efficacy may be related to both skeletal muscle relaxation and analgesia. A straightforward strategy to establish whether a spasmolytic drug produces any benefit is gradual withdrawal of the drug (89). The diversity of neurological disorders that culminate in spasticity and the subjectivity of many of the measurements make it difficult to establish efficacy of any one of the spasmolytic drugs (90). In summary, clinical evidence for efficacy of oral antispasmodic agents is scarce and weak.

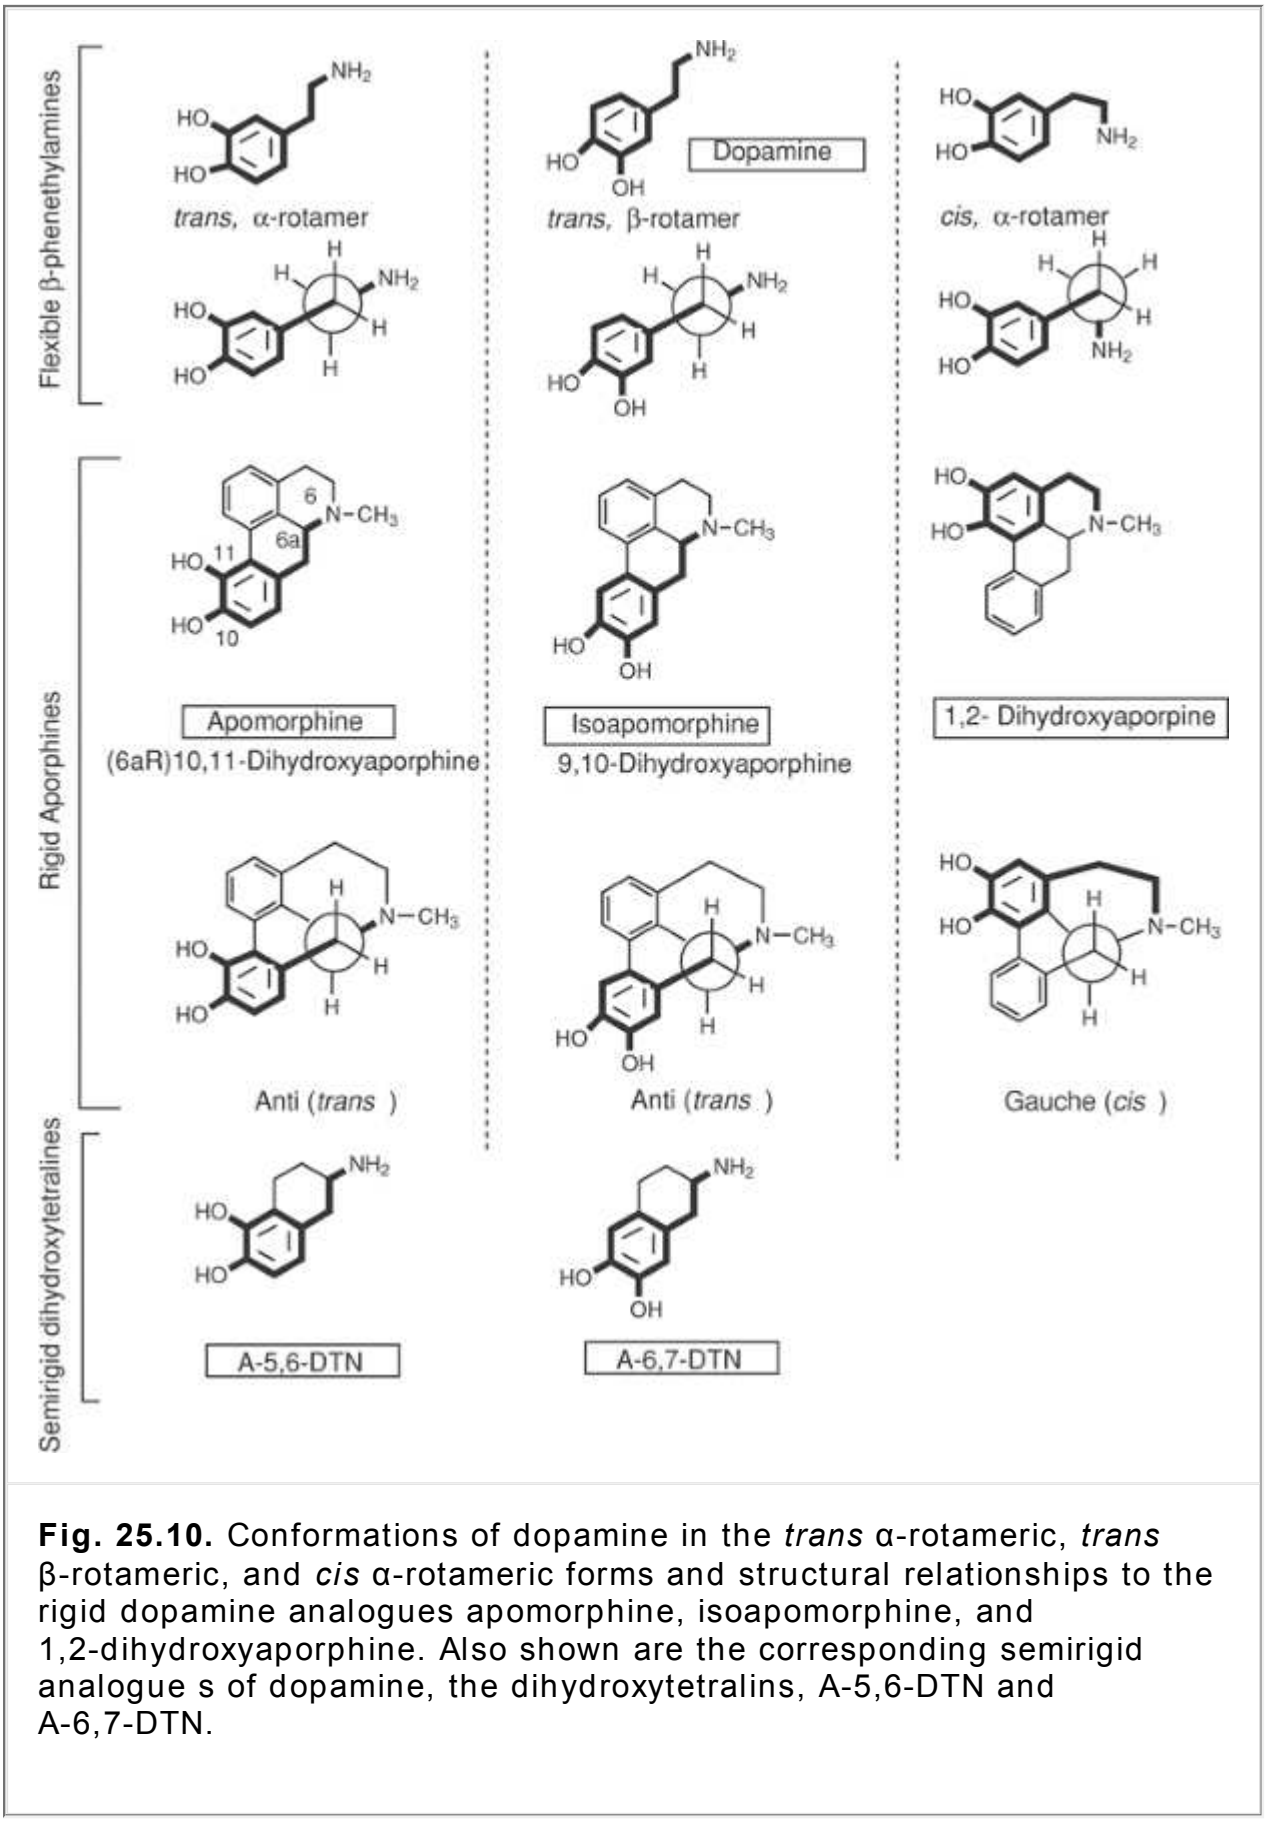

Fig. 25.10. Conformations of dopamine in the *trans* α-rotameric, *trans* β-rotameric, and *cis* α-rotameric forms and structural relationships to the rigid dopamine analogues apomorphine, isoapomorphine, and 1,2-dihydroxyaporphine. Also shown are the corresponding semirigid analogue s of dopamine, the dihydroxytetralins, A-5,6-DTN and A-6,7-DTN.

Spasmolytic Drugs

Skeletal Muscle Relaxants

Background

The drugs used for spasmolytic conditions are diverse in their chemical structures and their sites and mechanisms of action. The first drug recognized to exhibit spasmolytic activity was antodyne or 3-phenoxy-1,2-propanediol. In guinea pigs and rabbits,

antodyne produced prolonged paralysis without impairing consciousness. Antodyne was introduced into clinical medicine in 1910 as an analgesic and antipyretic. The duration of its skeletal muscle relaxant effect, however, was too short-lived to be clinically useful. In 1943, structure–activity relationship studies of a series of simple glyceryl ethers related to antodyne led to the development and introduction of mephenesin (Table 25.2) in 1946 (91). Pharmacological studies revealed that mephenesin selectivity depressed polysynaptic, while sparing monosynaptic, spinal cord reflexes. The relative safety and selective action of mephenesin on the spinal cord led to its use as the first widely prescribed centrally acting skeletal muscle relaxant. Accordingly, mephenesin is the prototype of the interneuronal blocking type of muscle relaxant, albeit mephenesin itself no longer is used. In general, the pharmacology of the mephenesin-like muscle relaxants is remarkably similar to that of sedative-hypnotics. Indeed, the only apparent difference is that the spasmolytics have greater selectivity for modulating effects mediated by the spinal cord, thus producing less sedation than general sedative-hypnotics. Both classes produce a reversible, nonspecific depression of the CNS, and sedation, dizziness, and muscle weakness are common side effects.

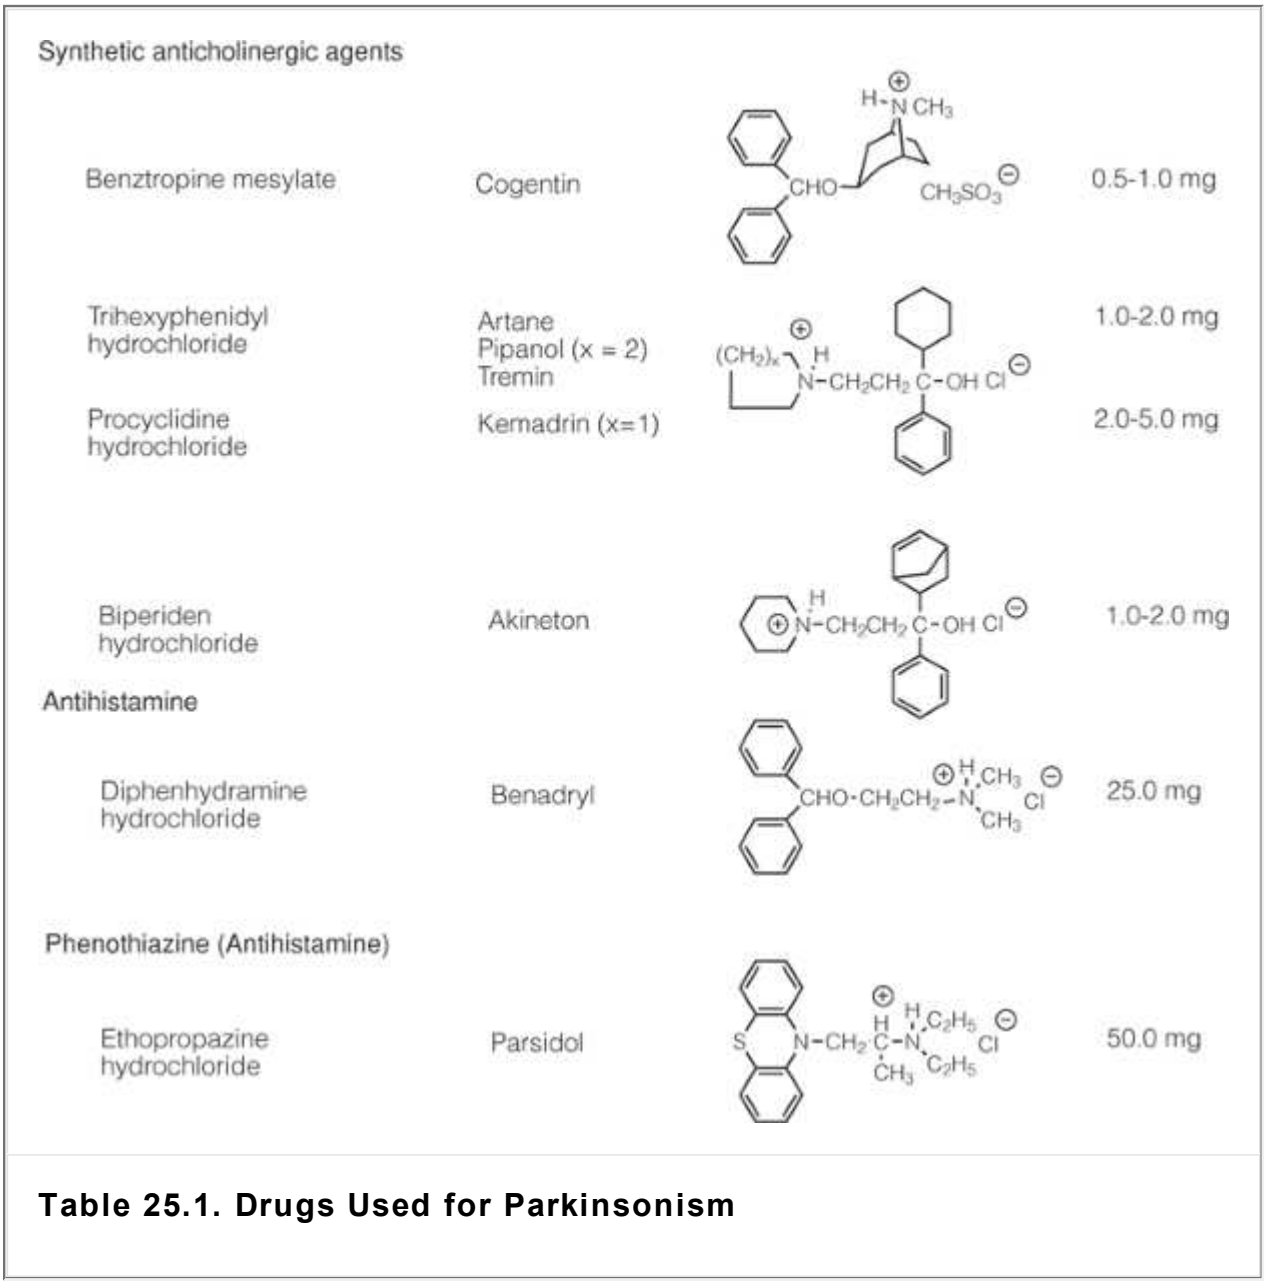

Table 25.1. Drugs Used for Parkinsonism

Table 25.2 shows several compounds with mephenesin-like pharmacological profiles that have been developed and marketed as antispasmodic muscle relaxants. Chlorphenesin carbamate and methocarbamol are carbamate analogues of mephenesin that are designed to be longer lasting. Their duration of action, however, has not been reported. The alcohol carbon of methocarbamol is chiral, and the *R*-(+)-enantiomer was found to have greater muscle relaxant activity in mice (92). The drug, however, is prescribed as the racemate. Meprobamate is the principal metabolite of carisoprodol; thus, the pharmacology of the two overlap. In clinical studies, carisoprodol has modest efficacy for treatment of low-back pain associated with sprain or strain. Carisoprodol and meprobamate have sedative and anxiolytic effects similar to benzodiazepines, such as diazepam, and carry a similar liability for abuse and dependency (88). Metaxalone, on the other hand, is not associated with abuse, and although no data from high-quality clinical trials are available, it generally is reported to achieve muscle

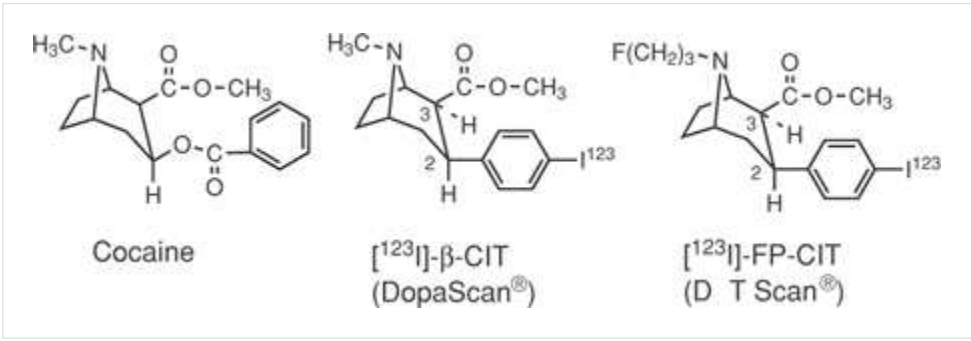
relaxation without excessive sedation. Chloroxazone is another agent marketed as a skeletal muscle relaxant, but with unclear efficacy in spasmodic conditions. A considerable drawback to empirical use of chloroxazone is that idiosyncratic hepatotoxicity and several sensitivity reactions

(urticaria, erythema, and pruritus) have been reported (88). Orphenadrine is an ethanolamine ether that is related both chemically and pharmacologically to diphenhydramine-type histamine H_1 antagonists. Although its efficacy is not clearly established, any muscle relaxant effects of orphenadrine may be caused by CNS anticholinergic activity, because this drug shows significant muscarinic receptor antagonism. Orphenadrine also is an NMDA receptor antagonist; however, it is unclear if this activity may lead to antispasmodic effects. The antimuscarinic activity of orphenadrine certainly leads to unpleasant peripheral side effects, such as dry mouth, blurred vision, and urinary retention. Cyclobenzaprine is another agent with prominent antimuscarinic activity that is used as a skeletal muscle relaxant, although its efficacy is modest. It is proposed that the muscle relaxant effects of cyclobenzaprine may result from antagonism of serotonin 5-HT_2 receptors in descending neurons of the spinal cord (93), but anticholinergic mechanisms cannot be ruled out. Although the presence of a double bond in the cycloheptyl ring of cyclobenzaprine is the only structural difference from the tricyclic antidepressant amitriptyline, cyclobenzaprine is not an efficacious antidepressant. Cyclobenzaprine has a long plasma half-life (1–3 days) and accumulation on multiple dosing contributes to its high incidence of sedation.

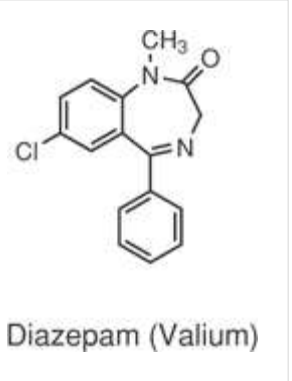
Clinical Applications: Radiopharmaceuticals in Diagnosis of Parkinson's Disease

Even for an experienced neurologist, a diagnosis of Parkinson's disease can be difficult to confirm, especially during the early stages of this disease. Disease progression is highly variable. The degree of disability can fluctuate dramatically, and no two people have exactly the same symptoms. In addition, a number of conditions mimic Parkinson's disease, but these conditions cannot be treated effectively with antiparkinsonism drugs.

Imaging techniques are increasingly applied to neuropharmacological studies of brain function. Positron-emission tomography (PET) and single-photon emission computed tomography (SPECT) are sensitive methods that can be used in such studies. Although spatial resolution remains somewhat greater with PET, several advantages are offered by SPECT technology. Positron-emitting nuclides have such short half-lives (^{11}C, 20 min; ^{18}F, 109 min) that they usually require an on-site cyclotron for their production, whereas SPECT nuclides have longer half-lives (^{123}I, 13 hr) so that they can be supplied commercially. Quantitative assessment of nigrostriatal presynaptic dopaminergic nerve terminal function also has been a useful diagnostic tool for the early diagnosis of Parkinson's disease (81). Previously, 6-[^{18}F]fluoro-L-dopa ([^{18}F]-DOPA) has been used in PET to assess dopamine nerve terminal function in human brain. Meanwhile, it has been known for some time that cocaine and its radiolabeled derivatives bind to the dopamine neurotransporter located on presynaptic dopaminergic nerve terminals. Researchers have investigated whether it might be possible to depict these dopamine neurotransporter proteins using radiolabeled analogues of cocaine (82). Although radiolabeled cocaine analogues have been shown to bind to the neurotransporter, rapid hydrolysis of its benzoyl ester function limits its use in SPECT imaging. By removal of the ester group and directly linking the phenyl ring to the heterocyclic ring system, more stable tropane molecules are obtained that can be radiolabeled for imaging purposes.



The first radiopharmaceutical to emerge from this research, [^{123}I]2-β-carbomethoxy-3β-(4-iodophenyl)tropane, is known as [^{123}I]β-CIT or RTI-55 (83,84). The radioactive iodine atom in the para position of the phenyl ring provides for the imaging properties of [^{123}I]β-CIT. A limiting factor with [^{123}I]β-CIT, however, is that it must be administered 8 hours before imaging to achieve peak uptake to dopamine nerve terminal regions. In an effort to improve the pharmacokinetic profile of [^{123}I]β-CIT, Neumeyer et al. (85) developed the N-3-fluoropropyl analogue of β-CIT, known as [^{123}I]FP-CIT. This dopamine nerve terminal imaging agent rapidly reaches its target sites (dopamine reuptake proteins) so that patients can be imaged 1 to 2 hours after injection of [^{123}I]FP-CIT. Moreover, researchers developed a radioligand suitable for PET imaging by replacement of the fluorine atom with [^{18}F] and replacement of the [^{123}I] atom with iodine in [^{123}I]FP-CIT (86). In Europe, [^{123}I]FP-CIT is approved for clinical use, and both [^{123}I]β-CIT and [^{123}I]FP-CIT are used as research tools to assess dopamine nerve terminal function in neurodegenerative and neuropsychiatric disorders.



Diazepam

The second group of antispastic drugs to be developed were the benzodiazepines, typified by diazepam. Diazepam exerts its skeletal muscle relaxant effect by binding as an agonist at the benzodiazepine

receptor of the $GABA_A$ receptor complex, which enhances GABA potency to increase chloride conductance (see Chapter 22). The muscle relaxant properties of classical benzodiazepines, such as diazepam, appear to be mediated mainly by the $GABA_A$ α_2 and α_3 subunits (94,95). The result is neuronal hyperpolarization, probably at both supraspinal and spinal sites for spasmolytic activity. Its actions are sufficient to relieve spasticity in patients with lesions affecting the spinal cord and in some patients with cerebral palsy (96). Few high-quality clinical trials have evaluated diazepam as a muscle relaxant, but these few suggest that diazepam is no more efficacious than, for example, carisoprodol, cyclobenzaprine, or tizanidine (i.e., efficacy is marginal) (87,88). Moreover, diazepam produces drowsiness and fatigue in most patients at doses required to significantly reduce muscle tone.

Glycerol monoethers and derivatives			
Mephenesin			1-2 g (oral)
Chlorphenesin carbamate	Maolate (R_1 = H, R_2 = Cl)		800 mg (oral)
Methocarbamol	Robaxin (R_1 = OCH_3, R_2 = H)		1-2 g (oral) 500 mg IM 1-3 g daily (IV)
Subtituted alkanediols and derivatives			
Meprobamate	Equanil Miltown (R = H)		400 mg
Carisoprodol	Rela Soma (R = $CH(CH_3)_2$)		250-350 mg
Metaxalone	Skelaxin		800 mg
Benzazole			
Chlorzoxazone	Paraflex		250-750 mg
Miscellaneous			
Orphenadrine citrate	Norflex		100 mg (oral) 0 mg IM or IV
Cyclobenzaprine	Iexari l		10 mg

Table 25.2. Skeletal Muscle Relaxants

Baclofen

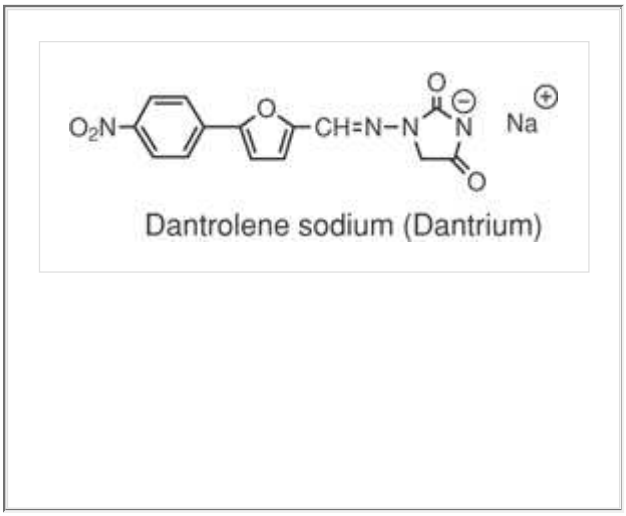
Baclofen (β-*p*-chlorophenyl-GABA) is a $GABA_B$ receptor agonist and is one of the most commonly used antispastic agents.

P.694

The (*R*)-(–)-enantiomer is the active isomer at $GABA_B$ receptors, but the racemate (Lioresal) is approved for use as a spasmolytic agent. The molecular mechanisms of $GABA_B$ receptors in muscle spasticity are not understood any better than other putative receptor-based mechanisms discussed above. It is proposed that baclofen inhibits spinal cord monosynaptic and polysynaptic reflexes via $GABA_B$ receptor-mediated opening of neuronal potassium channels that leads to hyperpolarization of primary afferent fiber terminals. Baclofen also may reduce the release of excitatory neurotransmitters and substance P in the brain and/or spinal cord via $GABA_B$-mediated neuronal hyperpolarization (90,96). Adverse effects of oral baclofen include sedation, excessive weakness, vertigo, and psychological disturbances. It is used for the treatment of spasticity in paraplegia and quadriplegia, patients with multiple sclerosis, and traumatic lesion to the spinal cord (96). Baclofen is completely absorbed after oral administration, undergoes minimal hepatic metabolism, and is excreted mainly as the parent compound in urine and feces, with a half-life of approximately 3 to 4 hours. Intrathecal administration via an implanted infusion pump is used to control severe spasticity and pain that is not responsive to medication given by oral or other parenteral routes.

Dantrolene

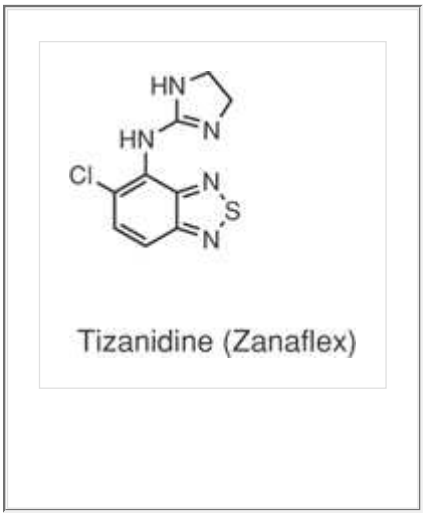
Dantrolene is a hydantoin derivative that acts peripherally to reduce spasticity and is indicated for use in spinal cord injury, stroke, cerebral palsy, and multiple sclerosis (97).



The site of action of dantrolene is believed to be at the sarcoplasmic reticulum in skeletal muscle cells. Dantrolene binds to a calcium channel protein (ryanodine receptor) on the sarcoplasmic reticulum to close the channel and inhibit the release of calcium; the alkaloid ryanodine activates the same receptor to open the channel. Dantrolene is believed to act directly on the contractile mechanism of skeletal muscle to decrease the force of contraction in the absence of any demonstrated effects on neural pathways, on the neuromuscular junction, or on the excitable properties of the muscle fiber membranes (97). Cardiac muscle and smooth muscle are minimally affected by dantrolene, likely because calcium release from sarcoplasmic reticulum of these muscle cell types occurs via a mechanism that differs from skeletal muscle. The muscle relaxant effect of dantrolene on skeletal muscle, however, is not specific, and generalized muscle weakness occurs as a major adverse side effect. Like other hydantoins, dantrolene is a weak base (pK_a = 7.5) that can cross the blood-brain barrier; thus, CNS depressant side effects (e.g., sedation) are common. Dantrolene sodium salt is slowly absorbed from the gastrointestinal tract. The mean half-life of the drug in adults is approximately 9 hours after a 100-mg dose. It is slowly metabolized by the liver to give the 5-hydroxy and acetamido (nitro reduction and acetylation) metabolites, as well as unchanged drug, excreted in the urine. Interestingly, dantrolene also is valuable in alleviating the signs of malignant hyperthermia. This rare, genetically determined condition, which can be triggered by a variety of stimuli, including inhalation anesthetics and neuromuscular blocking drugs, involves an impaired ability of the sarcoplasmic reticulum to sequester calcium. For treating malignant hyperthermia, dantrolene is administered intravenously.

Tizanidine

Tizanidine is a centrally acting adrenergic α_2 receptor agonist used to treat chronic muscle spasticity conditions, such as multiple sclerosis.



Tizanidine (Zanaflex)

Postulated mechanisms include α_2 receptor-mediated decreased release of norepinephrine and serotonin from spinal interneurons (98). Tizanidine is structurally related to the α_2 agonist clonidine that is used to treat hypertension; however, the blood pressure–lowering potency of tizanidine is approximately 10 to 20% that of clonidine. Nevertheless, patients may experience hypotension with tizanidine, together with muscle weakness, that may result in dizziness and falls in mobile patients. Tizanidine is rapidly and almost completely absorbed from the gastrointestinal tract; however, the estimated bioavailability is only 10 to 15% because of extensive first-pass metabolism, mainly by CYP1A2 (99), which results in oxidative degradation of the imidazoline ring and hydroxylation of the aromatic system (100). Elevated liver enzyme values are not frequent with tizanidine use. Hepatic injury and death because of liver failure have been reported, however, and this complication should be considered in view of its marginal antispasmodic efficacy (87,88). Other frequently reported side effects of tizanidine are drowsiness and dry mouth. Clonidine also has been used to treat spasticity; however, even less high-quality clinical study data are available for this agent.

Acknowledgements

The author wishes to express his gratitude to Drs. John L. Neumeyer and Ross J. Baldessarini for guidance in preparing this chapter.

Case Study

Victoria F. Roche

S. William Zito

ST is a 68-year-old female who traded in her stressful job as an academic administrator at a major academic health center for the relaxed life of Northern California. Heading to “wine country” with her cats, retirement funds, and a few family heirlooms, she purposefully sought a new life, making new friends and doing the things she loves most. She's been very politically and culturally active in her community, and she thoroughly enjoys her job as the social events planner at a small, family-owned winery that is just now beginning to gain regional notoriety. Attendance at her nightly “wine and cheese” gatherings has increased dramatically over the past year, giving ST a chance to network with clients and to showcase the high quality of her employer's “vino.”

Life seemed perfect until a diagnosis of Parkinson's disease was established three months ago. ST's symptoms are characteristic of this dopamine deficiency disorder and include rigidity, difficulty speaking, and slowed movements. She is still able to function at

work but is obviously worried about what the future holds. She began levodopa therapy immediately (400 mg b.i.d.) but is struggling to cope with drug-induced nausea and vomiting severe enough to limit her usually passionate involvement with a local Parkinson's research advocacy group. In addition, although previously normotensive, she has experienced an increase in blood pressure that is now being treated with a thiazide diuretic.

You meet up with ST at a wine-tasting event at the vineyard, and in a private moment, she asks for your professional advice and counsel. Consider the structure of the compounds drawn below, and decide which might benefit this patient.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity relationship analysis of all structures provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient

Chapter 26

Cardiac Agents: Cardiac Glycosides, Antianginal, and Antiarrhythmic Drugs

Ahmed S. Mehanna

Those drugs with BP (British Pharmacopeia) designation are available only in Canada and countries other than the United States.

Heart diseases are grouped into three major disorders: cardiac failure or contractile dysfunction, ischemic heart disease (with angina as its primary symptom), and cardiac arrhythmia.

Drugs for the Treatment of Heart Failure

Congestive Heart Failure

Cardiac failure can be described as inability of the heart to pump blood effectively at a rate that meets the needs of metabolizing tissues. This is the direct result of a reduced contractility of the cardiac muscles, especially those of the ventricles, which causes a decrease in cardiac output, increasing the blood volume of the heart (hence the term “congested”). As a result, the systemic blood pressure and the renal blood flow are both reduced, which often lead to the development of edema in the lower extremities and the lung (pulmonary edema) as well as renal failure. A group of drugs known as the cardiac glycosides were found to reverse most of these symptoms and complications.

Drugs for the Treatment of Congestive Heart Failure

Cardiac glycosides: positive ionotropic drugs

The cardiac glycosides are an important class of naturally occurring drugs, the actions of which include both beneficial and toxic effects on the heart. Their desirable cardiotonic action is of particular benefit in the treatment of congestive heart failure (CHF) and associated edema, and their preparations have been used as medicinal agents as well as poisons since 1500 BC. This dual application serves to highlight the toxic potential for this class of life-saving drugs. Despite the extended use and obvious therapeutic benefits of the cardiac glycosides, it was not until the famous monograph by William Withering in 1785, “An Account of the Foxglove and Some of its Medical Uses,” that cardiac glycoside therapy started to become more standardized and rational (1,2,3). The therapeutic use of purified cardiac glycoside preparations has occurred only over the last century. Today, the cardiac glycosides represent one of the most important drug classes available to the physician for the treatment of treat CHF.

Clinical Significance

Cardiovascular disease is by far the leading cause of death in industrialized nations. Although improved treatments have lowered this death rate, an additional result is a growing number of patients who are surviving with diseased hearts and who require intensive drug therapy regimens.

The cardiac glycosides and, most recently, digoxin have been used for centuries, but only within the last decade has their role been clarified by modern clinical trials. Still, many questions remain, including the precise mechanism(s) of action beyond the positive inotropic effect, the ideal dose and serum concentration, and the best methods to avoid toxicity and drug interactions. In particular, understanding how the structure of digoxin affects its pharmacokinetics allows the clinician to anticipate problems when it is used with potentially interacting drugs or in patients with organ dysfunction.

In many clinical situations, antiarrhythmic drugs have given way to implantable defibrillators for potentially life-threatening arrhythmias, but they are still commonly used both as adjunct therapy and in other arrhythmias, such as atrial fibrillation. The sheer number of antiarrhythmic agents with diverse mechanisms of action and the possibility of serious or even lethal adverse effects makes understanding how the structure of these drugs contributes to their efficacy and toxicity a high priority for pharmacists.

Chemistry of the cardiac glycosides

Cardiac glycosides and other similar glycosides are composed of two portions: the sugar moiety, and the nonsugar (the aglycone) moiety.

Aglycones

The aglycone portion of the cardiac glycosides is a steroid nucleus with a unique set of fused rings, which makes these agents easily distinguished from the other steroids. Rings A-B and C-D are *cis* fused, whereas rings B-C have a *trans* configuration. Such ring fusion gives the aglycone nucleus of cardiac glycosides the characteristic "U-shape," as shown in Figure 26.1. The steroid nucleus also carries, in most cases, two angular methyl groups at C-10 and C-13. Hydroxyl groups are located at C-3, the site of the sugar attachment, and at C-14. The C-14 hydroxyl is normally unsubstituted; however, additional hydroxyl groups may be found at C-12 and C-16, the presence or absence of which distinguishes the important genins: digitoxigenin, digoxigenin, and gitoxigenin (Fig. 26.2). These additional hydroxyl groups have significant impact on the partitioning and pharmacokinetics for each glycoside, as discussed later. The lactone ring at C-17 is another major structural feature of the cardiac aglycones. The size and degree of unsaturation of the lactone ring varies with the source of the glycoside. In most cases, the cardiac glycosides of plant origin, the cardenolides, possess a 5-membered, α,β-unsaturated lactone ring, whereas those derived from animal origin, the bufadienolides, possess a 6-membered lactone ring with two conjugated double bonds (generally referred to as α-pyrone) (Fig. 26.1).

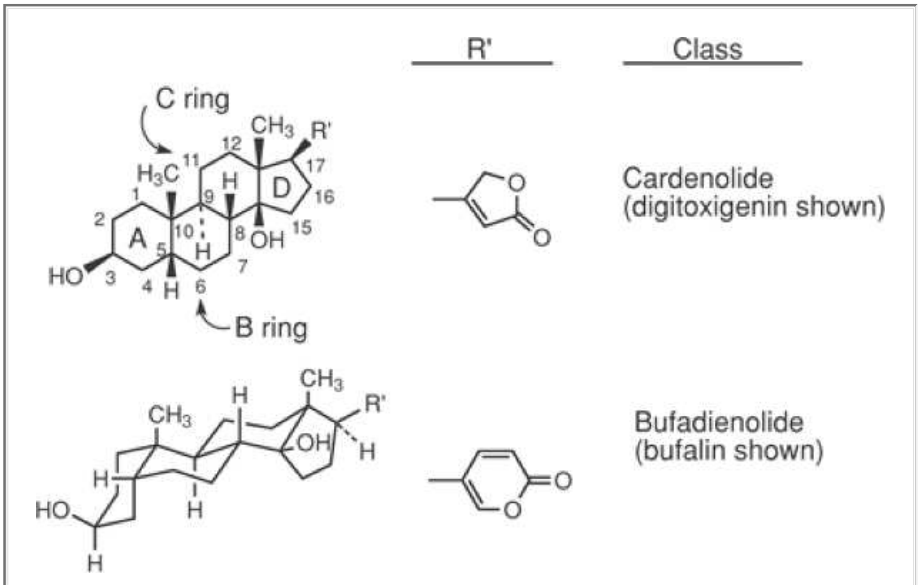

Fig. 26.1. Cardenolide and bufadienolide aglycones.

Sugars

The hydroxyl group at C-3 of the aglycone portion usually is conjugated to a monosaccharide or a

polysaccharide with β-1,4-glucosidic linkages. The number and identity of sugars vary from one glycoside to another, as

detailed subsequently. The most commonly found sugars in the cardiac glycosides are D-glucose, D-digitoxose, L-rhamnose, and D-cymarose (Fig. 26.3). These sugars predominately exist in the cardiac glycosides in the β-conformation. In some cases, the sugars exist in the acetylated form. The presence of an O-acetyl group on a sugar greatly affects the lipophilic character and pharmacokinetics of the entire glycoside, as discussed subsequently.

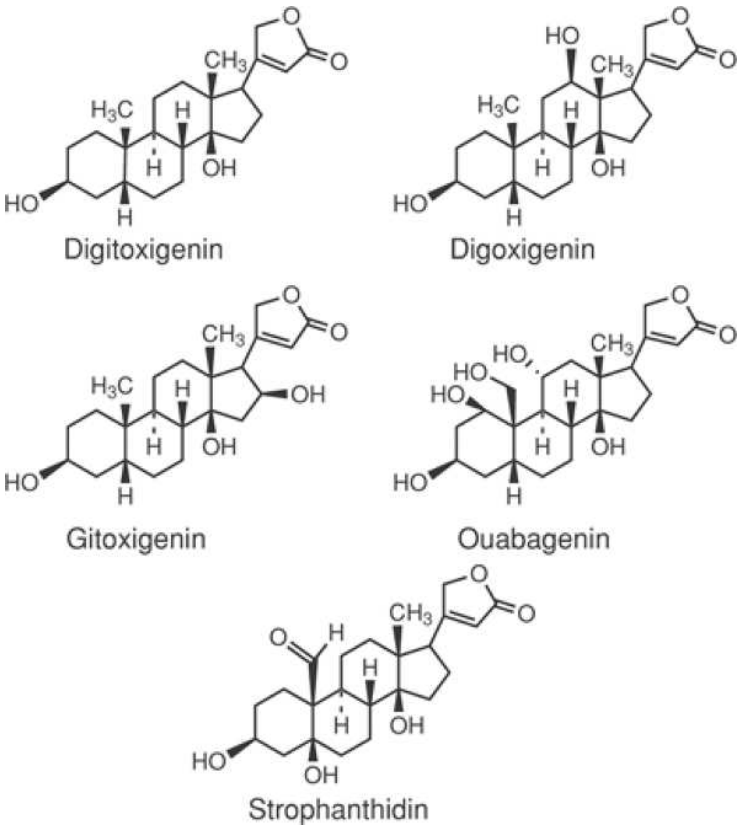

Fig. 26.2. Major cardenolide aglycones.

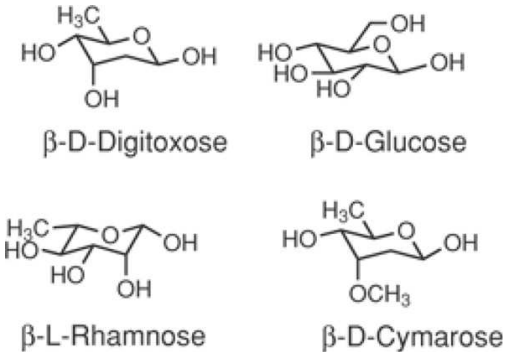

Fig. 26.3. Selected sugars found in naturally occurring cardiac glycosides.

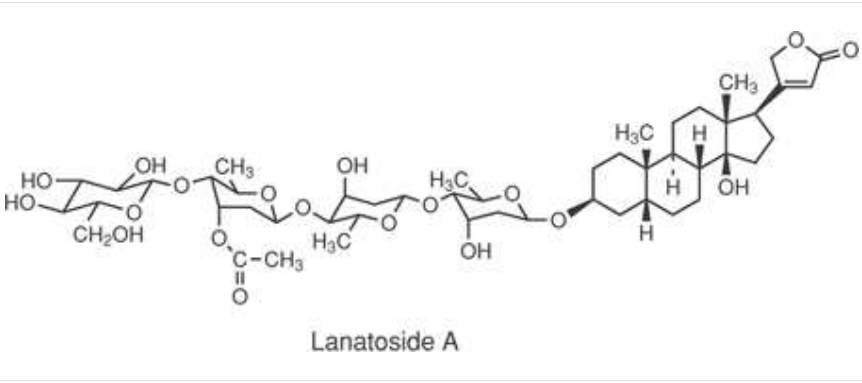
Sources and common names of cardiac glycosides

The cardiac glycosides occur mainly in plants and, in rare cases, in animals, such as poisonous toads. *Digitalis purpurea* or the foxglove plant, *Digitalis lanata, Strophanthus gratus*, and *Strophanthus kombe* are the major plant sources of the cardiac glycosides. Based on the nature and number of sugar molecules and the number of hydroxyl groups on the aglycone moiety, each combination of sugars and aglycones assumes different generic names. The site of the glycosides concentration in the plant, the types of glycosides, and the names of the structural components of these glycosides are summarized in Table 26.1.

Digitalis lanata

Lanatoside A is composed of the aglycone digitoxigenin (genin indicates no sugar) connected to three digitoxose sugar molecules, the third of which carries a 3-acetyl group, and a terminal glucose molecule. In other words, the structure sequence is glucose$_4$-3-acetyldigitoxose$_3$-digitoxose$_2$-digitoxose$_1$-digitoxigenin.



Lanatoside A

Lanatoside B has the identical sugar portion to lanatoside A, except that the aglycone has extra hydroxyl group at C-16 and is given the name gitoxigenin. The structural sequence is glucose$_4$-3-acetyldigitoxose$_3$-digitoxose$_2$-digitoxose$_1$-gitoxigenin.

Lanatoside C also has the same sugars found in both lanatosides A and B; however, the aglycone has the nucleus of lanatoside A plus an additional hydroxyl group at C-12. This cardenolide is named digoxigenin. The structural sequence is glucose$_4$-3-acetyldigitoxose$_3$-digitoxose$_2$-digitoxose$_1$-digoxigenin.

Partial hydrolysis of the glucose molecule and the acetate group from lanatoside A and C produces, respectively, two new and most important cardiac glycosides, digitoxin and digoxin, with the following sequences: digitoxin, (digitoxose)$_3$-digitoxigenin; and digoxin, (digitoxose)$_3$-digoxigenin.

Digitalis purpurea

Purpurea glycosides A and B have structures identical to those of lanatosides A and B, but with no acetyl group on the third digitoxose. Therefore, the purpurea glycosides A and B sometimes are called desacetyl digilanides A and B. Their sequences are as follows: purpurea glycoside A, glucose-(digitoxose)$_3$-digitoxigenin; and purpurea glycoside B, glucose-(digitoxose)$_3$-gitoxigenin. There is no purpurea glycoside C.

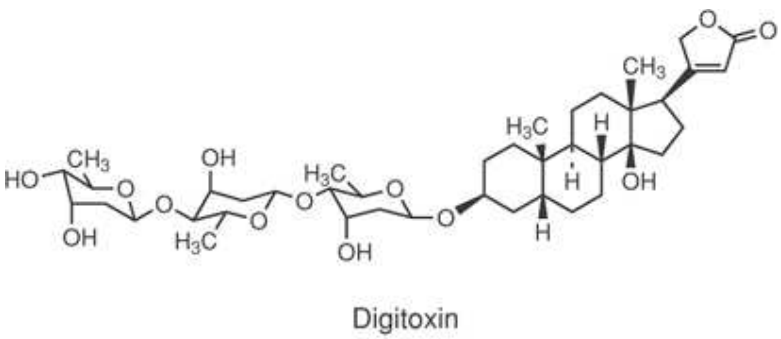
Table 26.1. Selected Natural Cardiac Glycosides and Their Sources

Source	Glycoside	Aglycone	Sugara
Digitalis lanata (leaf)	Lanatoside A (digilanide A)	Digitoxigenin Gitoxigenin	Glucose-3-acetyldigitoxose-

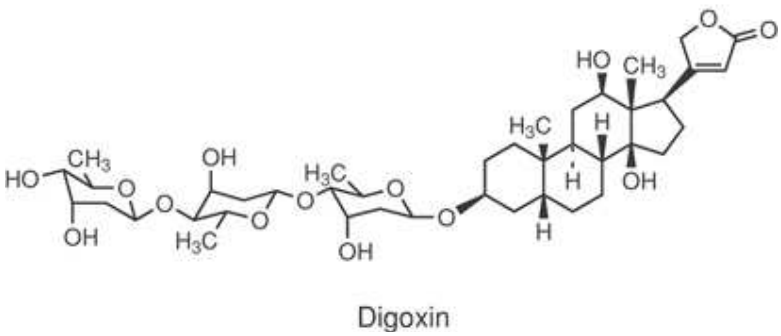
	Lanatoside B (digilanide B) Lanatoside C (digilanide C)	Digoxigenin	digitoxose-digitoxose
Digitalis purpurea (leaf)	Purpurea glycoside A (desacetyl digilanide A) Purpurea glycoside B (desacetyl digilanide B)	Digitoxigenin Gitoxigenin	Glucose-digitoxose-digitoxose-digitoxose
Strophanthus gratus (seed)	G-Strophanthin	Oubagenin	Rhamnose
Strophanthus kombe (seed)	k-Strophanthoside	Strophanthidin	Glucose-glucose-cymarose

[a]Conjugated with the C-3 hydroxyl of the aglycone via the sugar to the far right. All sugars are conjugated via β-1,4–glucosidic bond.

P.701



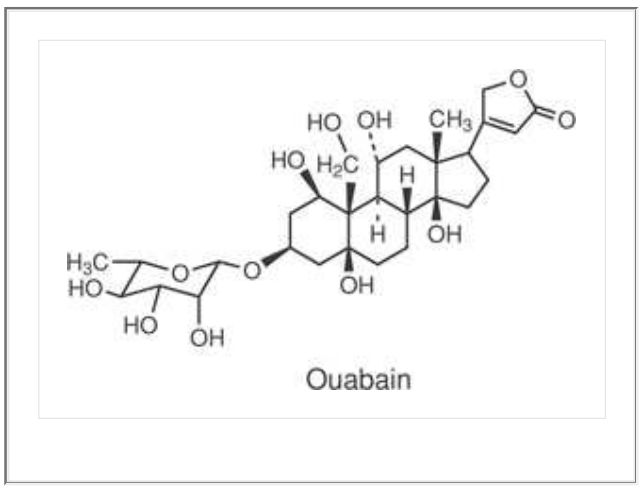
Digitoxin



Digoxin

Strophanthus gratus and Strophanthus kombe

The glycosides extracted from the plants *Strophanthus gratus* and *Strophanthus kombe* are called g-strophanthin (or ouabain) and k-strophanthoside, respectively. The corresponding aglycone for ouabain is ouabagenin, and that for k-strophanthoside is strophanthidin. Ouabagenin has a polyhydroxylated steroidal nucleus, and strophanthidin has an additional hydroxyl group at C-5 with an angular aldehyde group at C-10, replacing the traditional methyl group at that position (Fig. 26.2). Ouabagenin is conjugated only to a single molecule of L-rhamnose, whereas strophanthidin is conjugated to a molecule of cymarose, which is further linked to two molecules of glucose.



The medicinally used preparations are mainly obtained from *Digitalis purpurea* and *Digitalis lanata* plants. These glycosides generally are referred to as digitalis glycosides, cardiac glycosides, or simply, cardenolides. *Strophanthus* glycosides (e.g., ouabain) are no longer used therapeutically but were previously administered only intravenously because of poor oral absorption. Cardiac glycosides from animal sources (generally referred to as bufadienolides) are rare and of far less medicinal importance because of their high toxicity. Pharmaceutical preparations of whole plants and partially hydrolyzed glycosides of *Digitalis lanata* and *Digitalis purpurea* have been widely used clinically. Advancements in isolation and purification techniques, however, have made it possible to obtain highly purified digoxin preparations.

Pharmacology

Cardiac glycosides affect the heart in a dual fashion, both directly (on the cardiac muscle and the specialized conduction system of sinoatrial [SA] node, atrioventricular [AV] node, and His-Purkinje system) and indirectly (on the cardiovascular system mediated by the autonomic nervous reflexes). The combined direct and indirect effects of the cardiac glycosides lead to changes in the electrophysiological properties of the heart, including alteration of the contractility; heart rate; excitability; conductivity; refractory period; and automaticity of the atrium, ventricle, Purkinje fibers, AV node, and SA node. The heart response to the cardiac glycosides is a dose-dependent process and varies considerably between the normal hear and the heart with CHF. The effects observed after the administration of low doses (therapeutic doses) differ considerably from those observed at high doses (cardiotoxic doses). The pharmacological effects discussed consequently relate mainly to therapeutic doses administered to patients with CHF. The effects of cardiac glycosides on the properties of the heart muscle and different sites of the conduction system are summarized in Table 26.2. The increased force and rate of myocardial contraction (positive inotropic effect) and the prolongation of the refractory period of the AV node are the effects most relevant to the CHF problem. Both of these effects result from the direct action of the cardiac glycosides on the heart. The indirect effects are manifested as increased vagal nerve activity, which probably results from the glycoside-induced sensitization of the baroreceptors of the carotid sinus to changes in the arterial pressure; in other words, any given increase in the arterial blood pressure results in an increase in the vagal activity (parasympathetic) coupled with a greater decrease in the sympathetic activity. The vagal effect with uncompensated sympathetic response results in decreased heart rate and decreased peripheral vascular resistance (afterload). Therefore, cardiac glycosides reverse most of the symptoms associated with CHF as a result of increased sympathetic system activity, including increased heart rate, vascular resistance, and afterload. The administration of cardiac

glycosides to a patient with CHF increases cardiac muscle contraction, reduces heart rate, and decreases both edema and the heart size.

Table 26.2. Effects of Cardiac Glycosides on the Heart

	Atrium	Purkinje Ventricle	AV Fiber	SA Node	Node
Contractility	↑	↑	—	—	—
Excitability	0	Variable	↑	—	—
Conductivity	↑	↑	↓	↓	—
Refractory period	↓	↓	↑	↑	—
Automaticity	—	—	↑	—	↓

AV, atrioventricular; SA, sinoatrial; ↑ increased action; ↓ decreased action; 0, no action; —, no data available.

P.702

Biochemical mechanism of action

The mechanism whereby cardiac glycosides cause a positive inotropic effect and electrophysiological changes is still not completely known despite years of active investigation. Several mechanisms have been proposed, but the most widely accepted mechanism involves the ability of cardiac glycosides to inhibit the membrane-bound Na^+/K^+–adenosine triphosphatase (Na^+/K^+-ATPase) pump responsible for sodium/potassium exchange. To understand better the correlation between the pump and the mechanism of action of cardiac glycosides on the heart muscle contraction, one has to consider the sequence of events associated with cardiac action potential that ultimately leads to muscular contraction. The process of membrane depolarization/repolarization is controlled mainly by the movement of the three ions, Na^+, K^+, Ca^{2+}, in and out of the cell.

At the resting state (no contraction), the concentration of sodium is high outside the cell. On membrane depolarization, Na^+ fluxes in, leading to an immediate elevation of the action potential. Elevated intracellular sodium triggers the influx of Ca^{2+}, which occurs slowly and is represented by the plateau region of the cardiac action potential. The influx of calcium results in efflux of potassium out of the myocardium. The Na^1/K^+ exchange occurs at a later stage of the action potential to restore the membrane potential to its normal level (for further detail, see the discussion of antiarrhythmic agents and their classification at the end of this chapter). The Na^1/K^+ exchange requires energy and is catalyzed by the enzyme Na^+/K^+-ATPase. Cardiac glycosides are proposed to inhibit this enzyme, with a net result of reduced sodium exchange with potassium (i.e., increased intracellular sodium), which in turn results in increased intracellular calcium. Elevated intracellular calcium concentration triggers a series of intracellular biochemical events that ultimately result in an increase in the force of the myocardial contraction, or a positive inotropic effect. (The events that lead to muscle contraction are covered in further detail in the discussion of the mechanism of action of the calcium channel blockers later in this chapter.)

This mechanism of the cardiac glycosides via inhibiting the Na^+/K^+-ATPase pump is in agreement with the fact that the action of the cardiac glycosides is enhanced by low extracellular potassium and inhibited by high extracellular potassium. The cardiac glycosides–induced changes in the

electrophysiology of the heart also can be explained based on the inhibition of Na^+/K^+-ATPase. It has been suggested that the intracellular loss of potassium because of inhibition of the pump causes a decrease in the cellular transmembrane potential approaching zero. This decrease in the membrane potential is sufficient to explain the increased excitability and other electrophysiological effects observed following cardiac glycosides administration.

Structural requirements for intrinsic activity

Many hypotheses have been put forth to explain the cardiac glycoside structure–activity relationships (SARs). Some of the difficulty in arriving at a universally acceptable SAR model has been attributed to the early method of testing cardiac glycoside preparations and the lack of a well-characterized cardiac glycoside "receptors." Until the early 1970s, nearly all the cardiac glycosides were evaluated based on their cardiac toxicity rather than on the more therapeutically relevant criteria. This was partly because of the belief that the cardiac toxicity was, in fact, an extension of the desired cardiotonic action. Thus, comparisons of cardiac glycoside preparations were based on the amount of drug required to cause cardiac arrest in test animals, usually anesthetized cats. More recently, most SAR studies have relied, at least initially, on results obtained with isolated cardiac tissue or whole-heart preparations. In these models, inotropic activity, contractility, and so forth can be directly assessed. In addition, the recognition of cardiac Na^+/K^+-ATPase as the probable receptor for the cardiac glycosides has made the inhibition of this enzyme system an important criterion for the cardiac glycosides activity.

Much of the interest in the effects of structural modification on cardiotonic activity results from the desire to develop agents with less toxic potential. Early studies based primarily on cardiac toxicity testing data suggested the importance of the steroid "backbone" shape, the 14-β-hydroxyl and the 17-unsaturated lactone for activity. More recent studies have been directed toward characterizing the interaction of the cardiac glycosides with Na^+/K^+-ATPase, the putative cardiac glycoside receptor. Using this enzyme model with enzyme inhibition as the biological end point, a number of hypotheses for cardiac glycoside receptor–binding interactions have been put forth. Many of these suggested that the 17-lactone plays an important role in receptor binding. Using synthetic analogues, it was found that unsaturation in the lactone ring was important, with the saturated lactone analogue showing diminished activity (4,5). Further investigations of synthetic compounds in which the lactone was replaced with open-chain structures of varying electronic and steric resemblance to the lactone showed that, in fact, the α,β-unsaturated lactone ring at C-17 was not an absolute requirement and that several α,β-unsaturated open-chain groups could be replaced with little or no loss in activity (4,5). For example, analogs possessing an α,β-unsaturated nitrile at the 17-β position had high activity. In light of this, most current theories point toward a key interaction of the carbonyl oxygen (or nitrile nitrogen) with the cardiac glycoside binding site on Na^+/K^+-ATPase (6,7). Some controversy, however, exists regarding this point. The importance of the "rest" of the cardiac glycoside molecule must not be ignored. Despite the apparently dominant role of the 17-lactone, it is the steroid (A-B-C-D) ring system that provides the lead structure for cardiac glycoside activity. Lactones alone, when not attached to the steroid ring system, show no Na^1/K^+-ATPase inhibitory activity. Some important steroid structural features have become apparent.

The C-D *cis* ring juncture appears to be critical for activity in compounds possessing the unsaturated butyrolactone in the normal 17-β position. This apparent requirement may be a reflection of changes in the spatial orientation of the 17-substituent (7). Moreover, the 14-β-OH is now believed to be dispensable, and the contribution to activity previously attributed to this group is thought to be related to the need to retain the sp^3 and *cis* character of the C-D ring juncture. The earlier interpretation arose from the fact that 14-deoxy analogues often had unsaturation in the D ring in place of the 14-β-OH. This double bond markedly influenced the position of the C-17 substituent, thereby complicating interpretation of 14-β-OH group importance. Finally, the A-B *cis* ring juncture also appears not to be mandatory for cardiac glycosides activity. This feature, however, is characteristic of all clinically useful cardiac glycosides, and conversion to an A-B trans ring system generally leads to a marked drop in activity unless compensating modifications are made elsewhere in the molecule.

Pharmaceutical preparations

The cardiac glycoside preparations that have been used range from powdered digitalis leaf to

purified individual glycosides, including gitalin, lanatoside C, its partially hydrolyzed product deslanatoside C (desacetyl lanatoside C), digoxin, and ouabain (Table 26.3). Currently, digoxin is the only cardiac glycoside commercially available for therapeutic use in the United States. To arrive at an effective plasma concentration, a large initial dose (i.e., digitalizing or loading dose) often is given. The purpose of this large initial dose is to achieve a therapeutic blood and tissue level in the shortest possible time. Depending on the condition of the patient and the desired therapeutic goal, the loading dose may be much less than, or almost equal to, the dose that is likely to cause toxicity. Once the desired effect is obtained, the amount of drug lost from the body per day is replaced with a maintenance dose.

Absorption, metabolism, and excretion

The therapeutic effects of all cardiac glycosides on the heart are qualitatively similar; however, the glycosides largely differ in their pharmacokinetic properties. The latter are greatly influenced by the lipophilic character of each glycoside. In general, cardiac glycosides with more lipophilic character are absorbed faster and exhibit longer duration of action as a result of a slower urinary excretion rate. The lipophilicity of a cardiac glycoside is measured by its partitioning between chloroform and water mixed with methanol: The higher the concentration of the cardiac glycoside in the chloroform phase, the higher its partition coefficient, and the more lipophilic it is. The partition coefficients for five cardiac glycosides are listed in Table 26.4. It is evident from a comparison of the coefficients that their lipophilicity is markedly influenced by the number of sugar molecules and the number of hydroxyl groups on the aglycone part of a given glycoside. Lanatoside C, with a partition coefficient of 16.2, is far less lipophilic than that of acetyldigoxin (partition coefficient, 98), which structurally differs only in lacking the terminal glucose molecule. Likewise, a comparison of digitoxin and digoxin structures reveals that they only differ by an extra hydroxyl in digoxin at C-12. This seemingly minor difference in their partition coefficients from 96.5 to 81.5 for digitoxin and digoxin, respectively, results in significant differences in their pharmacokinetic behavior (Table 26.5). Table 26.4 also illustrates that the

presence of the 3-O-acetyl group on acetyldigoxin enhances its lipophilic character more than that of desacetyl analogue, digoxin (partition coefficients of 98 and 81.5, respectively). The glycoside G-strophanthin (ouabain) possesses a very low lipophilic character because of the presence of five free hydroxyl groups on the steroid nucleus of the aglycone ouabagenin.

Table 26.3. Cardiac Glycosides and Their Dosage Forms

Name[a]	Dosage Forms
Digoxin USP and BP	Tablets, elixir, pediatric
Digitalis powder (Leaf) BP	Tablets, capsules
Digitoxin BP	Tablets, injection
Lanatoside C BP	Tablets
Ouabain BP	Injection (G-Strophanthin)
Deslanatoside C BP	Injection (desacetyllanatoside C)

[a] Those cardiac glycosides with *only* the BP (British Pharmacopeia) designation are available only in Canada and other countries except the United States.

Table 26.4. Effect of Glycoside Structure on Partition Coefficient

Glycoside	Partition Coefficient ($CHCl_3$/16% aq.MeOH)
Lanatoside C (glucose-3-acetyldigitoxose–digitoxose$_2$–digoxigenin)	16.2
Digoxin (digitoxose$_3$-digoxigenin)	81.5
Digitoxin (digitoxose$_3$-digitoxigenin)	96.5
Acetyldigoxin (3-acetyldigitoxose-digitoxose$_2$-digoxigenin)	98.0
G-Strophanthin (rhamnose-ouabagenin)	very low

Table 26.5. Comparison of the Pharmacokinetic Properties for Digoxin and Digitoxin

	Digoxin	Digitoxin
Gastrointestinal absorption	70–85%	95–100%
Average half life	1–2 days	5–7 days
Protein binding	25–30%	90–95%
Enterohepatic cycling	5%	25%
Excretion	Kidneys; largely unchanged	Liver metabolism
Therapeutic plasma level	0.5–2.5 ng/ml	20–35 ng/ml
Digitalizing	Oral: 0.75–1.5	Oral: 0.8–1.2
dose (mg)	IV: 0.5–1.0	IV: 0.8–1.2
Maintenance dose (oral mg)	0.125–0.5	0.05–0.2

Digoxin is the most frequently used cardiac glycoside. The absorption of digoxin from the

gastrointestinal tract is a passive process that depends on its lipid solubility, dissolution, and membrane permeability of the drug. The oral bioavailability of digoxin following oral administration exhibits interindividual variability, ranging from 70 to 85% of an administered dose. This interindividual variability has been attributed to intestinal P-gp efflux and P-gp–dependent renal elimination. Although digoxin is not extensively metabolized, it is transported from intestinal enterocytes along its epithelium into the intestinal lumen (effluxed) by P-glycoprotein (P-gp), which is also expressed in the kidney and liver. Alterations in P-gp transport may be the basis for several digoxin–drug interactions. For this reason, it is important to establish carefully the effective dose of digoxin for each patient to avoid digitalis toxicity.

Once the cardiac glycosides are absorbed, they bind to plasma proteins; digoxin has only 30% binding. The half-life of digoxin in patients with normal renal function is 1.5 to 2.0 days. Biliary excretion of digoxin is minimal. Digoxin is eliminated primarily unchanged by renal tubule excretion.

Contributing to the discontinuance of digitoxin as a therapeutic agent was a half-life range between 5 and 7 days because of its enterohepatic circulation. Approximately 25% of an absorbed dose of digitoxin is excreted in the bile unchanged, to be reabsorbed via enterohepatic circulation. Digitoxin, however, is extensively metabolized by the liver to a variety of metabolites, including $(digitoxose)_2$-digitoxigenin, $(digitoxose)_1$-digitoxigenin, and $(digitoxose)_1$-digitoxigenin. Trace amounts of digoxin have been discovered in the urine. The pharmacokinetic data for digoxin and digitoxin is summarized in Table 26.5.

Drug interactions

Digoxin–drug interactions are common causes of digitalis toxicity. Recently, the clinical significance of the P-gp–dependent renal tubular secretion of digoxin associated with the well-documented digoxin–quinidine interaction has been reported (8). The discovery that digoxin is actively secreted into the urine by the renal tubular cell via the P-gp efflux pump has led to the conclusion that the digoxin–quinidine interaction can be attributed to inhibition of renal tubular secretion of digoxin by quinidine (a P-gp substrate). Quinidine competitively binds to P-gp in the renal tubule reducing the renal secretion of digoxin by as much as 60%, raising digoxin's plasma concentration to toxic levels. Other drugs that are substrates for renal P-gp also are likely to be associated with digoxin–drug interactions. Another documented digoxin–drug interaction associated with increased digoxin blood levels and toxicity is with verapamil. Unlike quinidine, verapamil inhibits intestinal P-gp efflux of digoxin, thereby blocking the intestinal secretion of digoxin into the lumen of the intestine and raising digoxin blood levels to toxic levels. On the other hand, the rifampin–digoxin interaction involves the rifampin induction of intestinal P-gp expression, thereby increasing the P-gp–mediated secretion of digoxin. This results in the lowering of digoxin blood levels to subtherapeutic concentrations. The P-gp transporters and their substrates, inhibitors, or inducers (see Table 10.16 for list) appear to play an important role in controlling the digoxin area under the curve (AUC) values through the renal tubular and intestinal secretion of digoxin and, subsequently, to digoxin–drug interactions and digitalis toxicity. Concurrent use of the cardiac glycosides with antiarrhythmics, sympathomimetics, β-adrenergic blockers, and calcium channel blockers that are substrates for P-gp may alter control of arrhythmias.

The absorption of digoxin after oral administration also can be significantly altered by other drugs concurrently present in the gastrointestinal tract. For example, laxatives may interfere with the absorption of digoxin because of increased intestinal motility. The presence of the drug cholestyramine, an agent used to treat hyperlipoproteinemia, decreases the absorption of digoxin by binding to and retaining digoxin in the gastrointestinal tract. Antacids, especially magnesium trisilicate, and antidiarrheal adsorbent suspensions also may inhibit the absorption of the digoxin. Potassium-depleting diuretics, such as thiazides, may increase the possibility of digitalis toxicity because of the additive hypokalemia. Several other drugs that are known to bind to plasma proteins, such as thyroid hormones, have the potential to displace digoxin from its plasma-binding sites, thereby increasing its free drug concentration to a toxic level.

Therapeutic uses

Although the primary clinical use for digoxin is in the treatment of CHF, this agent also is used in cases of atrial flutter or fibrillation and paroxysmal atrial tachycardia.

Toxicity

All cardiac glycosides preparations have the potential to cause toxicity. Because the minimal toxic dose of the glycosides is only two- to threefold the therapeutic dose, intoxication is quite common. In mild to moderate toxicity, the common symptoms are anorexia, nausea and vomiting, muscular weakness, bradycardia, and ventricular premature contractions. The nausea is a result of excitation of the chemoreceptor trigger zone in the medulla. In severe toxicity, the common symptoms are blurred vision, disorientation, diarrhea, ventricular tachycardia, and AV block, which may progress into ventricular fibrillation. It generally is accepted that the toxicity of the cardiac glycosides results from inhibition of the Na^+/K^+-ATPase pump, which results in increased intracellular levels of Ca^{2+}. Hypokalemia (decreased potassium), which can be induced by coadministration of

thiazide diuretics, of glucocorticoids, or by other means, can be an important factor in initiating a toxic response. It has been shown that low levels of extracellular K^+ partially inhibit the Na^+/K^+-ATPase pump. In a patient stabilized on a cardiac glycoside, the Na^+/K^+-ATPase pump already is partially inhibited, and the hypokalemia only further inhibits the pump, causing an intracellular buildup of sodium, which leads to an increase in intracellular calcium levels. The high levels of calcium are responsible for the observed cardiac arrhythmias characteristic of the cardiac glycosides toxicity.

A common procedure used in treating cardiac glycoside toxicity is to administer potassium salts to increase extracellular potassium level, which stimulates the Na^+/K^+-ATPase pump, resulting in decreased intracellular sodium levels and, thus, decreased intracellular calcium. In treating any cardiac glycoside–induced toxicity, it is important to discontinue administration of the drug in addition to administering a potassium salt. Other drugs that may be useful in treating the tachyarrhythmias present during toxicity are lidocaine, phenytoin, and propranolol. Specific antibodies directed toward digoxin (Dig-Bind) have been used experimentally and proven to be very effective.

Nonglycosidic Positive Inotropic Agents

Nonglycosidic positive inotropic drugs can be divided into two main classes: those that act via stimulating the synthesis of cyclic adenosine monophosphate (cAMP), such as adrenergic and dopaminergic agonists; and those that inhibit the hydrolysis of cAMP, such as phosphodiesterase 3 (PDE3) inhibitors.

Phosphodiesterase 3 Inhibitors

The mechanism of cardiac contraction involves a G-protein signal transduction pathway, which regulates intracellular calcium concentrations. Activation of the G_s-protein involves the formation of intracellular cAMP, which thereby increases intracellular calcium, stimulating cardiac muscle contraction (see Chapter 4). Relaxation occurs when the released cAMP is hydrolyzed by cytosolic cAMP-dependent PDE3, one of the phosphodiesterase isofoms. Therefore, inhibition of PDE3 increases intracellular cAMP, promoting cardiac muscle contraction but vasodilation of vascular smooth muscle. (See Chapter 17 for more information about phosphodiesterases.)

The overall cardiostimulatory and vasodilatory actions of PDE3 inhibitors make them suitable for the treatment of heart failure, because vascular smooth muscle relaxation reduces ventricular wall stress and the oxygen demands placed on the failing heart. The cardiostimulatory effects of the PDE3 inhibitors increases inotropy, which further enhances stroke volume and ejection fraction. Clinical trials have shown that long-term therapy with PDE3 inhibitors increases mortality in heart failure patients. Therefore, these PDE3 inhibitors are not used for the long-term, chronic therapy of CHF. They are very useful, however, in treating acute, decompensated heart failure or temporary bouts of decompensated chronic failure. They are not used as a monotherapy. Instead, they are used in conjunction with other treatment modalities, such as diuretics, angiotensin-converting enzyme inhibitors, β-blockers, or cardiac glycosides. The PDE3 inhibitors contract cardiac muscle and are used for treating heart failure, whereas the phosphodiesterase 5 (PDE5) inhibitors are vasodilators and are used for treating male erectile dysfunction. Note that the generic names for PDE3 inhibitors end in “one,” and those for the PDE5 inhibitors end in “fil.”

Side effects and contraindications

The most common and severe side effect of PDE3 inhibitors is ventricular arrhythmias, some of which may be life-threatening. Other side effects included headaches and hypotension, which are not uncommon for drugs that increase cAMP in cardiac and vascular tissues, with other examples being β-agonists.

Milrinone (Primacor®) and imamrinone (Inocor®)

Although the digitalis glycosides may be the principal therapeutic agents for the treatment of CHF, they are not the only positive inotropic agents available. Among the "nonglycoside" inotropic agents are the bipyridines, inamrinone and milrinone, which are selective PDE3 inhibitors (Fig. 26.4). Inamrinone and milrinone are positive inotrope and vasodilators indicated for the short-term intravenous management of CHF in patients who have not responded adequately to digitalis, diuretics, and/or vasodilators (9,10). Milrinone is the drug of choice from among the currently available PDE3 inhibitors because of its greater selectivity for PDE3, shorter half-life (30–60 min), and fewer side effects. Imamrinone is associated with thrombocytopenia in 10% of patients. Inamrinone was introduced in 1978, and it produces both positive inotropic and concentration-dependent vasodilatory effects. Despite similar positive inotropic action to the cardiac glycosides, the inotropic action involves inhibition of PDE3, as previously described. Inamrinone was approved for the short-term intravenous administration in patients with severe heart failure refractory to other measures. Although inamrinone is orally active, several adverse side effects have dampened enthusiasm for long-term oral inamrinone therapy. These effects include gastrointestinal disturbances, thrombocytopenia, and impairment of the liver function. For intravenous infusion, inamrinone lactate and milrinone lactate injection solutions may be

diluted in sodium chloride injection. Inamrinone lactate for injection is preserved with sodium metabisulfite and needs protection from light. It should not be diluted with solutions containing dextrose because a chemical reaction occurs in 24 hours. For milrinone, an immediate chemical interaction with furosemide with the formation of a precipitate is observed when furosemide is injected into an infusion of milrinone. Patients sensitive to bisulfites may also be sensitive to inamrinone lactate injection, which contains sodium metabisulfite.

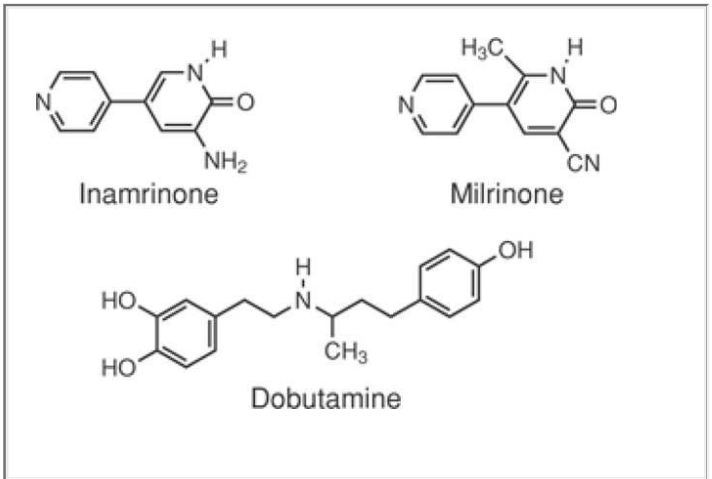


Fig. 26.4. Miscellaneous inotropic agents.

The pharmacokinetics for inamrinone shows a half-life in healthy volunteers of approximately 3 to 4 hours, whereas in patients with CHF, the plasma half-life increases approximately 50% (5–8 hours). For infants younger than 4 weeks, the half-life life is 12.7 to 22.2 hours, and infants older than 4 weeks, the half-life is 3.8 to 6.8 hours. Time to peak effect is less than 10 minutes, with its duration of action ranging from 30 minutes to 2 hours depending on the dosage. Approximately 63% of imamrinone is eliminated via the urine as unchanged drug, and 18% is eliminated in the feces. Elderly patients are more likely to have age-related impairment of renal function, which may require adjustment of dosage in patients receiving inamrinone.

The limited success of inamrinone led to the development of structurally related newer agents, such as milrinone, with a mechanism of action similar to inamrinone. Milrinone, however, is an order of magnitude more potent than inamrinone. Furthermore, preliminary reports show it to be better tolerated, with no apparent thrombocytopenia or gastrointestinal disturbances. Milrinone is excreted largely unchanged in the urine, and accordingly, patients with impaired renal function require reduced dosages.

The pharmacokinetics for milrinone following intravenous injections to patients with CHF showed an elimination half-life of 2 to 3 hours. Its primary route of excretion is via the urine as unchanged milrinone (83%) and its O-glucuronide metabolite (12%). In patients with renal function impairment, elimination of unchanged milrinone is reduced, suggesting that a dosage adjustment may be necessary.

β-Adrenergic Receptor Agonists

Another promising area for the development of new positive inotropic agents is that of β-adrenergic receptor agonists (11) (see Chapter 13). The myocardium has mostly β_1-adrenergic receptors, and stimulation of these receptors by a variety of β-adrenergic agonists produces a potent positive inotropic response involving the G-protein signal transduction process increasing intracellular cAMP levels that lead to a cascade of events that ultimately produce an increase in intracellular Ca^{2+}, thereby increasing myocardial contractility (discussed in Chapters 4 and 13). Although many drugs possess β-adrenergic agonist activity, most have side effects that make them inappropriate for the treatment of CHF. For example, the well-known catecholamines, norepinephrine and epinephrine, are potent nonselective adrenergic receptor agonists. Because the actions of these agents are not limited to the myocardial β_1-receptors, however, they produce undesirable positive chronotropic effects, exacerbate arrhythmias, and result in vasoconstriction. These effects limit their utility in the treatment of CHF.

Dobutamine (Dobutrex)

Among the most promising β_1 adrenergic agonists are those derived from dopamine, the endogenous precursor to norepinephrine. Dopamine itself is a potent stimulator of the β_1-receptors, but it results in many of the undesirable side effects described in Chapter 13. The new analogs of dopamine that have been developed retain the potent inotropic effect but possess fewer effects on heart rate, vascular tone, and arrhythmias. Dobutamine is a prime representative of this group of agents. Dobutamine is a potent β_1-adrenergic agonist on the myocardium (as well as α_1-agonist and -antagonist activities; see Chapter 13 for details concerning its mechanism of action) with beneficial effects, the composite of a variety of actions on the heart and the peripheral vasculature. Dobutamine is active only by the intravenous route because of its rapid first-pass metabolism via COMT (catechal-O-methyl transferase). Therefore, its use is limited to critical care situations. Nonetheless, its parenteral success has led to the search and development of orally active drugs. One of the major limitations associated with β_1-agonists is the phenomenon of myocardial β-receptor desensitization. This lowered responsiveness (desensitization) of the receptors appears to be due to a decrease in the number of β_1-receptors and partial uncoupling of the receptors from adenylate cyclase.

Drugs for The Treatment of Angina

Angina Pectoris

Angina pectoris is the chronic disease affecting the coronary arteries, which supply oxygenated blood from the left ventricle to all heart tissues, including the ventricles themselves. When the lumen of the coronary artery becomes restricted, it becomes less efficient in supplying blood and oxygen to the heart, and the heart is said to be “ischemic” (oxygen deficient). Angina is the primary symptom of ischemic heart disease and is characterized by a sudden, severe pain originating in the chest, often radiating to the left shoulder and down the left arm. Angina is further subclassified into typical or variant angina based on the precipitating factors and the electrophysiological changes observed during the attack. Typical angina usually is the result of an advanced state of atherosclerosis and is provoked by food, exercise, and emotional factors. It is characterized by low ST segment of the electrocardiogram. Variant or acute angina results from sudden spasm in the coronary artery unrelated to atherosclerotic narrowing of the coronary circulation and can occur at rest. It is

characterized by an increase in the ST segment of the electrocardiogram.

Antianginal Drugs

Therapy of angina is directed mainly toward alleviating and preventing anginal attacks by altering the oxygen

supply/oxygen demand ratio to the cardiac muscle or dilating the coronary vessels. Three classes of drugs are found to be very efficient in this regard, although via different mechanisms. These include organic nitrates, calcium channel blockers, and β-adrenergic blockers.

Organic Nitrates

Organic nitrates have dominated the treatment of acute angina over the last 100 years. Although the recent introduction of the calcium channel blockers and the β-blockers as antianginal agents has expanded the physician therapeutic arsenal, organic nitrates are still the class of choice in the treatment of acute anginal episodes.

Overview

Organic nitrates are esters of simple organic alcohols or polyols with nitric acid. This class was developed after the antianginal effect of amyl nitrite (ester of isoamyl alcohol with nitrous acid) was first observed in 1857. Five members of this class are in clinical use today: amyl nitrite (amyl nitrite inhalant USP), nitroglycerin, isosorbide dinitrate, erythrityl tetranitrate, and pentaerythritol tetranitrate (Fig. 26.5). Two additional organic nitrates, tenitramine and propatylnitrate, are currently available in Europe (Fig. 26.5). This class usually is referred to as organic nitrates, because all of these agents, except amyl nitrite, are nitrate esters. It should be noted that the generic names do not always precisely describe the chemical nature of the drug but, rather, are used for simplicity. For example, the drug nitroglycerin is not really a nitro compound, because a nitro compound means a nitro group attached to a carbon atom (i.e., NO_2-C); the correct chemical name of nitroglycerin is glyceryltrinitrate. Another example is amyl nitrite, the structure of which indicates that it is an ester of isoamyl alcohol with nitrous acid; the correct chemical name of this drug is isoamyl nitrite.

The chemical nature of these molecules as esters constitutes some problems in formulating these agents for clinical use. The small lipophilic ester character makes them volatile. Volatility is an important concern in drug formulation because of the potential loss of the active principle from the dosage form. In addition, moisture should be avoided during storage to minimize the hydrolysis of the ester bond, which can lead to a decrease in the therapeutic effectiveness. Lastly, because these agents are nitrate esters, they possess explosive properties, especially in the pure concentrated form. Dilution in a variety of vehicles and excipients eliminates this potential hazard. The lipophilic nature of these esters, however, makes these agents very efficient in emergency treatment of anginal episodes as a result of their rapid absorption through biomembranes.

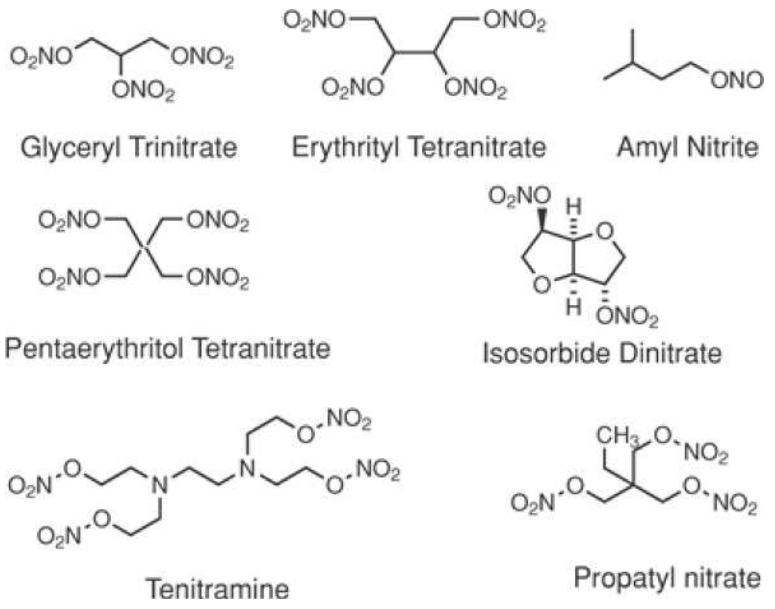

Fig. 26.5. Organic nitrates and nitrites.

Pharmacological actions

The oxygen requirements of the myocardial tissues are related to the workload (oxygen demand) of the heart, which is, in part, a function of the heart rate, the systolic pressure, and the peripheral resistance of the blood flow (oxygen supply). Myocardial ischemia occurs when the oxygen supply is insufficient to meet the myocardial oxygen demand. This can occur, as explained previously, because of atherosclerotic narrowing of the coronary circulation (typical) or vasospasm of the coronary artery (variant). The nitrates have been shown to be effective in treating angina resulting from either cause. The vasodilating effect of organic nitrates on the veins leads to pooling of the blood in the veins and decreased venous return to the heart (decreased preload), whereas vasodilation of the coronary arterioles decreases the resistance of the peripheral tissues (decreased afterload). The decrease in both preload and afterload results in a generalized decrease in the myocardial workload, which translates into a reduced oxygen demand by the myocardium. Organic nitrates restore the balance between oxygen supply by venous dilation and oxygen demand by decreasing the myocardial workload.

Biochemical mechanism of action

The organic nitrates (Fig. 26.5) are pharmacological sources of nitric oxide (NO) for the body. In the cardiovascular system, NO is naturally produced by vascular endothelial cells. This endothelial-derived NO has several important functions, including relaxation of vascular smooth muscle, inhibiting platelet aggregation (antithrombotic), and inhibiting leukocyte-endothelial interactions (anti-inflammatory). These actions involve NO-stimulated formation of cyclic guanosine monophosphate (cGMP) (see Chapter 29). Nitrodilators are drugs that mimic the actions of endogenous NO by releasing NO or forming NO within tissues. Free tissue sulfhydryl groups play a key role in the venodilation effect of nitroglycerin, which is supported by experimental evidence showing that prior administration of N-acetylcysteine, which should increase the availability of free sulfhydryl groups, resulted in an increase in the venodilating effect of organic nitrates. Similarly, pretreatment with reagents that react with free sulfhydryl groups, such as ethacrynic acid, blocked glyceryl trinitrate venodilation in vitro (13). A more complex mechanism for nitrate venodilation, however, was proposed

by Ignarro et al. (14). They suggested that the nitrates act indirectly, by stimulating the enzyme guanylate (also known as guanylyl) cyclase and, thereby, producing elevated levels of cGMP, which in turn leads to venodilation. The initial stimulation of soluble guanylate cyclase is believed to be

mediated by a nitrate-derived nitrosothiol metabolite produced intracellularly. In support of this mechanism is the observation that a variety of synthetic nitrosothiols were found to increase markedly soluble guanylate cyclase activity and to produce venodilation in vitro (15,16,17,18,19). Such a mechanism is consistent with the requirement for free sulfhydryl groups described previously. A unifying mechanism suggests that the organic nitrates through the formation of NO via a nitrosothiol-intermediate activate soluble guanylate cyclase, increasing intracellular cGMP concentrations, which in turn blocks the Ca^{2+}-catalyzed vascular contractions (Fig. 29-3) (20,21,22,23). Depletion of sulfhydryl groups during this metabolic process may be a major factor in the development of nitrate tolerance, along with compensatory physiologic mechanisms. Data also exist suggesting that organic nitrates increase intraplatelet cGMP concentrations, thereby inhibiting platelet aggregation. These pharmacological actions of organic nitrates appear to preferentially occur within portions of blood vessels containing damaged endothelium, thus making them extremely useful in the pharmacotherapy of acute ischemic events.

Pharmaceutical preparations and dosage forms

Organic nitrates are administered by inhalation; by infusion; as sublingual, chewable, and sustained-release tablets; as capsules; as transdermal disks; and as ointments.

Absorption, metabolism, and therapeutic effects

Organic nitrates are used for both treatment and prevention of painful anginal attacks. The therapeutic approaches to achieve these two goals, however, are distinctly different. For the treatment of acute anginal attacks (i.e., attacks that have already begun), a rapid-acting preparation is required. In contrast, preventative therapy requires a long-acting preparation with more emphasis on duration and less emphasis on onset. The onset of organic nitrate action is influenced not only by the specific agent chosen but also by the route of administration. Sublingual administration is used predominantly for a rapid onset of action. The duration of nitrate action is strongly influenced by rate of metabolism. All of the organic nitrates are subject to rapid first-pass metabolism not only by the action of glutathione-nitrate reductase in the liver, but also in extrahepatic tissues, such as the blood vessel walls themselves (24,25). In addition, rapid uptake into the vessel walls plays a significant role in the rapid disappearance of organic nitrates from the bloodstream. Sublingual, transdermal, and buccal administration routes have been used in an attempt to avoid at least some of the hepatic metabolism.

Acute angina most frequently is treated with sublingual glyceryl trinitrate. This sublingual preparation is rapidly absorbed from the sublingual, lingual, and buccal mucosa and usually provides relief within 2 minutes. The duration of action also is short (~30 minutes). Other treatments include amyl nitrite by inhalation and sublingual isosorbide dinitrate. Amyl nitrite is by far the fastest-acting preparation, with an onset of action in approximately 15 to 30 seconds, but the duration of action is only approximately 1 minute. Isosorbide dinitrate, although usually used as a long-acting agent, may be used to treat acute angina. Sublingually administered isosorbide dinitrate has a somewhat slower onset than glyceryl trinitrate (~3 minutes), but its action may last for 4 to 6 hours. Although the onset appears to be almost as rapid as that of glyceryl trinitrate, waiting an additional minute for relief may be deemed unacceptable by some patients.

To prevent recurring angina, long-acting organic nitrate preparations are used. Several agents fall into this category, such as orally administered isosorbide dinitrate, pentaerythritol tetranitrate, and erythrityl tetranitrate. In addition, a number of long-acting glyceryl trinitrate preparations are available. These include oral sustained-release forms, glyceryl trinitrate ointment, transdermal patches, and buccal tablets. Of these therapeutic options, isosorbide dinitrate and glyceryl trinitrate preparations are by far the most frequently used. At first, the whole concept of prophylactic nitrate use was met with skepticism by many physicians, both because early studies indicated that oral nitrates were almost completely broken down by first-pass metabolism (24,25) and because blood levels of the parent drug appeared to be virtually nil. These findings, in conjunction with several clinical studies showing equivocal efficacy, led Needleman et al. (25) to conclude, “There is no rational basis for the use of ‘long-acting' nitrates (administered orally) in the prophylactic therapy of angina pectoris.” More recent studies, however, suggest that oral prophylactic nitrates may be effective if appropriate doses are used (26). Moreover, some metabolites of long-acting nitrates are active as venodilators, albeit less potent than the parent drug. An example of this is isosorbide dinitrate, which is metabolized primarily in the liver by glutathione-nitrate reductase, which also

participates in the metabolism of other organic nitrates, catalyzing the denitration of the parent drug to yield two metabolites, 2- and 5-isosorbide mononitrate (27). Of these, the 5-isomer is still a potent vasodilator, and its plasma half-life of approximately 4.5 hours is much longer than that of isosorbide dinitrate itself. The extended half-life, because of the metabolite's resistance to further metabolism, indicates that it may be contributing to the prolonged duration of action associated with use of isosorbide dinitrate (27).

Adverse effects

Most patients tolerate the nitrates fairly well. Headache and postural hypotension are the most common side effects of organic nitrates. Dizziness, nausea, vomiting, rapid pulse, and restlessness are among the additional side effects reported. These symptoms may be controlled by administering low doses initially

and then gradually increasing the dose. Fortunately, tolerance to nitrate-induced headache develops after a few days of therapy. Because postural hypotension may occur in some individuals, advise the patient to sit down when taking a rapid-acting nitrate preparation for the first time. An effective dose of nitrate usually produces a fall in upright systolic pressure of 10 mm Hg and a reflex rise in heart rate of 10 beats per minute.

Another concern associated with prophylactic nitrate use is the development of tolerance (26,28). Tolerance, usually in the form of shortened duration of action, is commonly observed with chronic nitrate use. The clinical importance of this tolerance is, however, a matter of controversy. Because tolerance to nitrates has not been reported to lead to a total loss of activity, some physicians feel that it is not clinically relevant. In addition, an adjustment in dosage can compensate for the reduced response (26). It also has been reported that intermittent use of long-acting and sustained-release preparations may limit the extent of tolerance development.

Drug interactions

The most significant interactions of organic nitrates are with those agents that cause hypotension, such as other vasodilators, alcohol, and tricyclic antidepressants, in which the potential for orthostatic hypotension may arise. On the other hand, concurrent administration with sympathomimetic amines, such as ephedrine and norepinephrine, may lead to a decrease in the antianginal efficacy of the organic nitrates.

Nitric oxide donor

Molsidomine (Corvaton) is an oral NO donor known as a sydnone imine, a mesionic compound that is soluble in both water and organic solvents. Molsidomine is enzymatically metabolized by liver esterases to its active metabolite, linsodimine, which is spontaneously converted in the blood into its nitroso metabolite SIN-1A (Fig. 26.6). Molecular oxygen is required to release NO from SIN-1A. The beneficial effects of molsidomine in treatment of angina were recognized before the role of endogenous NO for causing vasodilation was identified. A possible explanation may revolve around activation of K^+ channels. Molsidomine has a slower onset and longer duration of action than conventional nitrates because of the relatively slow rate of conversion to linsodimine, which has a rapid onset and short duration of action. Nitric oxide acts as a cellular messenger, leading to activation of soluble guanylate cyclase to release cGMP (see Chapter 29) and vasodilation. Because the metabolites of molsidomine generate NO without the need for enzymes or cofactors, other than the presence of oxygen, tolerance to prolonged exposure does not occur. This mechanism differs from organic nitrates in which cysteine or thiol donors are required for conversion into NO. It is believed that cysteine depletion is the major factor in the development of nitrate tolerance.

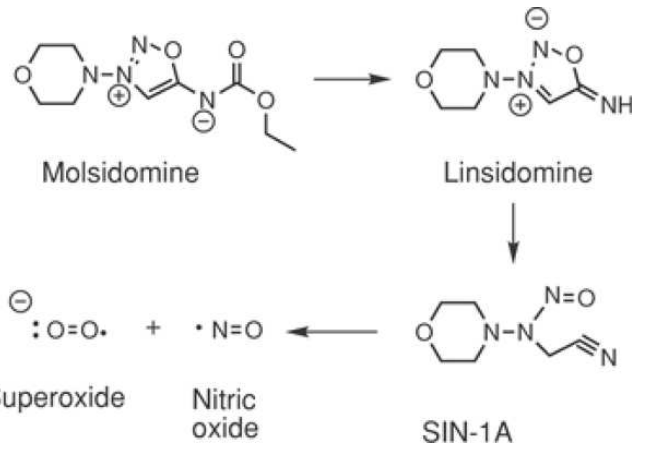

Fig. 26.6. Molsidomine metabolism to nitric oxide.

Molsidomine and lindosimine are therapeutic alternatives to traditional organic nitrates in treatment of stable angina, coronary vasospasm, and heart failure. Unlike organic nitrates, however, molsidomine and lindosimine have significant antiplatelet activity at therapeutic doses. The cogeneration of superoxide during the release of NO is a major concern limiting its therapeutic potential in the treatment of angina. Its short duration of action necessitates an increased dose frequency, which might be inconvenient in a clinical setting. The light sensitivity of molsidomine necessitates careful protection of infusion bags and tubing during administration.

Calcium Channel Blockers

The second major therapeutic approach to the treatment of angina is the use of calcium channel blockers (29.30) (see also the corresponding subsection in Chapter 28). In the 1906s, it was recognized that inhibition of calcium ion (Ca^{2+}) influx into myocardial cells may be advantageous in preventing angina. Currently, three classes of calcium channel blockers are approved for use in the prophylactic treatment of angina: the dihydropyridines nifedipine, nicardipine, and amlodipine; the benzothiazepine derivative diltiazem; as well as the aralkyl amine derivative verapamil and the diaminopropanol ether bepridil (Fig. 26.7). The last-mentioned are reserved for treatment failures in that serious arrhythmias may occur.

Chemistry

The structural dissimilarity of these agents is apparent and serves to emphasize the fact that each is distinctly different from the others in its profile of effects. Although nifedipine and similar drugs belong to the dihydropyridine family, diltiazem belongs to the benzo[*b*-1,5]thiazepine family. Verapamil is structurally characterized by a central basic nitrogen to which alkyl and aralkyl groups are attached. It is noteworthy that diltiazem and verapamil are both chiral, possessing asymmetric centers. In each case, the dextro-rotatory (i.e., the (+)-enantiomer) is approximately one order of magnitude more potent as a calcium channel blocker than the levo-rotatory (i.e., (–)-enantiomer).

Pharmacological Effects

Calcium ions are known to play a critical role in many physiologic functions. Physiologic calcium is found in a

variety of locations, both intracellular and extracellular. Because calcium plays such a ubiquitous role in normal physiology, the overall therapeutic effect of the calcium channel blockers often is the composite of numerous pharmacological actions in a variety of tissues. The most important of these tissues associated with angina are the myocardium and the arterial vascular bed. Because of the dependency of myocardial contraction on calcium, these drugs have a negative inotropic effect on the heart. Vascular smooth muscle also depends on calcium influx for contraction. Although the

underlying mechanism is somewhat different, inhibition of calcium channel influx into the vascular smooth muscles by the calcium channel blockers leads to arteriolar vasodilation. The venous beds appear to be less affected by the calcium channel blockers. The negative inotropic effect and arterial vasodilation result in decreased heart workload and afterload, respectively. The preload is not affected because of a lesser sensitivity of the venous bed to the calcium channel blockers.

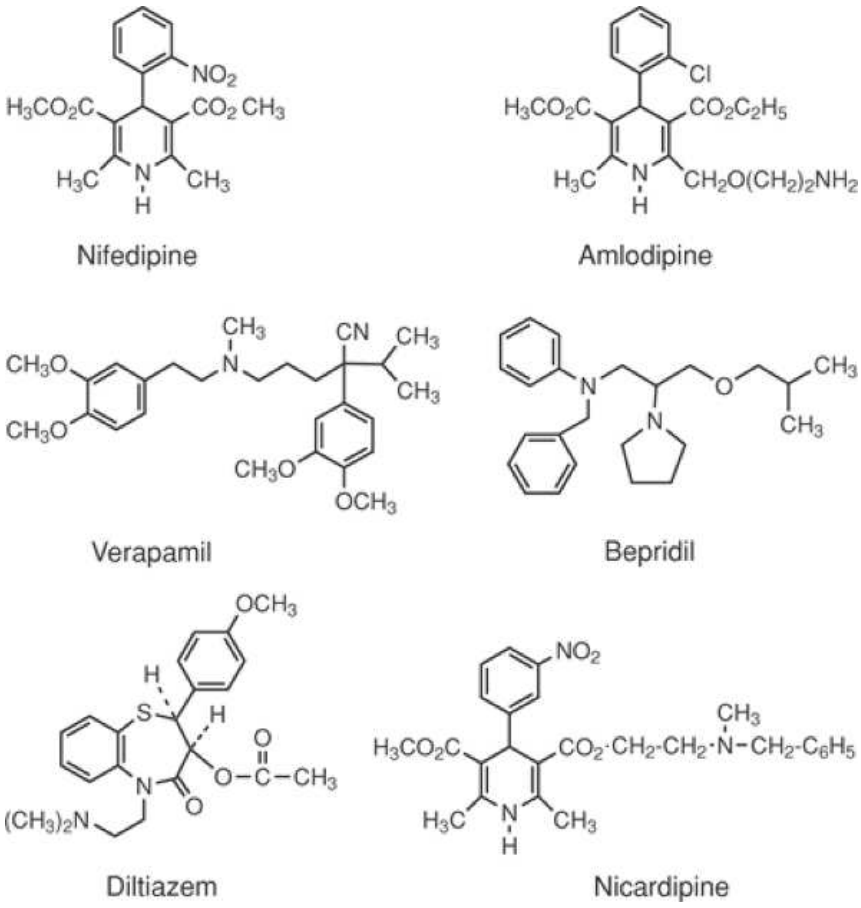

Fig. 26.7. Calcium channel blockers.

Mechanism of Action

The depolarization and contraction of the myocardial cells are mediated, in part, by calcium influx. As previously explained, the overall process consists of two distinct, inward ion currents: First, sodium ions flow rapidly into the cell through the “fast channels,” and subsequently, calcium enters more slowly through the “slow channels.” The calcium ions trigger contraction indirectly by binding and inhibiting troponin, a natural suppressor of the contractile process. Once the inhibitory effect of troponin is removed, actin and myosin can interact to produce the contractile response. The calcium channel blockers produce a negative inotropic effect by interrupting the contractile response. In vascular smooth muscles, calcium causes constriction by binding to a specific intracellular protein calmodulin to form a complex that initiates the process of vascular constriction. The calcium channel blockers inhibit vascular smooth muscle contraction by depriving the cell from the calcium ions.

The effects of the three classes of calcium channel blockers on the myocardium and the arteries vary from one class to the other. Although verapamil and diltiazem affect both the heart and the arteriolar bed, the dihydropyridines have much less effect on the cardiac tissues and higher specificity for the arteriolar vascular bed. Therefore, both verapamil and diltiazem are used clinically in the management of angina, hypertension, and cardiac arrhythmia, whereas the dihydropyridines are used more frequently as antianginal and antihypertensive agents. Because nicardipine has a less negative inotropic effect than nifedipine, it may be preferred over nifedipine for patients with angina pectoris or hypertension who also have CHF dysfunction.

The recognition of the pivotal role of calcium flux on biological functions led to the reexamination of several therapeutic agents already in clinical use to see if their effects also were mediated through calcium-dependent mechanisms. Interestingly, many drugs were found to influence calcium movement and availability. In many cases, however, this effect was not found to contribute significantly to the desirable pharmacological activity, with other mechanisms playing more dominant roles.

Pharmaceutical Preparations

Calcium channel blockers are administered as oral tablets and capsules as regular or sustained-release forms. Verapamil and diltiazem also are administered by injection.

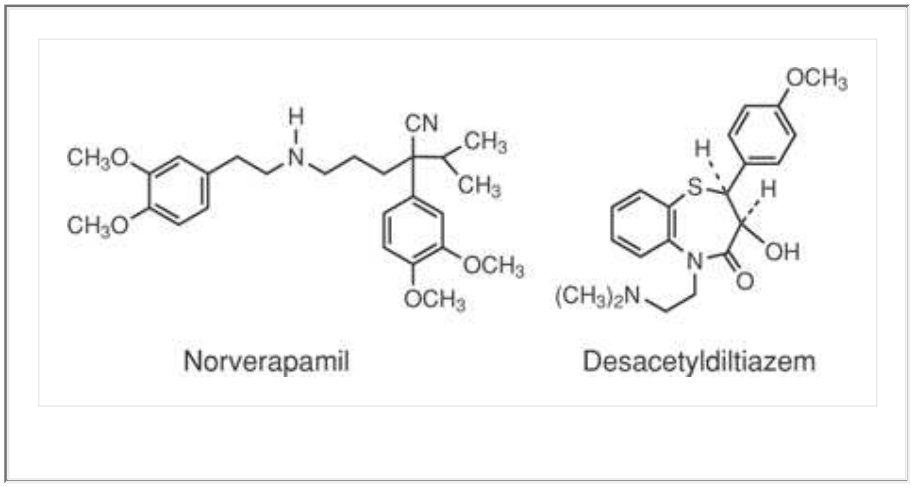
Absorption, Metabolism, and Excretion

The calcium channel blockers are rapidly and completely absorbed after oral administration (see Table 28.11 for summary of pharmacokinetic parameters). Prehepatic first-pass metabolism by CYP3A4 enzymes occurs with some orally administered calcium channel blockers, especially verapamil, with its low bioavailability of 20 to 35%. The bioavailability of diltiazem is 40 to 67%, of nicardipine 35%, of nifedipine 45 to 70%, and of amlodipine 64 to 90%. Verapamil is metabolized by CYP3A4 N-demethylation to its principal metabolite, norverapamil, which retains approximately 20% of the activity of verapamil, and by O-demethylation (CYP2D6) into inactive metabolites. Diltiazem is metabolized by enzyme hydrolysis to its primary metabolite, desacetyl derivative, which retains approximately 25 to 50% of the activity of diltiazem. The oral bioavailability of diltiazem and verapamil may be increased with chronic use and increasing dose (i.e., bioavailability is nonlinear). Diltiazem undergoes

N-demethylation by CYP3A4 and O-demethylation by CYP2D6. The N-demethylated metabolism pathway results in mechanism-based inhibition of CYP3A4. The major metabolite, detected following oral and continuous intravenous administration but not following rapid intravenous administration, is desacetyl diltiazem, which has one-quarter to one-half the arteriolar vasodilation activity of the parent compound. Its elimination half-life ranges from 5 to 8 hours, depending on the dosage. Its onset of action following oral administration is 30 to 60 minutes; 2 to 4% is excreted unchanged. For extended-release capsules, the onset of action is 2 to 3 hours. CYP3A4 inhibition by diltiazem and substrate for CYP2D6 provide a rational basis for pharmacokinetically significant interactions when they are coadministered with drugs that are cleared primarily by CYP3A4 or CYP2D6 mediated pathways. Considerable variability for verapamil may be observed in the elimination half-life of 1.5 to 7 hours. In addition, the plasma half-life may not always accurately predict the duration of action because of the presence of active metabolites. Less than 5% of an orally administered dose of verapamil is excreted unchanged into the urine. Its protein binding is approximately 90%.

A well-documented drug interaction between digoxin and verapamil that increases the AUCs for digoxin has been attributed to verapamil blocking the intestinal P-gp efflux of digoxin (previously described under digoxin–drug interactions). The fact that verapamil is a substrate for P-gp transport of drugs may be a potential source of other drug interactions. The oral coadministration of verapamil with CYP3A4 inhibitors (see Table 10.10 for a list of inhibitors) has resulted in at least a 100 to 200 times increase in the blood AUCs for verapamil and, thereby, a toxic dose.

The dihydropyridines are metabolized largely to a variety of inactive metabolites. Their binding to plasma proteins is high, ranging from 70 to 98% depending on the individual agent: For verapamil, protein binding is 90%; for diltiazem, 70 to 80%; for nifedipine, 92–98%; for nicardipine, greater than 90%; and for amlodipine, greater than 90%. Less than 4% of the dihydropyridine dose is excreted unchanged into the urine. The duration of action of the calcium channel blockers ranges from 4 to 8 hours (verapamil, 4 hours; diltiazem, 6–8 hours; nifedipine, 4–8 hours; and nicardipine, 6–8 hours). Amlodipine has a 24-hour duration of action. Thus, it is the only calcium channel blocker that can be given once daily as a nonsustained-release product.



Adverse Effects

The most common side effects of the calcium channel blockers include dizziness, hypotension, headache, and peripheral and pulmonary edema. These symptoms are related mainly to the excessive vasodilation, especially with the dihydropyridines. Verapamil was reported to cause constipation to some patients.

Drug Interactions

Clinically significant drug interactions between calcium channel blockers and coadministration of CYP3A4 inhibitors, such as 6 to 8 oz. of grapefruit juice, HIV protease inhibitors, and erythromycin, have resulted in a 100- to 200-fold increase in the AUC for some calcium channel blockers (31). On the other hand, the coadministration of CYP3A4 inducers, such as rifampin or phenobarbital, result in an approximately 50% decrease in the AUC of calcium channel blockers. With other vasodilators, antihypertensive drugs, and alcohol, excessive hypotension may arise because of an additive effect. The high-protein-binding nature of these drugs precipitates a potential for mutual plasma displacement with other drugs known to possess the same property, such as oral anticoagulants, digitalis glycosides, oral hypoglycemic agents, sulfa drugs, and salicylates. Dose adjustment may be necessary in some cases.

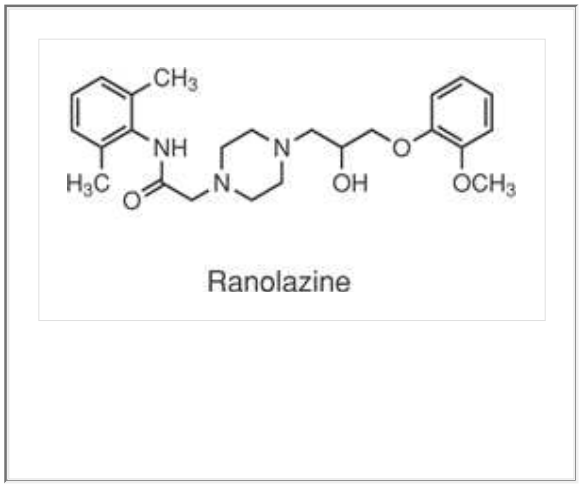
Therapeutic Uses

Calcium channel blockers are clinically used as antianginal, antiarrhythmic, and antihypertensive agents (see corresponding subsection in Chapter 28).

β-Adrenergic Blocking Agents

The use of β-adrenergic blockers as antianginal agents is limited to the treatment of exertion-induced angina. Propranolol is the prototype drug in this class, but several newer agents have been approved for clinical use in the United States (see Chapter 13). Although these agents may be used alone, they often are used in combination therapy with nitrates, calcium channel blockers, or both. In several instances, combination therapy was found to provide more improvement than with either agent alone. This, however, is not always the case.

Modulators of Myocardial Metabolism



Ranolazine

Ranolazine (Ranexa) is a novel metabolic modulator approved for the treatment of chronic angina in combination with amlodipine, β-adrenoceptor antagonists, or

nitrates in patients who have not achieved an adequate response with other antianginals. Although the exact mechanism of its antianginal and anti-ischemic effect is unknown, its antianginal and anti-ischemic action is not dependent on heart rate or blood pressure reduction, and it does not increase myocardial workload. Numerous studies suggest that ranolazine modulates myocardial metabolism by shifting myocardial energy metabolism from free fatty acids to glucose by inhibition of fatty acid oxidation, increasing glucose oxidation and, thus, generating more adenosine triphosphate (ATP) per molecule of oxygen consumed. Ranolazine mainly affects the late sodium current across the membrane with the potential to reduce the cardiac ischemic burden without significantly changing blood pressure and heart rate.

The oral bioavailability of ranolazine from extended-release tablets is 76%, and plasma concentration is not effected by food. Metabolism is mainly by CYP3A4 and, to a lesser degree, by CYP2D6, with less than 5% being excreted unchanged in the urine and feces. After a single oral dose of ranolazine solution, approximately 75% of the dose is excreted in the urine and approximately 25% in feces. Its elimination half-life for extended-release tablets is 7 to 9 hours. Ranolazine is an inhibitor of P-gp transporter. Ranolazine plasma concentrations are increased by CYP3A4 inhibitors. The CYP2D6 inhibition has a negligible effect on ranolazine exposure.

Miscellaneous Coronary Vasodilators

Another approach to the treatment of myocardial insufficiency is the use of the coronary vasodilators dipyridamole and papaverine. Dipyridamole, a PDE3 inhibitor, (Fig. 26.8) causes a long-acting and selective coronary vasodilation by increasing coronary blood flow via selective dilation of the coronary arteries. The state of the coronary arteries may determine the effect of dipyridamole on coronary blood flow and metabolic responses. Blood flow increased by 80% in unobstructed coronary vessels, whereas in stenotic coronary arteries, flow increased by approximately 40%. In patients with single-vessel coronary artery disease, intravenous dipyridamole increases flow to the ischemic area, probably by increasing collateral blood flow. Dipyridamole increases intracellular concentrations of the coronary vasodilator adenosine and cAMP and inhibits adenosine metabolism and uptake by vascular endothelial cells. The increased concentration of adenosine in vascular smooth muscle stimulates adenylate cyclase activity, leading to increased cAMP synthesis and, consequently, to relaxation of vascular smooth muscle (vasodilation). The effect of dipyridamole may not result only from its effect on adensoine but also from its ability to increase prostacyclin (vasodilator and platelet inhibitor) production by increasing cAMP concentration. Dipyridamole also increases intracellular cAMP by inhibiting PDE3, decreasing cAMP breakdown. Adenosine is a natural vasodilatory substance released by the myocardium during hypoxic episodes. Some structural similarity of adenosine to dipyridamole is apparent and substantiates this mechanism. Dipyridamole generally is used prophylactically, but its efficacy in reducing the incidence and severity of anginal attacks is not universally accepted.

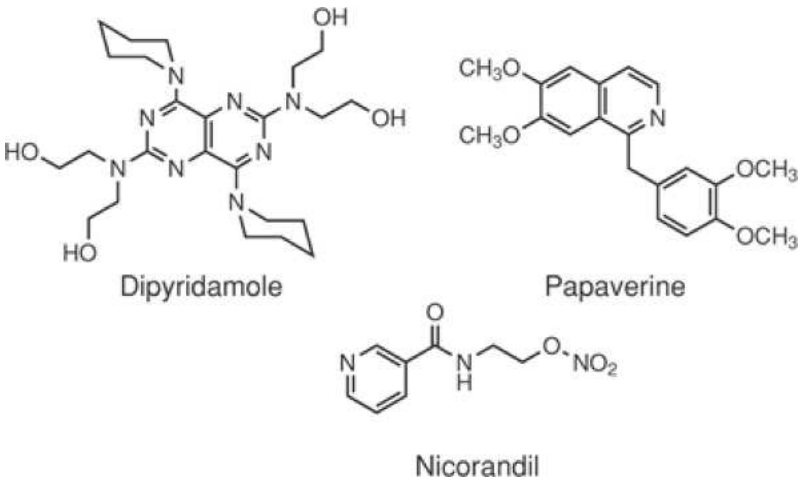


Fig. 26.8. Miscellaneous coronary vasodilators.

Papaverine (Fig. 26.8) is a benzoisoquinoline vasodilator that produces generalized, nonspecific arteriolar dilatation and smooth muscle relaxation. Its oral bioavailability ranges from 30 to 50%, suggesting first-pass metabolism. Increased levels of intracellular cAMP secondary to inhibition of phosphodiesterase may contribute to its vasodilatation and relaxation effects without involving nerve supply. Large doses of papaverine can cause hypotension and tachycardia. Other studies suggest that it also depresses cardiac conduction and prolongs the refractory period.

The natriuretic polypeptide nesiritide (Natrecor) is manufactured in the United States using recombinant DNA technology for intravenous use to treat cases of angina and CHF. Nesiritide has the same amino acid sequence of the natural, 32-amino-acid natriuretic peptide that normally is released during cardiac ischemia and acts as vasodilator. Nesitride acts as a coronary vasodilator by binding to the soluble guanylate cyclase receptors in vascular smooth muscles, leading to increased intracellular concentrations of the vasodilator cGMP.

Nicorandil (Dancor, Ikorel) is a nicotinamide-nitrate ester (Fig. 26.8) used for the treatment of angina pectoris and CHF and has a dual mechanism of action. Structurally, it is a hybrid between organic nitrates and potassium channel activators. Although nicorandil contains a nitrate moiety, its pharmacological properties differ from organic nitrates. The nicotinamide moiety is responsible for the effect on K^+-ATP channels, which produces vascular smooth muscle relaxation by increasing potassium flux through ATP-sensitive sarcolemmal potassium channels. This leads to hyperpolarization of the cell membrane and subsequent decreases in levels of cytoplasmic calcium (calcium channel blockade) and dilation of arterial resistance vessels. Other agents in this class are minoxidil and diazoxide. The nitrate group explains its NO-like vasodilation on large coronary arteries, whereas its potassium channel–opening action is responsible for the dilatation of coronary resistance vessels,

enabling it to decrease both preload and afterload and to increase coronary blood flow.

Nicorandil induces nitrate-like activation of soluble guanylate cyclase, increasing intracellular levels of cGMP with resultant dilation of venous capacitance vessels. Increases in cGMP are less than those observed with conventional nitrates, although the degree of vasodilation produced appears to be similar. Its oral bioavailability ranges from 75 to 80%. Food reduces the rate, but not the extent, of absorption. Nicorandil is extensively metabolized via denitration to inactive N-(2-hydroxyethyl)-nicotinamide, which undergoes further side-chain degradation to nicotinuric acid and, subsequently, nicotinamide and nicotinamide metabolites (e.g., nicotinic acid and N-methylnicotinamide). The nicotinamide derived from nicorandil merges into the endogenous pool of nicotinamide adenine dinucleoside coenzymes. Its elimination half-life is approximately 1 hour. Approximately 30% of nicorandil is excreted into the urine as metabolites, with less than 1% excreted unchanged.

Drugs for the Treatment of Cardiac Arrhythmia

Arrhythmia

Arrhythmia is an alteration in the normal sequence of electrical impulse rhythm that leads to contraction of the myocardium. It is manifested as an abnormality in the rate, the site from which the impulses originate, or in the conduction through the myocardium. The rhythm of the heart normally is determined by a pacemaker site called the SA node, which consists of specialized cells that undergo spontaneous generation of action potentials at a rate of 100 to 110 action potentials ("beats") per minute. This intrinsic rhythm is strongly influenced by the vagus nerve, overcoming the sympathetic system at rest. This "vagal tone" brings the resting heart rate down to a normal sinus rhythm of 60 to 100 beats per minute. Sinus rates below this range are termed "sinus bradycardia," and sinus rates above this range are termed "sinus tachycardia." The sinus rhythm normally controls both atrial and ventricular rhythm. Action potentials generated by the SA node spread throughout the atria, depolarizing this tissue and causing atrial contraction. The impulse then travels into the ventricles via the AV node. Specialized conduction pathways within the ventricle rapidly conduct the wave of depolarization throughout the ventricles to elicit ventricular contraction. Therefore, normal cardiac rhythm is controlled by the pacemaker activity of the SA node. Abnormal or irregular cardiac rhythms (heartbeats) may occur when the SA node fails to function normally, when other pacemaker sites (e.g., ectopic pacemakers) trigger depolarization, or when a dysfunction occurs along the normal conduction pathways.

Causes of Arrhythmias

Many factors influence the normal rhythm of electrical activity in the heart. Arrhythmias may occur either because pacemaker cells fail to function properly or because of a blockage in transmission through the AV node. Underlying diseases, such as atherosclerosis, hyperthyroidism, or lung disease, also may be initiating factors. Some of the more common arrhythmias are those termed "ectopic," which occur when electrical signals spontaneously arise in regions other than the pacemaker and then compete with the normal impulses. Myocardial ischemia, excessive myocardial catecholamine release, stretching of the myocardium, and cardiac glycoside toxicity have all been shown to stimulate ectopic foci. A second mechanism for the generation of arrhythmias is from a phenomenon called reentry. This occurs when the electrical impulse does not die out after firing but, rather, continues to circulate and reexcite resting heart cells into depolarizing. The result of this reexcitation may be a single, premature beat or runs of ventricular tachycardia. Reentrant rhythms are common in the presence of coronary atherosclerosis.

Drugs for the Treatment of Antiarrhythmias and Their Classification

It is widely accepted that most currently available antiarrhythmic drugs may be classified into four categories, which are grouped on the basis of their effects on the cardiac action potential and, consequently, on the electrophysiological properties of the heart. To understand the basis of classification and the pharmacology of these agents, an understanding of normal cardiac electrophysiology is necessary.

Normal Physiologic Action

Normal cardiac contractions largely are a function of the action of a single atrial pacemaker, a fast and generally uniform conduction in predictable pathways, and a normal duration of the action potential and refractory period. Figure 26.9 depicts a normal cardiac action potential from a Purkinje fiber. The resting cell has a membrane potential of approximately -90 mV, with the

inside of the cell being electronegative relative to the outside of the cell. This is termed the "transmembrane resting potential." On excitation, the transmembrane potential reverses, and the inside of the membrane rapidly becomes positive with respect to the outside. On recovery from excitation, the resting potential is restored. These changes have been divided into five phases: Phase 0 represents depolarization and reversal of the transmembrane potential, phases 1–3 represent different stages of repolarization, and phase 4 represents the resting potential. During phase 0, which also is referred to as rapid depolarization, the permeability of the membrane for

sodium ions increases, and sodium rapidly enters the cell, causing it to become depolarized. Phase 1 results from the ionic shift, which creates an electrochemical and concentration gradient that reduces the rate of sodium influx but favors the influx of chloride and efflux of potassium. Phase 2, the plateau phase, results from the slow inward movement of calcium, which is triggered by the rapid inward movement of sodium in phase 0. During this time, there also is an efflux of potassium that balances the influx of calcium, thus resulting in little or no change in membrane potential. Phase 3 is initiated by a slowing of the calcium influx coupled with a continued efflux of potassium. This continued efflux of potassium from the cell restores the membrane potential to normal resting potential levels. During phase 4, the Na^+, K^+-ATPase pump restores the ions to their proper local concentrations. The action potential is a coordinated sequence of ion movements in which sodium initially enters the cell, followed by a calcium influx, and finally, a potassium efflux returns the cell to its resting state. Several antiarrhythmic agents exert their effects by altering these ion fluxes.

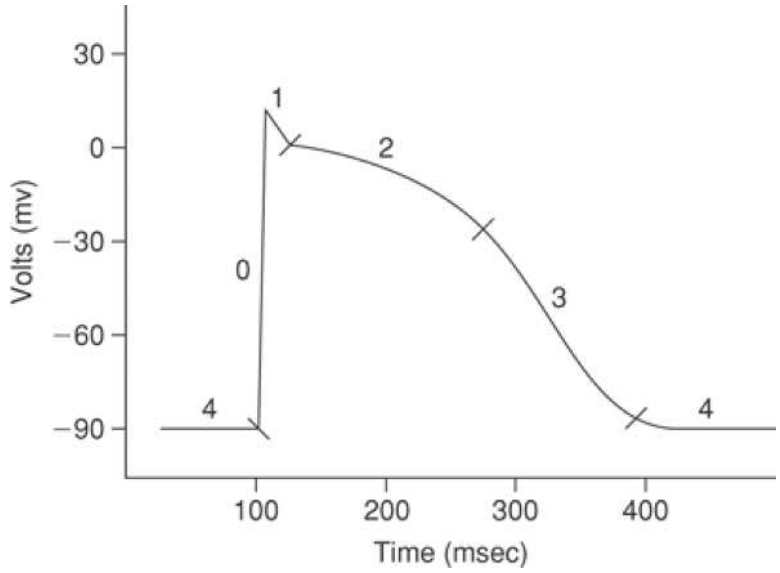

Fig. 26.9. Cardiac action potential recorded from a Purkinje fiber.

Classification of Antiarrhythmic Drugs

Class IA antiarrhythmic drugs

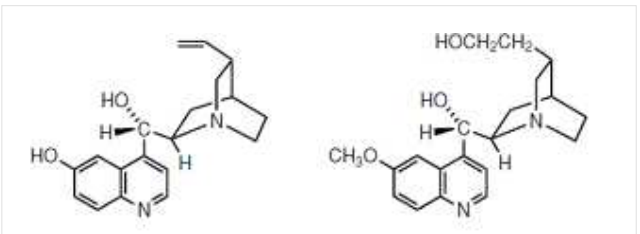
Class IA drugs generally are local anesthetics acting on nerve and myocardial membranes to slow conduction by blocking fast Na^+ channels, inhibiting phase 0 of the action potential (Fig. 26.9). Myocardial membranes show the greatest sensitivity. Class IA drugs decrease the maximal rate of depolarization without changing the resting potential. They also increase the threshold of excitability, increase the effective refractory period, decrease conduction velocity, and decrease spontaneous diastolic depolarization in pacemaker cells. The decrease in diastolic depolarization tends to suppress ectopic foci activity. Prolongation of the refractory period tends to abolish reentry arrhythmias. Table 26.6 summarizes these effects. Quinidine is considered to be the prototype drug for class IA.

Quinidine

Quinidine (Fig. 26.10) is widely used for acute and chronic treatment of ventricular and supraventricular arrhythmias, especially supraventricular tachycardia. It is a member of a family of alkaloids found in Cinchona bark (*Cinchona officinalis* L.) and is the diastereomer of quinine. Despite their structural similarity, quinidine and quinine differ markedly in their effects on the cardiac muscles, with the effects of quinidine being much more pronounced. Structurally, quinidine is composed of a quinoline ring and the bicyclic quinuclidine ring system, with a hydroxymethylene bridge connecting these two components. Examination of quinidine reveals two basic nitrogens, with

the quinuclidine nitrogen (pK_a = 11) being the stronger of the two. Because of the basic character of quinidine, it is always used as water-soluble salt forms. These salts include quinidine sulfate, gluconate, and polygalacturonate. Good absorption (~95%) is observed with each of these forms after oral administration. In special situations, quinidine may be administered intravenously as the gluconate salt. The use of intravenous quinidine, however, is rare. The gluconate salt is particularly suited for parenteral use because of its high water solubility and lower irritant potential.

Quinidine's bioavailability appears to depend on a combination of metabolism and P-gp efflux. The bioavailabilities of quinidine sulfate and gluconate are 80 to 85% and 70 to 75%, respectively. Once absorbed, quinidine is subject to hepatic first-pass metabolism and is approximately 85% plasma protein bound, with an elimination half-life of approximately 6 hours. Quinidine is metabolized mainly in the liver, and renal excretion of unchanged drug also is significant (~10–50%). The metabolites are hydroxylated derivatives at either the quinoline ring through first-pass O-demethylation or at the quinuclidine ring through oxidation of the vinyl group. These metabolites possess only about one-third the activity of quinidine. Their contribution to overall therapeutic effect of quinidine is unclear. Recently, the clinical significance of the well-documented digoxin–quinidine interaction was described previously under digoxin–drug interactions. Apparently, quinidine (a P-gp substrate) inhibits the renal tubular secretion of digoxin via the P-gp efflux pump, resulting in increased plasma concentration for digoxin.



In addition, a common contaminant in quinidine preparations, dihydroquinidine, which is derived from reduction of the quinuclidine vinyl group at C-3 to an ethyl group, also may contribute to its activity (32). Although similar to quinidine in pharmacodynamic and pharmacokinetic behavior, this contaminant is both more potent as an antiarrhythmic and more toxic. Thus, levels of this contaminant may contribute to variability between commercial preparations. The most frequent adverse effects associated with quinidine therapy are gastrointestinal

disturbances, such as nausea, diarrhea, and vomiting.

Table 26.6. Summary of the Cardiac Physiological Effects of the Antiarrhythmic Drugs

Classification	Mechanism of Action	Primary Sites of Action	Drug Examples
Class IA	-Na^+ channel blockade -intermediate rate of dissociation from sodium channels		Quinidine Procainamide
	-slows phase 0 depolarization -prolongs action	Atrial and ventricular tissue	Disopyramide

	potential duration -slows conduction		
Class IB	-Na^+ channel blockade -rapid rate of dissociation from sodium channels		Lidocaine Mexiletine
	-shorten phase 3 repolarization -shortens action potential duration	Ventricular tissue	Phenytoin Tocainide
Class 1C	- Na^+ channel blockade -slow rate of dissociation from sodium channels -markedly slows phase 0 depolarization -slows conduction	Ventricular tissue	Flecainide Encainide Propafenone Moricizine
Class II	- blocks sympathetic stimulation of β_1 adrenergic receptors -slow phase 4 depolarization -slows firing of SA node and conduction through AV node prolonging repolarization	SA node AV node	Propranolol Sotalol β_1 blockers
Class III	- K^+ channel blockade (block delayed rectifier current) -prolong phase 3 repolarization -prolongs duration of action potential which prolongs refractory period	Atrial and ventricular tissue	Amiodarone Sotalol Bretylium Ibutilide
Class IV	-Ca^{+2} channel blockade	SA node	Verapamil
	-slow phase 4	AV node	Diltiazim

depolarization -slows firing of SA node and conduction through AV node prolonging repolarization of AV node		

Procainamide

Procainamide (Fig. 26.10) is effective in the treatment of several types of cardiac arrhythmias. Its actions are similar to those of quinidine, yet procainamide may be effective in patients who are unresponsive to quinidine. The initial development of procainamide was stimulated by the observation that the local anesthetic procaine (the ester bio-isostere of procainamide), when administered intravenously, produced significant though short-lived antiarrhythmic effects. Unfortunately, considerable central nervous system toxicity, in addition to the short duration, limited the usefulness of this agent. Moreover, procaine is not active orally because of its short duration of action caused by both chemical and plasma esterase hydrolysis. A logical modification of this molecule was the isosteric replacement of the ester with an amide group. This produced orally active procainamide, which is more resistant to both enzymatic and chemical hydrolysis. Peak plasma levels of procainamide are observed within 45 to 90 minutes after oral administration, and approximately 70 to 80% of the dose is bioavailable. Approximately half of this dose is excreted unchanged, and the remaining half undergoes acetylation metabolism in the liver. Metabolites of procainamide include p-aminobenzoic acid and N-acetylprocainamide. Interestingly, the acetylated metabolite is also active as an antiarrhythmic. Its formation accounts for up to one-third of the administered dose and is catalyzed by the liver enzyme N-acetyl transferase. Because acetylation is strongly influenced by an individual's genetic background, marked variability in the amounts of this active metabolite may be observed from patient to patient. Renal excretion dominates, with approximately 90% of a dose excreted as unchanged drug and metabolites. The elimination half-life is approximately 3.5 hours. A substantial percentage (60–70%) of patients on procainamide show elevated levels of antinuclear antibodies after a few months. Of these patients, between 20 and 30% develop a drug-induced lupus syndrome if therapy is continued. These adverse effects, which are attributed to

the aromatic amino group, are observed more frequently and more rapidly in “slow acetylators.” Usually, the symptoms associated with procainamide-induced lupus syndrome subside fairly rapidly after the drug is discontinued. These problems, however, have discouraged long-term procainamide therapy.

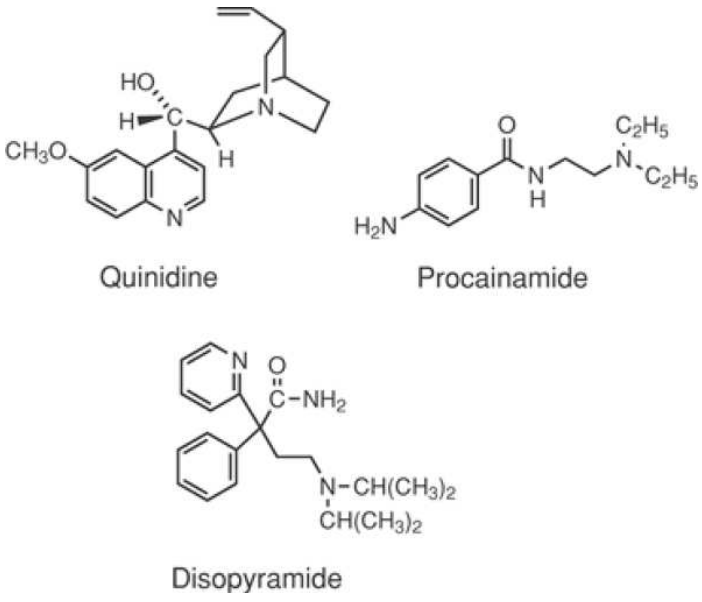


Fig. 26.10. Class IA antiarrhythmics.

Disopyramide

Disopyramide phosphate is used orally for the treatment of certain ventricular and atrial arrhythmias. Despite its structural dissimilarity to procainamide (Fig. 26.10), its cardiac effects are very similar. Disopyramide is rapidly and completely absorbed from the gastrointestinal tract. Peak plasma level is usually reached within 1 to 3 hours, and a plasma half-life of 5 to 7 hours is common. Approximately half of an oral dose is excreted unchanged in the urine. The remaining drug undergoes hepatic metabolism, principally to the corresponding N-dealkylated form. This metabolite retains approximately half the antiarrhythmic activity of disopyramide and also is subject to renal excretion. Adverse effects of disopyramide frequently are observed. These effects are primarily anticholinergic in nature and include dry mouth, blurred vision, constipation, and urinary retention.

Class IB antiarrhythmic drugs

Lidocaine

Lidocaine, similar to procaine, is an effective, clinically used local anesthetic (Fig. 26.11) (see Chapter 16). Its cardiac effects, however, are distinctly different from those of procainamide or quinidine. Lidocaine normally is reserved for the treatment of ventricular arrhythmias and, in fact, usually is the drug of choice for emergency treatment of ventricular arrhythmias. Its utility in these situations results from the rapid onset of antiarrhythmic effects on intravenous infusion. In addition, these effects cease soon after the infusion is terminated. Thus, lidocaine therapy may be rapidly modified in response to changes in the patient's status. Lidocaine is effective as an antiarrhythmic only when given parenterally, and the intravenous route is the most common. Antiarrhythmic activity is not observed after oral administration because of the rapid and efficient first-pass metabolism by the liver. Parenterally administered lidocaine is approximately 60 to 70% plasma protein bound. Hepatic metabolism is rapid (plasma half-life, ~15–30 minutes) and primarily involves N-deethylation to yield monoethylglycinexylide, followed by amidase-catalyzed hydrolysis into N-ethylglycine and 2,6-dimethylaniline (2,6-xylidine) (Fig. 26.12).

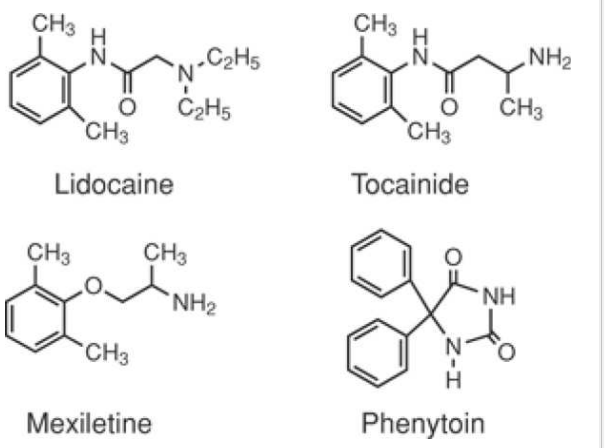

Fig. 26.11. Class IB antiarrhythmics.

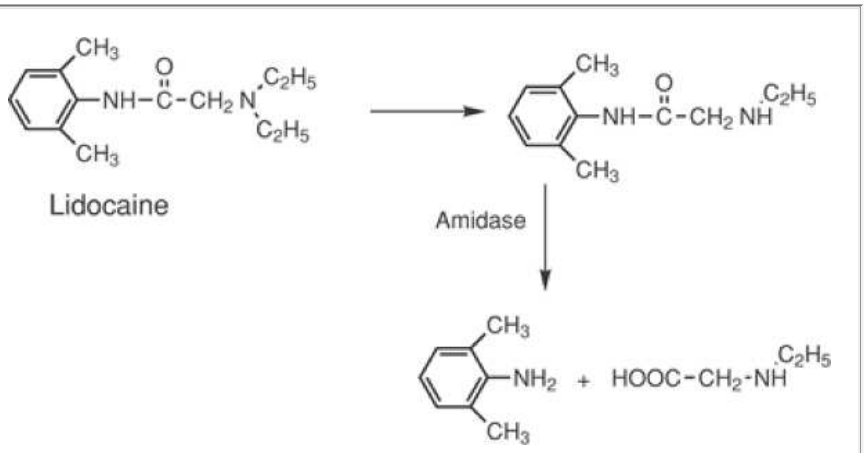

Fig. 26.12. Metabolism of lidocaine.

Monoethylglycinexylide has good antiarrhythmic activity. It is not clinically useful, however, because it undergoes rapid enzymatic hydrolysis. The adverse effects of lidocaine include emetic and convulsant properties that predominantly involve the central nervous system and heart. The central nervous system effects may begin with dizziness and paresthesia and, in severe cases, ultimately lead to epileptic seizures.

Tocainide

Tocainide (Tonocard) (Fig. 26.11) is an α-methyl analogue structurally related to monoethylglycinexylide, the active metabolite of lidocaine, which possesses very similar electrophysiologic effects to lidocaine. In contrast to lidocaine, tocainide is orally active, and its oral absorption is excellent. Like lidocaine, it usually is reserved for the treatment of ventricular arrhythmias. The α-methyl group is believed to slow the rate of metabolism and, thereby, to contribute to oral activity. The plasma half-life of tocainide is approximately 12 hours, and nearly 50% of the drug may be excreted unchanged in the urine. Adverse effects associated with tocainide are like those observed with lidocaine—specifically, gastrointestinal disturbances and central nervous system effects.

Mexiletine

Mexiletine (Mexitil)(Fig. 26.11) is similar to both lidocaine and tocainide in its effects and therapeutic

application. It is used principally to treat and prevent ventricular arrhythmias. Like tocainide, mexilitine has very good oral activity and absorption properties. Clearance depends on metabolism and renal excretion. A relatively long plasma half-life of approximately 12 to 16 hours is common. Adverse effects are similar to those experienced with tocainide and lidocaine.

Phenytoin

For 50 years, phenytoin (Fig. 26.11) has seen clinical use in the treatment of epileptic seizures (see Chapter 20). During this time, it was noticed that phenytoin also produced supposedly adverse cardiac effects. On closer examination, these adverse effects actually

were found to be beneficial in the treatment of certain arrhythmias. Currently, phenytoin is used in the treatment of atrial and ventricular arrhythmias resulting from digitalis toxicity. It is not, however, officially approved for this use.

Phenytoin may be administered either orally or intravenously and is absorbed slowly after oral administration, with peak plasma levels achieved after 3 to 12 hours. It is extensively plasma protein bound (~90%), and the elimination half-life is between 15 and 30 hours. These large ranges reflect the considerable variability observed from patient to patient. Parenteral administration of phenytoin is usually limited to the intravenous route. Phenytoin for injection is dissolved in a highly alkaline vehicle (pH 12). This alkaline vehicle is required because phenytoin is weakly acidic and has very poor solubility in its un-ionized form. Reportedly, however, its phosphate ester fosphenytoin has water solubility advantages over phenytoin for injection. Intramuscular phenytoin generally is avoided, because it results in tissue necrosis at the site of injection and erratic absorption because of high alkalinity. In addition, intermittent intravenous infusion is required to reduce the incidence of severe phlebitis.

Phenytoin metabolism is relatively slow and predominantly involves aromatic hydroxylation to p-hydroxylated inactive metabolites (see Chapter 20). Phenytoin also induces its own metabolism and is subject to large interindividual variability. The major metabolite, 5-p-hydroxyphenyl-5-phenylhydantoin, accounts for approximately 75% of a dose. This metabolite is excreted through the kidney as the β-glucuronide conjugate. Phenytoin clearance is strongly influenced by its metabolism; therefore, agents that affect phenytoin metabolism may cause intoxication. In addition, because phenytoin is highly plasma protein bound, agents that displace phenytoin also may cause toxicity.

Class IC antiarrhythmic drugs

Flecainide

Flecainide (Tamborcor) exhibits properties distinctly different from those of Class IA or IB antiarrhythmic drugs. Flecainide is a fluorinated benzamide derivative (Fig. 26.13), available as the acetate salt. Flecainide has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of ventricular arrhythmias. Clinical studies suggest that this agent may be more effective than either quinidine or disopyramide in suppressing premature ventricular contractions. Oral flecainide is well absorbed, and the plasma half-life is approximately 14 hours. About half of an oral dose is metabolized in the liver, and one-third is excreted unchanged in the urine. As with other antiarrhythmics, flecainide may produce adverse effects. The most severe is flecainide's occasional tendency to aggravate existing arrhythmias or to induce new ones. Although fewer than 10% of patients experience this effect, it may be life-threatening. Accordingly, it may be desirable to start therapy in the hospital. Other less serious side effects include blurred vision, headache, nausea, and abdominal pain.

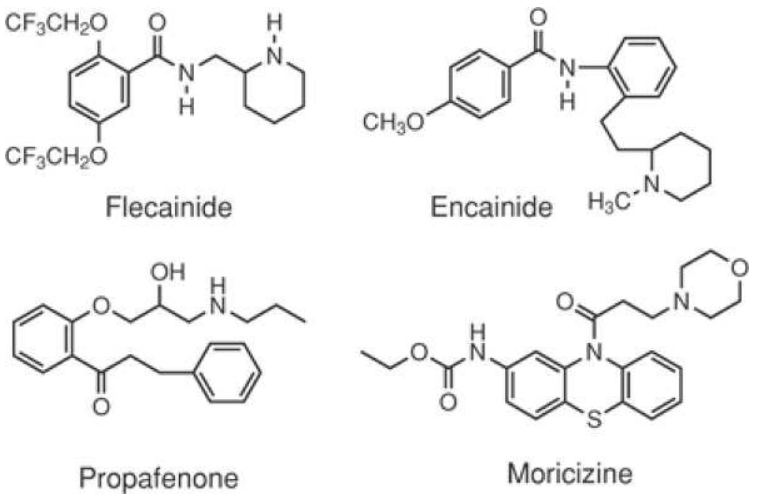

Fig. 26.13. Class IC antiarrhythmics.

Encainide

Encainide (Enkaid) (Fig. 26.13) represents another benzamide derivative, with similar pharmacological properties to flecainide but with less negative inotropic effect.

Propafenone

Propafenone (Rythmol) (Fig. 26.13) is a Class I, local anesthetic–type antiarrhythmic agent. Propafenone is structurally related to other Class IC antiarrhythmic drugs and also to β-adrenergic receptor blockers. It is used primarily for ventricular and supraventricular arrhythmias. The drug is administered orally and intravenously; however, the parenteral dosage forms are not commercially available in the United States. After oral administration, the drug is rapidly and almost completely absorbed from the gastrointestinal tract. Propafenone metabolism involves hepatic CYP2D6 enzymes. Its rate of metabolism is genetically determined by an individual's ability to metabolize the so-called phenotype compounds (fast or slow metabolizers) (see Chapter 10).

Moricizine

Moricizine (Ethmozine) (Fig. 26.13) is a phenothiazine analogue that processes the same electrophysiological effects on the heart as those of Class IC antiarrhythmics. Despite its short half-life after oral administration, its antiarrhythmic effects can persist for many hours, suggesting that some of its metabolites may be active.

Class II antiarrhythmic drugs

Class II antiarrhythmic drugs (Fig. 26.14) are β-adrenergic receptor blocking agents, which block the role of the sympathetic nervous system in the genesis of certain cardiac arrhythmias. Their dominant electrophysiological effect is to depress adrenergically enhanced calcium influx through β-receptor blockade. Drugs in this class decrease neurologically induced automaticity at normal therapeutic doses. At higher doses, these drugs also may exhibit anesthetic properties, which cause decreased excitability, decreased conduction velocity, and a prolonged effective refractory period. In normal therapeutic situations, the β-blocking effects are more important than any local anesthetic effects that these

drugs may have. Propranolol is the prototype β-adrenergic blocker drug for class II (see Chapter 13).

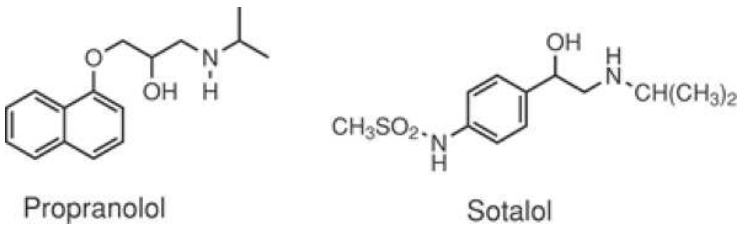

Fig. 26.14. Class III inhibitors of depolarization.

Propranolol

(+)-Propranolol, a nonselective β-adrenergic blocker, is the prototype for Class II antiarrhythmics. Its pharmacology and pharmacokinetics are discussed in detail in Chapters 13 and 29. Its use as an antiarrhythmic usually is for the treatment of supraventricular arrhythmias, including atrial flutter, paroxysmal supraventricular tachycardia, and atrial fibrillation. Propranolol also is reported to be effective in the treatment of digitalis-induced ventricular arrhythmias. Moreover, beneficial results may be obtained when propranolol is used in combination with other agents. For example, in certain cases, quinidine and propranolol together have proved to be more successful in alleviating atrial fibrillation than either agent has alone. Few serious adverse effects are associated with propranolol therapy.

Sotalol

(±)-Sotalol (Betapace, Sotacor), a nonselective β-adrenergic blocker, is a methanesulfonanilide antiarrhythmic agent. As an antiarrhythmic, it is dually classified as Class II and Class III because of the similarity of its cardiac effects to both classes. Sotalol is used orally to suppress and prevent the recurrence of life-threatening ventricular arrhythmia.

Class III inhibitors of repolarization

Class III drugs cause a homogeneous prolongation of the duration of the action potential. This results in a prolongation of the effective refractory period. It is believed that most of Class III antiarrhythmic agents act through Phase 3 of the action potential by blocking potassium channels. Figure 26.15 illustrates the chemical structures of members of Class III. Bretylium is the prototype drug for this class.

Bretylium tosylate

Bretylium tosylate is a quaternary ammonium salt derivative (Fig. 26.15) originally developed for use as an antihypertensive. Its antiarrhythmic use is limited to emergency, life-threatening situations in which other agents, such as lidocaine and procainamide, have failed. Generally, bretylium is used only in intensive care units and may be administered either intravenously or intramuscularly. The plasma elimination half-life usually is approximately 10 hours, and it is eliminated largely unchanged in the urine. The major adverse effect associated with bretylium tosylate is hypotension, including orthostatic hypotension, which may be very severe.

Amiodarone

Initially developed as an antianginal (coronary vasodilator), amiodarone (Fig. 26.15) has antiarrhythmic effects that are somewhat similar to those of bretylium. It is approved by the U.S. FDA for the treatment of life-threatening ventricular arrhythmias that are refractory to other drugs. Its

cardiac effects are not well characterized, but clinical studies indicate that it is primarily a Class III agent but also acts as a Class I, II, and IV antiarrythmic. It has a unique mechanism of action that involves alteration of the lipid membrane in which ion channels and receptors are located. Its severe toxicity, however, makes it the drug of last choice. As with bretylium tosylate, use of this agent should be initiated in a hospital setting.

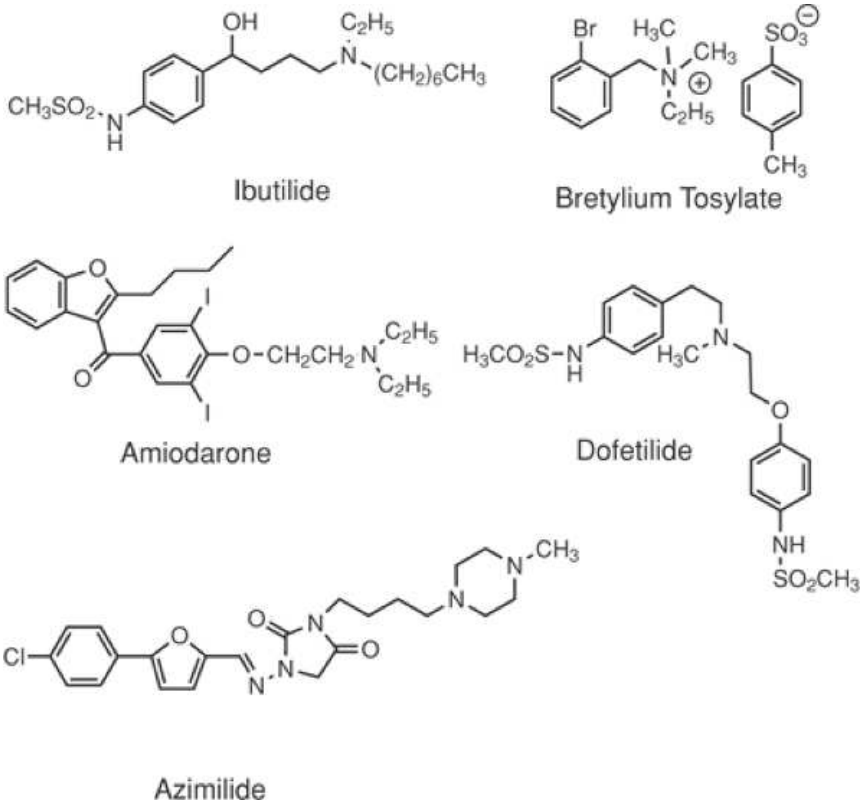

Fig. 26.15. Class III antiarrhythmic agents.

Ibutilide

Ibutilide (Corvert) is another methanesulfonanilide derivative (Fig. 26.15), but unlike sotalol, it lacks any β-adrenergic blocking activity. Like sotalol, it exhibits electrophysiologic effects characteristic of Class III. Ibutilide is used only by intravenous infusion as its fumarate salt.

Dofetilide

Dofetilide (Tikosyn) is a bis-methanesulfonanilide derivative that is essentially the non-β-blocking moiety of the sotalol molecule (Fig. 26.15). It exhibits only Class III electrophysiological effects, but like ibutilide, it lacks any β-adrenergic blocking activity. Dofetlide is used orally to suppress atrial fibrillation and flutter. It is more potent and selective than other Class III methanesulfonanilides, including sotalol. Dofetilide is well absorbed from the gastrointestinal tract, with a bioavailability of 96 to 100%. The bioavailability of oral dofetilide is not affected by food or antacids. Protein binding is 60 to 70%. Dofetilide is metabolized by the hepatic CYP3A4 enzyme system via N-dealkylation and N-oxidation to inactive or minimally active metabolites. Of the approximately 80% of a dose excreted in urine, approximately 80% is excreted unchanged, with the other 20% as metabolites.

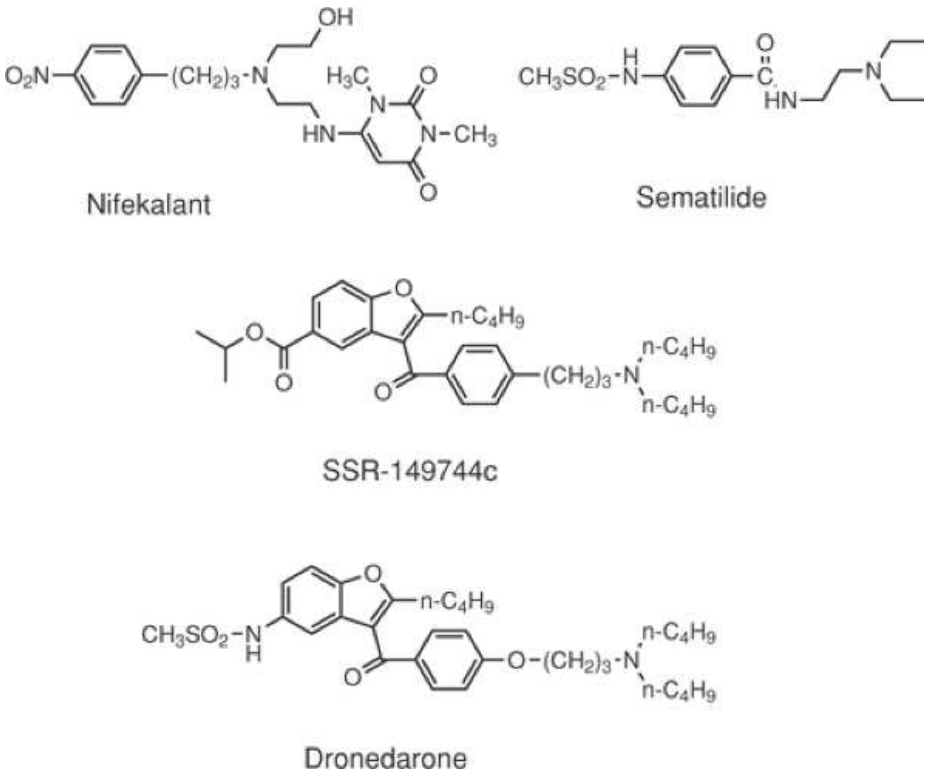

Fig. 26.16. Antiarrhythmic drugs in Phase III clinical trials.

Azimilide

Azimilde is another Class III antiarrhythmic agent structurally unrelated to any of the above agents (Fig. 26.15). Azimilide is not available in the United States; it is only available in Europe. Following oral administration, the drug is completely absorbed, with no effect of food. Protein binding is 94%. It is metabolized in the liver to an active carboxylate metabolite, but its concentration in plasma is less than 5% of the parent compound. Thus, it is considered to be therapeutically inactive. Renal excretion is approximately 10%. Its elimination half-life is 3 to 4 days.

Class IV calcium channel blockers

Class IV calcium channel antiarrhythmic drugs (Fig. 26.7) comprise a group of agents that selectively block the slow inward current carried by calcium (i.e., calcium channel blockers). The slow inward current in cardiac cells has been shown to be of importance for the normal action potential in SA node cells. It also has been suggested that this inward current is involved in the genesis of certain types of cardiac arrhythmias. Administration of a Class IV drug causes a prolongation of the refractory period in the AV node and the atria, a decrease in AV conduction, and a decrease in spontaneous diastolic depolarization. These effects block conduction of premature impulses at the AV node and, thus, are very effective in treating supraventricular arrhythmias. Verapamil and diltazem are prototype drugs for this class (Fig. 26.7), but dihydropyridine drugs are less effective in cardiac tissues. Refer to the section on calcium channel blocker under antianginal drugs for pharmacokinetic information.

Antiarrhythmic Drugs in Phase III Clinical Trials

Antiarrhythmic drugs in Phase III clinical trials are shown in Figure 26.16. Nifekalant is a pyrimidinone Class III agent. Sematilide is a Class III agent that is a benzamide derivative of ibutilide, and SSR-149744c and dronedarone are noniodinated analogues of amiodarone, reportedly with fewer adverse effects than amiodarone.

Case Study

Victoria F. Roche

S. William Zito

BZ shows up at the hospital where you work. He is a 30-year-old computer jock who works for one of the high-tech Internet companies. He has no history of any health-related problems, but today, he reports that he has been coming in from playing basketball on the company grounds feeling dizzy and thinking he is going to faint. At first, he thought it was the result of too much exertion in the heat of the summer; however, these symptoms have continued even when he is not strenuously exercising. In the emergency department, BZ is still experiencing these symptoms, and on questioning, he says he can feel his heart beating, is anxious, and is visibly out of breath when speaking. A physical examination reveals a pulse of 220 beats per minute, with normal temperature and lung sounds. An electrocardiogram reveals a regular narrow QRS complex at 200 to 220 beats per minutes. He is diagnosed with paroxysmal supraventricular tachycardia (PSVT) and treated with intravenous adenosine after vagal maneuvers fail (blowing on his thumb, “bearing down” as if he were forcing a bowel movement, or splashing his face with ice water) to restore him to normal sinus rhythm. BZ is admitted to the hospital for observation. Overnight and into the next day, BZ continues to have mild PSVTs; therefore, the cardiologist decides that prophylactic therapy is necessary. Evaluate structures 1 to 4 for possible use in this case.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 27

Diuretics

Gary O. Rankin

Introduction

Diuretics are chemicals that increase the rate of urine formation (1). By increasing the urine flow rate, diuretic usage leads to increased excretion of electrolytes (especially sodium and chloride ions) and water from the body without affecting protein, vitamin, glucose, or amino acid reabsorption. These pharmacological properties have led to the use of diuretics in the treatment of edematous conditions resulting from a variety of causes (e.g., congestive heart failure, nephrotic syndrome, and chronic liver disease) and in the management of hypertension. Diuretic drugs also are useful as the sole agent or as adjunct therapy in the treatment of a wide range of clinical conditions, including hypercalcemia, diabetes insipidus, acute mountain sickness, primary hyperaldosteronism, and glaucoma.

The primary target organ for diuretics is the kidney, where these drugs interfere with the reabsorption of sodium and other ions from the lumina of the nephrons, which are the functional units of the kidney. The amount of ions and accompanying water that are excreted as urine following administration of a diuretic, however, is determined by many factors, including the chemical structure of the diuretic, the site or sites of action of the agent, the salt intake of the patient, and the amount of extracellular fluid present. In addition to the direct effect of diuretics to impair solute and water reabsorption from the nephron, diuretics also can trigger compensatory physiological events that have an impact on either the magnitude or the duration of the diuretic response. Thus, it is important to be aware of the normal mechanisms of urine formation and renal control mechanisms to understand clearly the ability of chemicals to induce a diuresis.

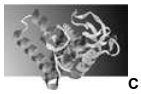
Normal Physiology of Urine Formation

Two important functions of the kidney are 1) to maintain a homeostatic balance of electrolytes and water and 2) to excrete water-soluble end products of metabolism. The kidney accomplishes these functions through the formation of urine by the nephrons (Fig. 27.1). Each kidney contains approximately 1 million nephrons and is capable of forming urine independently. The nephrons are composed of a specialized capillary bed called the glomerulus and a long tubule divided anatomically and functionally into the proximal tubule, loop of Henle, and distal tubule. Each component of the nephron contributes to the normal functions of the kidney in a unique manner; thus, all are targets for different classes of diuretic agents.

Urine formation begins with the filtration of blood at the glomerulus. Approximately 1,200 mL of blood per minute flows through both kidneys and reaches the nephron by way of afferent arterioles. Approximately 20% of the blood entering the glomerulus is filtered into Bowman's capsule to form the glomerular filtrate. The glomerular filtrate is composed of blood components with a molecular weight less than that of albumin (~69,000 daltons) and not bound to plasma proteins. The glomerular filtration rate (GFR) averages 125 mL/min in humans but can vary widely even in normal functional states.

The glomerular filtrate leaves the Bowman's capsule and enters the proximal convoluted tubule (S1, S2 segments, Fig 27.1), where the majority (50–60%) of filtered sodium is reabsorbed osmotically. Sodium reabsorption is coupled electrogenetically with the reabsorption of

glucose, phosphate, and amino acids and nonelectrogenetically with bicarbonate reabsorption. Glucose and amino acids are completely reabsorbed in this portion of the nephron, whereas phosphate reabsorption is between 80 and 90% complete. The early proximal convoluted tubule also is the primary site of bicarbonate reabsorption (80–90%), a process that is mainly sodium dependent and coupled to hydrogen ion secretion. The reabsorption of sodium and bicarbonate is facilitated by the enzyme carbonic anhydrase, which is present in proximal tubular cells and catalyzes the formation of carbonic acid from water and carbon dioxide. The carbonic acid provides the hydrogen ion, which drives the reabsorption of sodium bicarbonate. Chloride ions are reabsorbed passively in the proximal tubule, where they follow actively transported sodium ions into tubular cells.



Clinical Significance

It is important for the clinician to understand the medicinal chemistry of the diuretics to appropriately use them in individual patients. This diverse group of medications is classified in many ways: mechanism of action, site of action, chemical class, and effect on urine contents. Knowledge of structure–activity relationships helps to predict indications, possible off-label uses, magnitude of diuresis, potency, and side effect profile.

Consequently, diuretics have a variety of uses. Thiazide diuretics may be used either alone or in combination with other pharmacotherapy for the treatment of hypertension. Loop diuretics can provide immediate diuresis and are used for heart failure and in lieu of thiazides in patients with compromised renal function. In addition to more traditional uses, certain potassium-sparing diuretics provide added benefit to other pharmacotherapy in patients with primary hyperaldosteronism, heart failure, or post–acute myocardial infarction. Carbonic anhydrase inhibitors have limited use for diuresis; however, they may be used to reduce intraocular pressure and treat acute mountain sickness.

A thorough understanding of the medicinal chemistry, mechanisms of action, and pharmacokinetics helps the clinician to use available diuretics appropriately. As new medications are developed, the clinician will rely on these basic concepts to continue tailoring therapy to the individual patient with the goals to maximize outcomes, improve quality of life, and minimize adverse events.

Kimberly Birtcher Pharm.D.
Clinical Assistant Professor, Department of Clinical Sciences and Administration, University of Houston College of Pharmacy

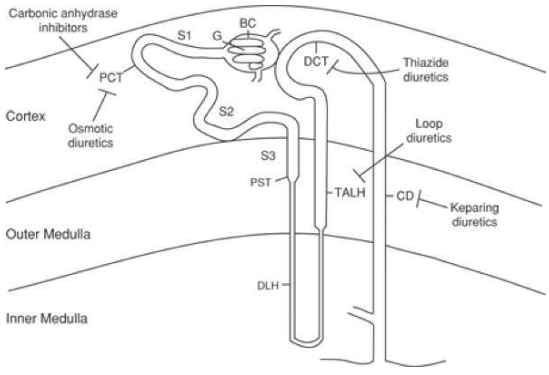


Fig. 27.1. The nephron. BC, Bowman's capsule; G, glomerulus; PCT, proximal convoluted tubule; PST, proximal straight tubule; DLH, descending limb of the Loop of Henle; TALH, thick ascending limb of the loop of Henle; DCT, distal convoluted tubule; CD, collecting duct.

The reabsorption of electrolytes and water also occurs isosmotically in the proximal straight tubule or pars recta (S3 segment, Fig. 27.1). By the end of the straight segment, between 65 and 70% of water and sodium, chloride, and calcium ions; 80 to 90% of bicarbonate and phosphate; and essentially 100% of glucose, amino acids, vitamins, and protein have been reabsorbed from the glomerular filtrate. The proximal tubule also is the site for active secretion of weakly acidic and weakly basic organic compounds. Thus, many of the diuretics can enter luminal fluid not only by filtration at the glomerulus but also by active secretion.

The descending limb of the loop of Henle is impermeable to ions, but water can freely move from the luminal fluid into the surrounding medullary interstitium, where the higher osmolality draws water into the interstitial space and concentrates luminal fluid. Luminal fluid continues to concentrate as it descends to the deepest portion of the loop of Henle, where the fluid becomes the most concentrated. The hypertonic luminal fluid next enters the water-impermeable, thick ascending limb of the loop of Henle. In this segment of the nephron, approximately 20 to 25% of the filtered sodium and chloride ions are reabsorbed via a cotransport system ($Na^+/K^+/2Cl^-$) on the luminal membrane. Reabsorption of sodium and chloride in the medullary portion of the thick ascending limb is important for maintaining the medullary interstitial concentration gradient. Reabsorption of sodium chloride in the cortical component of the thick ascending limb of the loop of Henle and the early distal convoluted tubule contributes to urinary dilution, and as a result, these two nephron sections sometimes are called the cortical diluting segment of the nephron.

P.724

Luminal fluid leaving the early distal tubule next passes through the late distal tubule and cortical collecting tubule (collecting duct), where sodium is reabsorbed in exchange for hydrogen and potassium ions. This process is partially controlled by mineralocorticoids (e.g., aldosterone) and accounts for the reabsorption of between 2 and 3% of filtered sodium ions. Although the reabsorption of sodium ions from these segments of the nephron is not large, this sodium/potassium/hydrogen ion exchange system determines the final acidity and potassium content of urine. Several factors, however, can influence the activity of this exchange system, including the amount of sodium ions delivered to these segments, the status of the acid-base balance in the body, and the levels of circulating aldosterone.

The urine formed during this process represents only approximately 1 to 2% of the original glomerular filtrate, with more than 98% of electrolytes and water filtered at the glomerulus being reabsorbed during passage through the nephron. Thus, a change in urine output of only 1 to 2% could double urine volume. Urine leaves the kidney through the ureters and travels to the bladder, where it is stored until urination removes the it from the body.

Normal Regulation of Urine Formation

The body contains several control mechanisms that regulate the volume and contents of urine. These systems are activated by changes in solute or water content of the body, by changes in systemic or renal blood pressure, and by a variety of other stimuli. Activation of one or more of these systems by diuretic drugs can modify the effectiveness of these drugs to produce their therapeutic response and may require additional therapeutic measures to ensure a maximal response.

The kidney has the ability to respond to changes in the GFR through the action of specialized distal tubular epithelial cells called the macula densa. These cells are in close contact with the glomerular apparatus of the same nephron and detect changes in the rate of urine flow and luminal sodium chloride concentration. An increase in the urine flow rate at this site (as can occur with the use of some diuretics) activates the macula densa cells to communicate with the granular cells and vascular segments of the juxtaglomerular apparatus. Stimulation of the juxtaglomerular apparatus causes renin to be released, which leads to the formation of angiotensin II and subsequent renal vasoconstriction. Renal vasoconstriction leads to a decrease in GFR and, possibly, a decrease in the effectiveness of the diuretic. Renin release also can be stimulated by factors other than diuretics, including decreased renal perfusion pressure, increased sympathetic tone, and decreased blood volume.

Another important regulatory mechanism for urine formation is antidiuretic hormone (ADH), also known as vasopressin, which is released from the posterior pituitary in response to reduced blood pressure and elevated plasma osmolality. In the kidney, ADH acts on the collecting tubule to increase water permeability and reabsorption. As a result, the urine becomes more concentrated, and water is conserved in the presence of ADH.

Disease States

The diuretic drugs are used primarily to treat two medically important conditions, edema and hypertension. Both conditions are common, although some patients exhibit refractory disease states that require additional modification of the drug regimen to include alternative diuretics or addition of nondiuretic drugs. Edema (excessive extracellular fluid) normally results from disease to the heart, kidney, or liver. Decreased cardiac function (e.g., congestive heart disease) can result in decreased perfusion of all organs (e.g., kidney) and limbs and an accumulation of edema fluid in the extremities, particularly around the ankles and in the hands. Left-sided heart failure can lead to the development of acute pulmonary edema, which is a medical emergency. Right-sided heart failure shifts extracellular fluid volume from the arterial circulation to the venous circulation, which leads to general edema formation.

Kidney dysfunction can lead to edema formation as a result of decreased formation of urine and the subsequent imbalance of water and electrolyte (e.g., sodium ion) homeostasis. Retention of salt and water results in an expansion of the extracellular fluid volume and, thus, edema formation. Thus, when salt intake exceeds salt excretion, edema can form. Edema formation also is associated with deceased protein levels in blood, as seen in nephrotic syndrome and liver disease. Cirrhosis of the liver leads to increased lymph in the space of Disse. Eventually, the increased lymph volume results in movement of fluid into the peritoneal cavity and ascites develops.

Hypertension develops from many causes and will be discussed in more detail elsewhere (see Chapter 29). In general, hypertension occurs when blood pressure is sustained at greater than 140/90 mm Hg. At this blood pressure level, patients are at increased risk for developing cardiovascular disease. One key element in controlling blood pressure is sodium ion, and early antihypertensive effects of diuretics are related to increased salt and water excretion. Additionally, however, diuretics have long-term effects resulting in decreased vascular resistance that contribute to blood pressure control. Although effects on vascular calcium-activated potassium channels have been proposed as contributing to the chronic antihypertensive effects of thiazide diuretics, the exact mechanisms of long term effects remain to be determined.

Diuretics also are useful in treating a number of other conditions including increased cranial (trauma or surgery) or intraocular (glaucoma) pressure (i.e., osmotic diuretics), diabetes insipidus (i.e., thiazides), hypercalcemia (i.e., loop diuretics), acute mountain sickness (i.e.,

P.725

carbonic anhydrase inhibitors), primary hyperaldosteronism (i.e., aldosterone antagonists), and osteoporosis (i.e., thiazides).

General Therapeutic Approaches

Diuretic drugs may be administered acutely or chronically to treat edematous states. When immediate action to reduce edema (e.g., acute pulmonary edema) is needed, intravenous administration of a loop diuretic often is the approach of choice. Thiazide or loop diuretics normally are administered orally to treat nonemergency edematous states. The magnitude of the diuretic response is directly proportional to the amount of edema fluid that is present. As the volume of edema decreases, so does the magnitude of the diuretic response with each dose. If concern exists about diuretic-induced hypokalemia developing, then a potassium supplement or potassium-sparing diuretic may be added to the drug regimen. The development of hypokalemia is particularly important for patients with congestive heart failure who also are taking cardiac glycosides, such as digitalis. Digitalis has a narrow therapeutic index, and developing hypokalemia can potentiate digitalis-induced cardiac effects with potentially fatal results.

Diuretic drugs (thiazide and loop diuretics) are administered orally to help control blood pressure in the treatment of hypertension. Diuretics often are the first drugs used to treat hypertension, and they also may be added to other drug therapies used to control blood pressure with beneficial effects.

Diuretic Drug Classes

History

Compounds that increase the urine flow rate have been known for centuries. One of the earliest substances known to induce diuresis is water, an inhibitor of ADH release. Calomel (mercurous chloride) was used as early as the 16th century as a diuretic, but because of poor absorption from the gastrointestinal tract and toxicity, calomel was replaced clinically by the organomercurials (e.g., chlormerodrin). The organomercurials represented the first group of highly efficacious diuretics available for clinical use. The need to administer these drugs parenterally, the possibility of tolerance, and their potential toxicity, however, soon led to the search for newer, less toxic diuretics. Today, the organomercurials are no longer used as diuretics, but their discovery began the search for many of the diuretics used today. Other compounds previously used as diuretics include the acid-forming salts (ammonium chloride) and methylxanthines (theophylline).

Structure Classification

The diuretics currently in use today (Table 27.1) are classified by their chemical class (thiazides), mechanism of action (carbonic anhydrase inhibitors and osmotics), site of action (loop diuretics), or effects on urine contents (potassium-sparing diuretics). These drugs vary widely in their efficacy (i.e., their ability to increase the rate of urine formation) and their site of action within the nephron. Efficacy often is measured as the ability of the diuretic to increase the excretion of sodium ions filtered at the glomerulus (i.e., the filtered load of sodium) and should not be confused with potency, which is the amount of the diuretic required to produce a specific diuretic response.

Efficacy is determined, in part, by the site of action of the diuretic. Drugs (e.g., carbonic anhydrase inhibitors) that act primarily on the proximal convoluted tubule to induce diuresis are weak diuretics because of the ability of the nephron to reabsorb a significant portion of the luminal contents in latter portions of the nephron. Likewise, drugs (potassium-sparing diuretics) that act at the more distal segments of the nephron are weak diuretics,

P.726

because most of the glomerular filtrate has already been reabsorbed in the proximal tubule and ascending limb of the loop of Henle before reaching the distal tubule. Thus, the most efficacious diuretics discovered so far, the high-ceiling or loop diuretics, interfere with sodium chloride reabsorption at the ascending limb of the loop of Henle, which is situated after the proximal tubule but before the distal portions of the nephron and collecting tubule.

Table 27.1. Diuretics: Sites and Mechanisms of Action

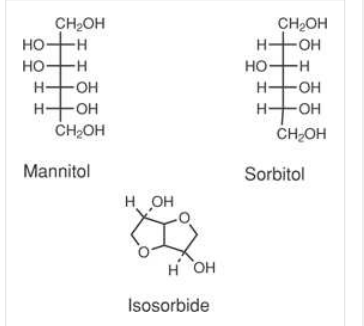
Class of Diuretic	Site of Action	Mechanism of Action
Osmotics	Proximal tubule	Osmotic effects decrease sodium and water reabsorption
	Loop of Henle	Increases medullary blood flow to decrease medullary hypertonicity and reduce sodium and water reabsorption
	Collecting tubule	Sodium and water reabsorption decreases because of reduced medullary hypertonicity and elevated urinary flow rate
Carbonic anhydrase inhibitors	Proximal convoluted tubule	Inhibition of renal carbonic anhydrase decreases sodium bicarbonate reabsorption
Thiazides and thiazide-like	Cortical portion of the thick ascending limb of loop of Henle and distal tubule	Inhibition of Na^+/Cl^- symporter
Loop or high-ceiling	Thick ascending limb of the loop of Henle	Inhibition of the luminal $Na^+/K^+/2Cl^-$ transport system
Potassium-sparing	Distal tubule and collecting duct	Inhibition of sodium and water reabsorption by: Competitive inhibition of aldosterone (spironolactone) Blockade of sodium channel at the luminal membrane (triamterene and amiloride)

Osmotic Diuretics

Mechanism of Action

Osmotic diuretics are low-molecular-weight compounds that are freely filtered through the Bowman's capsule into the renal tubules, are nonreabsorbable solutes, and are not extensively metabolized except for glycerin and urea (see Table 27.2) for their pharmacokinetic properties). Once in the renal tubule, osmotic diuretics have a limited reabsorption because of their high water solubility. When administered as a hypertonic (hyperosmolar) solution, these agents increase intraluminal osmotic pressure, causing water to pass from the body into the tubule. Since the osmotic agent and associated water are not reabsorbed from the nephron, a diuretic effect is observed. Osmotic diuretics increase the volume of urine and the excretion of water and almost all of the electrolytes.

Polyols, such as mannitol, sorbitol, and isosorbide, provide this effect. Sugars, such as glucose and sucrose, also can have a diuretic effect by this mechanism. Although not a polyol, urea has a similar osmotic effect and has been used in the past as an osmotic diuretic.



Therapeutic Applications

Osmotic diuretics are not frequently used in medicine today except in the prophylaxis of acute renal failure, in which these drugs inhibit water reabsorption and maintain

P.727

urine flow. They also may be helpful in maintaining urine flow in cases where urinary output is diminished because of severe bleeding or traumatic surgical experiences. The osmotic diuretics also have been used to acutely reduce increased intracranial or intraocular pressure. They are not considered to be primary diuretic agents in treating ordinary edemas, because osmotic diuretics can expand extracellular fluid volume.

Table 27.2. Pharmacokinetic Properties of the Nonthiazide Diuretics

Drug	Trade Name	Relative Potency	Oral Absorption (%)	Peak Plasma	Duration of Effect	Half-life	Route of Elimination
Osmotic diuretics							
Glycerin			>80	1–1.5 h	4–6 h	0.5–0.75 h	>90% metabolism
Isosorbide			>80	NA	NA	5–9.5 h	Urine unchanged
Mannitol			<20	1–3 h IV	3–8 h	1.5 h	Urine unchanged

Urea			<10	1–2 h IV	3–10 h	NA	Metabolized
Loop diuretics: high-ceiling diuretics							
Furosemide	Lasix	1	11–90a	4–5 h	6–8 h	0.5–4 h (>3 h)b	80% urine unchanged (20% metabolized)
Bumetanide	Bumex	40	80–100	<2 h	5–6 h	0.3–1.5 h (>3 h)b	50% urine unchanged 45% metabolized
Ethacrynic acid	Edecrin	0.7	>90	2 h	6–8 h	0.5–1 h	30–50% urine unchanged 30% mercapturate
Torsemide	Demadex	3	80–100%	NA	NA	0.8–4 h	30% urine 70% metabolized
Inhibitor of carbonic anhydrase							
Acetazolamide	Diamox		>90	1–3 h	NA	<6 h	Urine unchanged
Potassium-sparing diuretics (inhibitors of renal epithelial Na^1 channels)							
Amiloride	Midamor	1	~50a	3–4 h	10–24 h	6–9 h normal (21 h)b	50% urine unchanged
Triameterene	Dyrenium	0.1	>70	2–4 h	>24 h	2–3 h	Metabolized to active metabolites
Aldosterone antagonists; potassium-sparing diuretics (mineralocorticoid receptor antagonists)							
Spironolactone	Aldactone		>90c	1–2 h	2–3 d	1–3 h	Active metabolite
Canrenone			NA		13–24 h	3–4 h	Urine

Adverse Effects

Osmotic diuretics induce few adverse effects, but expansion of the extracellular fluid volume can occur, as noted above. Alteration of blood sodium levels can be seen, and these drugs should not be used in anuric or unresponsive patients. If cranial bleeding is present, mannitol or urea should not be used.

Specific Drugs

Mannitol

Mannitol is the agent most commonly used as an osmotic diuretic. Sorbitol also can be used for similar reasons. These compounds can be prepared by the electrolytic reduction of glucose or sucrose.

Mannitol is administered intravenously in solutions of 5 to 50% at a rate of administration that is adjusted to maintain the urinary output at 30 to 50 ml/hour. Mannitol is filtered at the glomerulus and is poorly reabsorbed by the kidney tubule. The osmotic effect of mannitol in the tubule inhibits the reabsorption of water, and the rate of urine flow can be maintained. It also is used to reduce intracranial pressure by reducing cerebral intravascular volume.

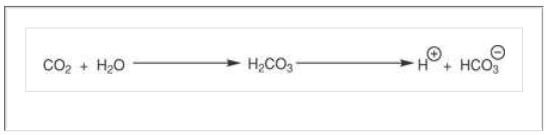
Isosorbide

Isosorbide is basically a bicyclic form of sorbitol that is used orally to cause a reduction in intraocular pressure in glaucoma cases. Although a diuretic effect is noted, its ophthalmologic properties are its primary value.

Carbonic Anhydrase Inhibitors

Mechanism of Action

In 1937, it was proposed that the normal acidification of urine was caused by secretion of hydrogen ions by the tubular cells of the kidney. These ions were provided by the action of the enzyme carbonic anhydrase, which catalyzes the formation of carbonic acid (H_2CO_3) from carbon dioxide and water.



It also was observed that sulfanilamide rendered the urine of dogs alkaline because of the inhibition of carbonic anhydrase. This inhibition of carbonic anhydrase resulted in a lesser exchange of hydrogen ions for sodium ions in the kidney tubule. Sodium ions, along with bicarbonate ions, and associated water molecules were then excreted, and a diuretic effect was noted. The large doses required and the side effects of sulfanilamide prompted a search for more effective carbonic anhydrase inhibitors as diuretic drugs.

It was soon learned that the sulfonamide portion of an active diuretic molecule could not be monosubstituted or disubstituted. It was reasoned that a more acidic sulfonamide would bind more tightly to the carbonic anhydrase enzyme. Synthesis of more acidic sulfonamides produced compounds more than 2,500-fold more active than sulfanilamide. Acetazolamide was introduced in 1953 as an orally effective diuretic drug. Before that time, the organic mercurials, which commonly required intramuscular injection, were the principal diuretics available.

Carbonic anhydrase inhibitors induce diuresis by inhibiting the formation of carbonic acid within proximal (proximal convoluted tubule; S2) and distal tubular cells to limit the number of hydrogen ions available to promote sodium reabsorption. For a diuretic response to be observed, more than 99% of the carbonic anhydrase must be inhibited. Although carbonic anhydrase activity in the proximal tubule regulates the reabsorption of approximately 20 to 25% of the filtered load of sodium, the carbonic anhydrase inhibitors are not highly efficacious diuretics. An increased excretion of only 2 to 5% of the filtered load of sodium is seen with carbonic anhydrase inhibitors because of increased reabsorption of sodium ions by the ascending limb of the loop of Henle and more distal nephron segments.

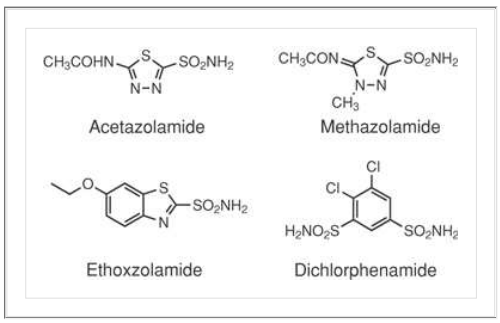
Therapeutic Applications

With prolonged use of the carbonic anhydrase inhibitor diuretics, the urine becomes more alkaline, and the blood becomes more acidic. When acidosis occurs, the carbonic anhydrase inhibitors lose their effectiveness as diuretics. They remain ineffective until normal acid-base balance in the body has been regained. For this reason, this class of compounds is limited in its diuretic use. Today, they are most commonly used in the treatment of glaucoma, in which they reduce the rate of aqueous humor formation and, subsequently, reduce the intraocular pressure. These compounds also have found some limited use in the treatment of absence seizures, to alkalinize the urine, to treat familial periodic paralysis, to reduce metabolic alkalosis, and prophylactically, to reduce acute mountain sickness.

Specific Drugs

Acetazolamide

Acetazolamide was the first of the carbonic anhydrase inhibitors to be introduced as an orally effective diuretic, with a diuretic effect that lasts approximately 8 to 12 hours (see Table 27.2 for its pharmacokinetic properties). As mentioned earlier, its diuretic action is limited because of the systemic acidosis it produces. Acetazolamide reduces the rate of aqueous humor formation and is used primarily for reducing intraocular pressure in the treatment of glaucoma. The dose is 250 mg to 1 g per day.



Glaucoma

The following carbonic anhydrase inhibitors are used orally in the treatment of glaucoma.

Methazolamide

Methazolamide is a derivative of acetazolamide in which one of the active hydrogens has been replaced by a methyl group. This decreases the polarity and permits a greater penetration into the ocular fluid, where it acts as a carbonic anhydrase inhibitor, reducing intraocular pressure. Its dose for glaucoma is 50 to 100 mg two to three times a day.

Ethoxzolamide and dichlorphenamide

Ethoxzolamide is another carbonic anhydrase inhibitor with properties and uses resembling those of acetazolamide. Dichlorphenamide is a disulfonamide derivative that shares the same pharmacological properties and clinical uses as the previously discussed compounds. The dose of dichlorphenamide is 25 to 100 mg one to three times a day.

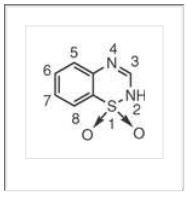
Benzothiadiazine or Thiazide Diuretics

Further study of the benzene disulfonamide derivatives was undertaken to find more efficacious carbonic anhydrase inhibitors. These studies provided some compounds with a high degree of diuretic activity. Chloro and amino substitution gave compounds with increased activity, but these compounds were weak carbonic anhydrase inhibitors. When the amino group was acylated, an unexpected ring closure took place. These compounds possessed a diuretic activity independent of the carbonic anhydrase inhibitory activity, and a new series of diuretics called the benzothiadiazines was discovered.

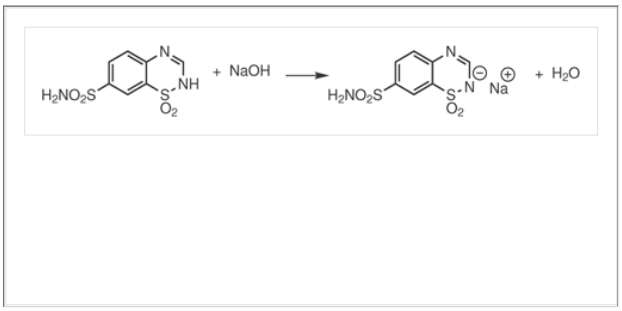
Mechanism of Action

The mechanism of action of the benzothiadiazine diuretics is primarily related to their ability to inhibit the Na^+/Cl^- symporter located in the distal convoluted tubule. These diuretics are actively secreted in the proximal tubule and are carried to the loop of Henle and to the distal tubule. The major site of action of these compounds is in the distal tubule, where these drugs compete for the chloride binding site of the Na^+/Cl^- symporter and inhibit the reabsorption of sodium and chloride ions. For this reason, they are referred to as saluretics. They also inhibit the reabsorption of potassium and bicarbonate ions, but to a lesser degree.

Structure–Activity Relationship



The thiazide diuretics are weakly acidic (see Appendix A for their pKa values), with a benzothiadiazine 1,1-dioxide nucleus. The structure for the thiazide diuretics, relative activities, and pharmacokinetic properties for the thiazides are shown in Table 27.3. Chlorothiazide is the simplest member of this series, having a pK_a of 6.7 and 9.5. The hydrogen atom at the 2-N is the most acidic because of the electron-withdrawing effects of the neighboring sulfone group. The sulfonamide group that is substituted at C-7 provides an additional point of acidity in the molecule but is less acidic than the 2-N proton. These acidic protons make possible the formation of a water-soluble sodium salt that can be used for intravenous administration of the diuretics.



An electron-withdrawing group is necessary at position 6 for diuretic activity. Little diuretic activity is seen with a hydrogen atom at position 6, whereas compounds with a chloro or trifluoromethyl substitution are highly active. The trifluoromethyl-substituted diuretics are more lipid-soluble and have a longer duration of action than their chloro-substituted analogues. When electron-releasing groups, such as methyl or methoxyl, are placed at position 6, the diuretic activity is markedly reduced.

Replacement or removal of the sulfonamide group at position 7 yields compounds with little or no diuretic activity. Saturation of the double bond to give a 3,4-dihydro derivative produces a diuretic that is 10-fold more active than the unsaturated derivative. Substitution with a lipophilic group at position 3 gives a marked increase in the diuretic potency. Haloalkyl, aralkyl, or thioether substitution increases the lipid solubility of the molecule and yields compounds with a longer duration of action. Alkyl substitution on the 2-N position also decreases the polarity and increases the duration of diuretic action. Although these compounds do have carbonic anhydrase activity, there is no correlation of this activity with their saluretic activity (excretion of sodium and chloride ions).

Therapeutic Applications

The thiazide diuretics are administered once a day or in divided daily doses. Some have a duration of action that permits administration of a dose every other day. Some of these compounds are rapidly absorbed orally and can show their diuretic effect in an hour (Table 27.3). These compounds are not extensively metabolized and are primarily

excreted unchanged in the urine. Thiazide diuretics are used to treat edemas caused by cardiac decompensation as well as in hepatic or renal disease. They also commonly are used in the treatment of hypertension. Their effect may be attributed to a reduction in blood volume and a direct relaxation of vascular smooth muscle.

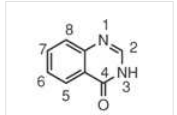
Adverse Effects

Thiazide diuretics may induce a number of adverse effects, including hypersensitivity reactions, gastric irritation, nausea, and electrolyte imbalances, such as hyponatremia, hypokalemia, hypomagnesemia, hypochloremic alkalosis, hypercalcemia, and hyperuricemia. Individuals who exhibit hypersensitivity reactions to one thiazide are likely to have a hypersensitivity reaction to other thiazides and sulfamoyl-containing diuretics (e.g., thiazide-like and some high-ceiling diuretics). Potassium and magnesium supplements may be administered to treat hypokalemia or hypomagnesemia, but their use is not always indicated. These supplements usually are administered as potassium chloride, potassium gluconate, potassium citrate, magnesium oxide, or magnesium lactate. The salts are administered as solutions, tablets, or timed-release tablets. Generally, approximately 20 mEq of potassium is given daily. In cases of hypokalemia, 40 to 100 mEq/day may be administered. Potassium-sparing diuretics (e.g., triamterene or amiloride) also may be used to prevent hypokalemia. Combination preparation of hydrochlorothiazide or a potassium-sparing diuretic are available (e.g., Diazide and Moduretic).

Long-term use of thiazide diuretics also may result in decreased glucose tolerance and increased blood lipid (low-density lipoprotein cholesterol, total cholesterol, and total triglyceride) content.

Quinazolinone Derivatives—Quinethazone and Metolazone



Overview

The quinazolin-4-one molecule has been structurally modified in a manner similar to the modification of the thiazide diuretics. Quinethazone and metolazone (pK_a = 9.7) are examples of this class (Table 27.4). The structural difference between the quinazolinone diuretics is the replacement of the 4-sulfone group (–SO_2–), with a 4-keto group (–CO–).

Because of their similar structures, it is not surprising that the quinazolinones have a diuretic effect similar to that of the thiazides.

Mechanism of Action and Therapeutic Applications

The pharmacokinetic properties for the quinazolinone diuretics are listed in Table 27.4. They have a long duration of action, usually as a result of protein binding. Although chlorothiazide has a duration of action of 6 to 12

hours, quinethazone a duration of 18 to 24 hours, and metolazone a duration of 12 to 24 hours. Metolazone has a bioavailability of 65% (Zaroxolyn) and a prolonged onset to reach peak plasma concentrations of action ranging from 8 to 12 hours. When reformulated as for Mykrox™, however, metolazone is almost completely absorbed, with peak plasma concentrations reached in 2 to 4 hours. Thus, other versions of metolazone cannot be interchanged with Mykrox. Approximately 50 to 70% of metolazone is bound to carbonic anhydrase in the erythrocytes. Metolazone also has an increased potency, and the mode of action for both compounds is similar to that of the thiazide derivatives. In contrast to thiazide diuretics, metolazone may be effective as a diuretic when the GFR falls below 40 mL/min. The dose of quinethazone is 50 to 100 mg daily and that of metolazone 2.5 to 20 mg given as a single oral dose. Side effects are similar to adverse effects induced by the thiazide diuretics.

Table 27.4. Pharmacokinetic Properties for the Thiazide-Like Diuretics

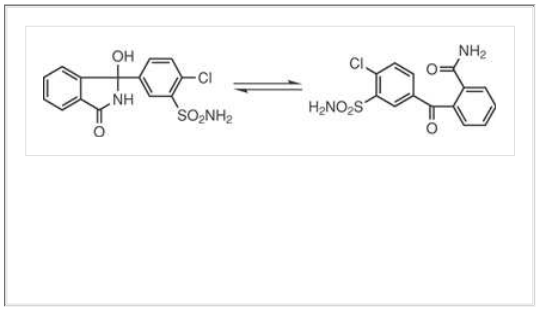
Table 27.4. Pharmacokinetic Properties for the Thiazide-Like Diuretics

Phthalimidine Derivatives—Chlorthalidone

Overview

Chlorthalidone (pK_a = 9.4) is an example of a diuretic in this class of compounds that bears a structural analogy to the quinazolinones (Table 27.4). This compound may be named as a 1-oxo-isoindoline or a phthalimidine. Although the molecule exists primarily in the phthalimidine form, the ring may be opened to form a benzophenone derivative.

The benzophenone form illustrates the relationship to the quinazolinone series of diuretics. It may be regarded as an open ring variation.



Therapeutic Application

Chlorthalidone has a long duration of action (48–72 hours) (see Table 27.3 for its other pharmacokinetic properties). Although quinethazone and metolazone are administered daily, chlorthalidone may be administered in doses of 25 to 100 mg three times a week. When chlorthalidone is formulated with the excipient povidone, the product, Thalitone, has greater bioavailability (>90%) and reaches peak plasma concentrations in a shorter time compared with its other products. Similar to the quinazolinones, it also is extensively bound to carbonic anhydrase in the erythrocytes. Chlorthalidone-induced effects on urine content and side effects are similar to those induced by thiazide diuretics.

Indolines—Indapamide

Mechanism of Action

The prototypic indoline diuretic is indapamide, which was reported as a diuretic in 1984. Indapamide contains a polar chlorobenzamide moiety and a nonpolar lipophilic methylindoline group. In contrast to the thiazides, indapamide does not contain a thiazide ring, and only one sulfonamide group is present within the molecular structure (pK_a = 8.8). It is rapidly and completely absorbed from the gastrointestinal tract and reaches its peak plasma level in 2 to 3 hours, with a duration of action of up to 8 weeks. This prolonged duration of action is associated with its extensive binding to carbonic anhydrase in the erythrocytes. It exhibits biphasic kinetics, with a half-life of 14 to 18 hours and an elimination half-life of 24 hours. Indapamide is extensively metabolized, with 60 to 70% of the oral dose being eliminated in the urine as glucuronide and sulfate metabolites and less than 10% being excreted unchanged. The remaining 20 to 30% is eliminated via extrahepatic cycling.

Therapeutic Application

Uses of indapamide include the treatment of essential hypertension and edema resulting from congestive heart failure. Like metolazone, indapamide is an effective diuretic drug when GFR falls below 40 mL/min. The duration of action is approximately 24 hours, with the normal oral adult dosage starting at 2.5 mg given each morning. The dose may be increased to 5.0 mg/day, but doses beyond this level do not appear to provide additional results. Effects on urine content and side effects are similar to effects induced by thiazide diuretics.

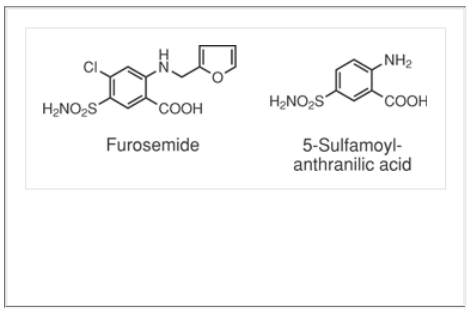
High-Ceiling or Loop Diuretics

Mechanism of Action

This class of drugs is characterized more by its pharmacological similarities than by its chemical similarities. These diuretics produce a peak diuresis much greater than that observed with the other commonly used diuretics, hence the name high-ceiling diuretics. Their main site of action is believed to be on the thick ascending limb of the loop of Henle, where they inhibit the luminal $Na^+/K^+/2Cl^-$ symporter. These diuretics are commonly referred to as loop diuretics. Additional effects on the proximal and distal tubules also are possible. High-ceiling diuretics are characterized by a quick onset and short duration of activity. Their diuretic effect appears in approximately 30 minutes and lasts for approximately 6 hours. The pharmacokinetic properties for the loop diuretics are listed in Table 27.2.

Specific Drugs

Furosemide



Structure–Activity Relationships

Furosemide is an example of a high-ceiling diuretic and may be regarded as a derivative of anthranilic acid or o-aminobenzoic acid.

P.732

Research on 5-sulfamoylanthranilic acids at the Hoechst Laboratories in Germany showed them to be effective diuretics. The most active of a series of variously substituted derivatives was furosemide.

The chlorine and sulfonamide substitutions are features also seen in previously discussed diuretics. Because the molecule possesses a free carboxyl group, furosemide is a stronger acid than the thiazide diuretics (pK_a = 3.9). This drug is excreted primarily unchanged. A small amount of metabolism, however, can take place on the furan ring, which is substituted on the aromatic amino group (see Table 27.2 for its other pharmacokinetic properties).

Therapeutic Applications

Furosemide has a saluretic effect 8- to 10-fold that of the thiazide diuretics; however, it has a shorter duration of action (~6–8 hours). Furosemide causes a marked excretion of sodium, chloride, potassium, calcium, magnesium, and bicarbonate ions, with as much as 25% of the filtered load of sodium excreted in response to initial treatment. It is effective for the treatment of edemas connected with cardiac, hepatic, and renal sites. Because it lowers the blood pressure similar to the thiazide derivatives, one of its uses is in the treatment of hypertension.

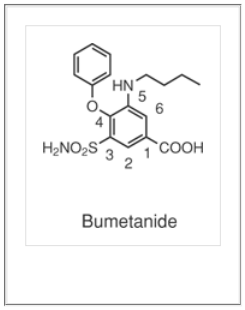
Furosemide is orally effective but may be used parenterally when a more prompt diuretic effect is desired, such as in the treatment of acute pulmonary edema. The

dosage of furosemide, 20–80 mg/day, may be given in divided doses because of the short duration of action of the drug and carefully increased up to a maximum of 600 mg/day.

Adverse Effects

Clinical toxicity of furosemide and other loop diuretics primarily involves abnormalities of fluid and electrolyte balance. As with the thiazide diuretics, hypokalemia is an important adverse effect that can be prevented or treated with potassium supplements or coadministration of potassium-sparing diuretics. Increased calcium ion excretion can be a problem for postmenopausal osteopenic women, and furosemide generally should not be used in these individuals. Hyperuricemia, glucose intolerance, increased serum lipid levels, ototoxicity, and gastrointestinal side effects might be observed as well. Hypersensitivity reactions also are possible with furosemide (a sulfonamide-based drug), and cross-reactivity with other sulfonamide containing drugs is possible.

Bumetanide



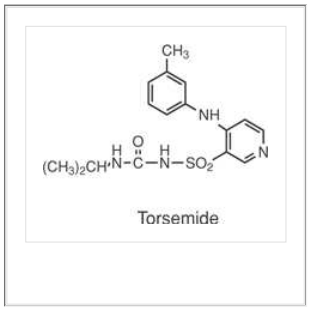
Therapeutic Applications

A diuretic structurally related to furosemide is bumetanide. This compound also functions as a high-ceiling diuretic in the ascending limb of the loop of Henle. It has a duration of action of approximately 4 hours. The uses of this compound are similar to those described for furosemide. The dose of bumetanide is 0.5 to 2 mg/day given as a single dose. Adverse effects are similar to those induced by furosemide.

Structure–Activity Relationships

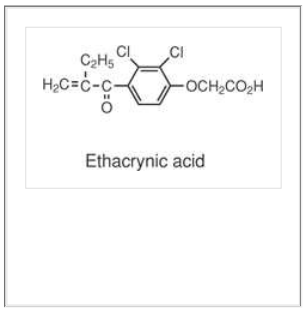
For bumetanide, a phenoxy group has replaced the customary chloro or trifluoromethyl substitutions seen in other diuretic molecules. The phenoxy group is an electron-withdrawing group similar to the chloro or trifluoromethyl substitutions. The amine group customarily seen at position 6 has been moved to position 5. These minor variations from furosemide produced a compound with a mode of action similar to that of furosemide, but with a marked increase in diuretic potency. The short duration of activity is similar, but the compound is approximately 50-fold more potent. Replacement of the phenoxy group at position 4 with a C_6H_5NH- or C_6H_5S- group also gives compounds with a favorable activity. When the butyl group on the C-5 amine is replaced with a furanylmethyl group, such as in furosemide; however, the results are not favorable.

Torsemide



Further modification of furosemide-like structures has led to the development of torsemide. Instead of the sulfonamide group found in furosemide and bumetanide, torsemide contains a sulfonylurea moiety. Similar to other high-ceiling diuretics, torsemide inhibits the luminal $Na^1/K^1/2Cl^-$ symporter in the ascending limb of the loop of Henle to promote the excretion of sodium, potassium, chloride, calcium, and magnesium ions and water. An additional effect on the peritubular side at chloride channels may enhance the luminal effects of torsemide. In contrast to furosemide and bumetanide, however, torsemide does not act at the proximal tubule and, therefore, does not increase phosphate or bicarbonate excretion. Peak diuresis is observed 1 to 2 hours following oral or intravenous administration, with a duration of action of approximately 6 hours. Torsemide is indicated for the treatment of edema resulting from congestive heart failure and for the treatment of hypertension. In patients with cirrhosis and ascites, Torsemide should be used with caution. Adverse effects are similar to those induced by furosemide.

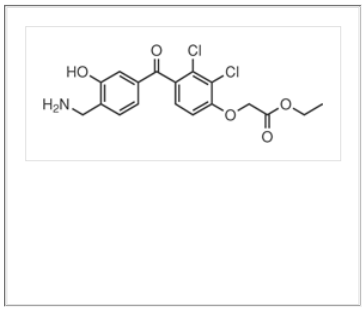
Ethacrynic acid



Mechanism of Action

Another major class of high-ceiling diuretics is the phenoxyacetic acid derivatives, of which ethacrynic acid is the prototypical agent. These compounds were developed at about the same time as furosemide but were designed to act mechanistically similar to the organomercurials (i.e., via inhibition of sulfhydryl-containing enzymes involved in solute reabsorption). The mechanism of action of ethacrynic acid appears to be more complex than the simple addition of sulfhydryl groups of the enzyme to the drug molecule. When the double bond of ethacrynic acid is reduced, the resultant compound is still active, although the diuretic activity is diminished. The sulfhydryl groups of the enzyme would not be expected to add to the drug molecule in the absence of the α,β-unsaturated ketone. The pharmacokinetic properties for ethacrynic acid are listed in Table 27.2.

In 1984, a new series of diuretics was reported (2,3). The following substance is representative of this series:



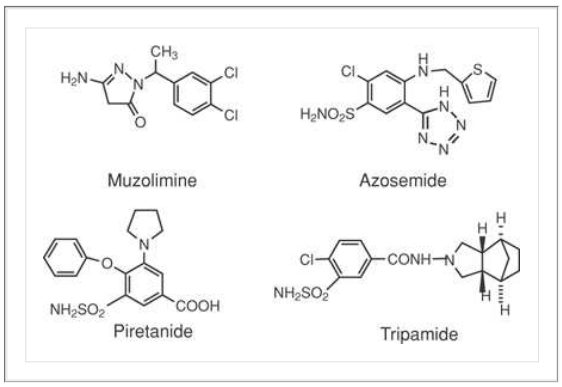
These compounds are potent high-ceiling diuretics that resemble ethacrynic acid in their mechanism of action. The ethyl ester group represents a pro-drug that can be easily hydrolyzed to the free carboxyl group. As in ethacrynic acid, a 2,3-dichloro substitution is necessary. In addition, a para-hydroxyl group and an unsubstituted aminomethyl group on the benzene ring are highly beneficial. The carbonyl group can be replaced with an ether or sulfide group. These compounds have no ability to add the sulfhydryl groups of the kidney enzymes. The complete mechanism of action of these compounds remains in doubt.

Similar to the other high-ceiling diuretics, ethacrynic acid inhibits the $Na^1/K^1/2Cl^-$ symporter in the ascending limb of the loop of Henle to promote a marked diuresis. Sodium, chloride, potassium, and calcium excretion are increased following oral or intravenous administration of ethacrynic acid. Oral administration of ethacrynic acid results in diuresis within 1 hour and a duration of action of 6 to 8 hours. Toxicity induced by ethacrynic acid is similar to that induced by furosemide and bumetanide. Ethacrynic acid is not widely used, however, because it induces a greater incidence of ototoxicity and more serious gastrointestinal effects than those of furosemide or bumetanide.

Structure–Activity Relationship

Optimal diuretic activity was obtained when an oxyacetic acid group was positioned para to an α,β-unsaturated carbonyl (or other sulfhydryl-reactive group) and chloro or methyl groups were placed at the 2- or 3-position of the phenyl ring. In addition, hydrogen atoms on the terminal alkene carbon also provided maximum reactivity. Thus, a molecule with a weakly acidic group to direct the drug to the kidney and an alkylating moiety to react with sulfhydryl groups and lipophilic groups seemed to provide the best combination for a diuretic in this class. These features led to the development of ethacrynic acid as the prototypic agent in this class.

New drugs



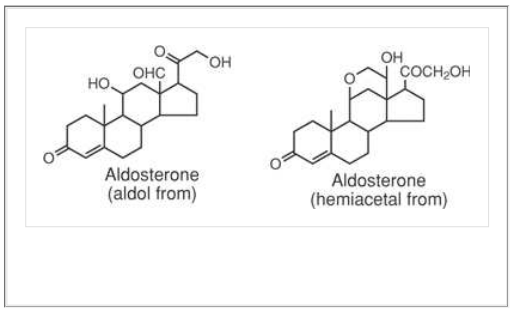
Four additional high-ceiling diuretics are azosemide, muzolimine, piretanide, and tripamide. Azosemide has low oral bioavailability (~10–15%) because of high first-pass metabolism in the liver, whereas piretanide has comparable pharmacokinetics to bumetanide.

As can be seen by these varied structures, the high-ceiling diuretics are characterized more by their pharmacological similarities than by their chemical similarities.

Potassium-Sparing Diuretics (Mineralocorticoid Receptor Antagonists)—Antihormone Diuretics

Mechanism of Action

The adrenal cortex secretes a potent mineralocorticoid called aldosterone, which promotes salt and water retention and potassium and hydrogen ion excretion.

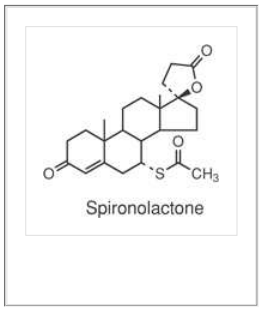


Other mineralocorticoids have an effect on the electrolytic balance of the body, but aldosterone is the most potent. Its ability to cause increased reabsorption of sodium and chloride ion and increased potassium ion excretion is approximately 3,000-fold that of hydrocortisone. A substance that antagonizes the effects of aldosterone could conceivably be a good diuretic drug. Spironolactone is such an antagonist.

Specific Drugs

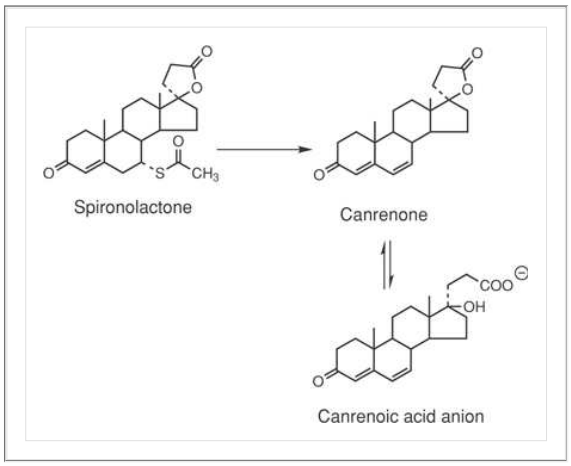
Spironolactone

Spironolactone is a competitive antagonist to the mineralocorticoids, such as aldosterone. The mineralocorticoid receptor is an intracellular protein that can bind aldosterone. Spironolactone binds to the receptor and competitively inhibits aldosterone binding to the receptor. The inability of aldosterone to bind to its receptor prevents reabsorption of sodium and chloride ions and the associated water. The most important site of these receptors is in the late distal convoluted tubule and collecting system (collecting duct).



Metabolism

On oral administration, approximately 90% of the dose of spironolactone is absorbed and is significantly metabolized during its first passage through the liver to its major active metabolite, canrenone (see Table 27.2 for their pharmacokinetic properties), which is interconvertible with its canrenoate anion. Canrenone is an antagonist to aldosterone.



The canrenoate anion is not active per se but acts as an aldosterone antagonist because of its conversion to canrenone, which exists in the lactone form. Canrenone has been suggested to be the active form of spironolactone as an aldosterone antagonist. The formation of canrenone, however, cannot fully account for the total activity of spironolactone. Both canrenone and potassium canrenoate are used as diuretics in other countries, but they are not yet available in the United States.

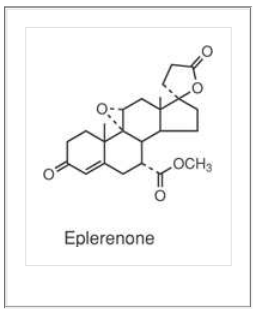
Therapeutic Applications

Spironolactone is useful in treating edema resulting from primary hyperaldosteronism and refractory edema associated with secondary hyperaldosteronism. Spironolactone is considered to be the drug of choice for treating edema resulting from cirrhosis of the liver. The dose of spironolactone is 100 mg/day given in single or divided doses. Another use of spironolactone is coadministration with a potassium-depleting diuretic (e.g., a thiazide or loop diuretic) to prevent or treat diuretic-induced hypokalemia. Spironolactone can be administered in a fixed-dose combination with hydrochlorothiazide for this purpose, but optimal individualization of the dose of each drug is recommended.

Adverse Effects

The primary concern with the use of spironolactone is the development of hyperkalemia, which can be fatal. Spironolactone may cause hypersensitivity reactions, gastrointestinal disturbances, peptic ulcer, gynecomastia, decreased libido, and impotence. It also has been implicated in tumor production during chronic toxicity studies in rats, but human risk has not been documented.

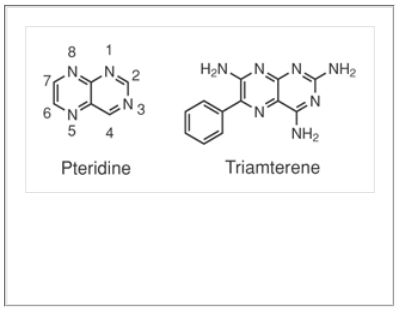
Eplerenone



A newer drug, eplerenone, has a structure similar to that of spironolactone and a similar mechanism of action. It was initially approved for use in the treatment of hypertension but it can now be used in the treatment of patients with left ventricular systolic dysfunction and congestive heart failure after myocardial infarction. It has a half-life of approximately 5 hours and undergoes hepatic metabolism to inactive metabolites as its main route of elimination. Clinical experience with eplerenone is currently limited.

Pteridines—Triamterene

Pteridines have a marked potential for influencing biological processes. Early screening of pteridine derivatives revealed that 2,4-diamino-6,7-dimethylpteridine was a fairly potent diuretic. Further structural modification led to the development of triamterene.



Mechanism of action

Triamterene interferes with the process of cationic exchange by blocking luminal sodium channels in the late distal convoluted tubule and collecting duct. Sodium channel inhibitors block the reabsorption of sodium ion and inhibit the secretion of potassium ion. Aldosterone is not antagonized by triamterene. The net result is increased sodium and chloride ion excretion

P.735

in the urine and almost no potassium excretion. Triamterene is more than 70% absorbed on oral administration (see Table 27.2 for its other pharmacokinetic properties). The diuretic effect occurs rapidly (~30 minutes) and reaches a peak plasma concentration in 2 to 4 hours, with a duration of action of more than 24 hours. Triamterene is extensively metabolized, and some of the metabolites are active as diuretics. Both the drug and its metabolites are excreted in the urine.

Structure–activity relationships

Modifications of the triamterene structure are not usually beneficial in terms of diuretic activity. Activity is retained if an amine group is replaced with a lower alkylamine group. Introduction of a para-methyl group on the phenyl ring decreases the activity by approximately half. Introduction of a para-hydroxyl group on the phenyl ring yields a compound that is essentially inactive as a diuretic.

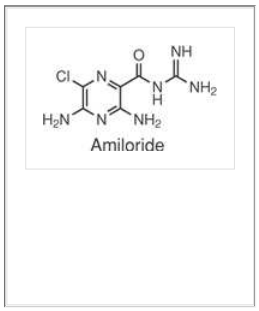
Therapeutic applications

Triamterene is useful in combination with a thiazide or loop diuretic in the treatment of edema or hypertension. Liddle's syndrome also may be treated with a sodium channel blocking drug, such as triamterene. Triamterene is administered initially in doses of 100 mg twice a day. A maintenance dose for each patient should be individually determined. This dose may vary from 100 mg a day to as low as 100 mg every other day.

Adverse effects

The most serious side effect associated with the use of triamterene is hyperkalemia. For this reason, potassium supplements are contraindicated, and serum potassium levels should be checked regularly. Triamterene also is used in combination with hydrochlorothiazide. Here, the hypokalemic effect of the hydrochlorothiazide counters the hyperkalemic effect of the triamterene. Other side effects that are seen with the use of triamterene are nausea, vomiting, and headache.

Aminopyrazines—Amiloride



Amiloride, another potassium-sparing diuretic, is an aminopyrazine structurally related to triamterene as an open-chain analogue. Similar to triamterene, it interferes with the process of cationic exchange in the distal convoluted tubule by blocking luminal sodium channels. It blocks the reabsorption of sodium ion and the secretion of potassium ion. It has no effect on the action of aldosterone. Oral amiloride is approximately 50% absorbed (see Table 27.2 for its other pharmacokinetic properties), with a duration of action of 10 to 12 hours, which is slightly longer than that for triamterene. Although triamterene is extensively metabolized, approximately 50% of amiloride is excreted unchanged. Renal impairment can increase its elimination half-life. Like triamterene, amiloride combined with a thiazide or loop diuretic is used to treat edema or hypertension. Aerosolized amiloride has shown some benefit in improving mucociliary clearance in patients with cystic fibrosis. As with triamterene, the most serious side effect associated with amiloride is hyperkalemia, and it also has the other side effects associated with triamterene. The dose of amiloride is 5 to 10 mg per day. Amiloride also is combined with hydrochlorothiazide in a fixed-dose combination.

P.736

Therapeutic Application of Diuretics

BD is a 67-year-old man who was admitted with a complaint of shortness of breath that has increased over the last few months. He also indicated that he has recently gained more than 12 pounds without changing his eating or exercise habits and that he often has trouble breathing when climbing stairs at home. Physical examination reveals signs and symptoms consistent with both right-sided (systemic edema, hepatomegaly, neck vein distension) and left-sided (weakness, fatigue, rales, cyanosis) heart failure. A diagnosis of congestive heart failure (CHF) is established, and a decision is made to limit sodium intake (low sodium diet) and to initiate oral therapy with digitalis to improve heart function. A diuretic also will be added to help remove edema fluid and decrease the workload on the heart. What diuretics would be appropriate to use in this patient?

ANSWER:

Selection of a diuretic would be based on the drug's ability to mobilize edema fluid and to help reduce the workload on the heart. Thiazide and loop (high-ceiling) diuretics are effective in mobilizing edema fluid and could be used in this patient. Osmotic diuretics are not effective at mobilizing edema fluid and will expand extracellular fluid, which would worsen the workload on the heart. Carbonic anhydrase inhibitors are weak diuretics and would not provide adequate diuresis to effectively reduce the workload on the heart. Potassium-sparing diuretics also are less effective than thiazides or loop diuretics in mobilizing edema fluid and would not be a diuretic of first choice in this patient.

Choosing between a thiazide or a loop diuretic depends on many factors, including the amount of edema present, severity of symptoms, and the patient's renal function. Loop diuretics (e.g., furosemide and torsemide) are more efficacious than thiazides and can remove edema fluid faster than thiazides can, thus providing quicker relief. Loop diuretics also have direct effects on the pulmonary venous system to help improve pulmonary symptoms related to the failing heart. Additionally, however, loop diuretics can cause more dramatic imbalances in extracellular volume and electrolyte levels than thiazides can, and loop diuretics can alter these levels sooner than with thiazide use. Thus, loop diuretics should be employed when moderate to severe CHF is present, but thiazides may be preferred when mild CHF is present. Because this patient has moderate to severe symptoms, furosemide is chosen as the diuretic to use in this patient.

If BD had been seen when his CHF was mild but his renal function was already impaired (glomerular filtration rate [GFR], 25 mL/min), how would these circumstances affect your selection of a diuretic?

ANSWER:

Although a thiazide diuretic normally would be the diuretic of choice in treating mild CHF, a thiazide generally is less effective in patients with

renal insufficiency. Thiazides can reach their site of action (the luminal sodium ion–chloride ion transporter of the distal convoluted tubule) following filtration at the glomerulus. The amount of drug filtered at the glomerulus depends on the extent of plasma protein binding for that drug. In addition, because thiazides are weakly acidic drugs (pK_a, 7.0–9.0), they are substrates for active secretion by the organic anion transport system of the proximal tubular cells. With the exception of metolazone and indapamide, however, most thiazides are ineffective as diuretics when the GFR is 30 to 40 mL/min (normal GFR, 125 mL/min).

Loop diuretics reach their site of action (luminal sodium ion–potassium ion–2 chloride ion transporter of the ascending limb of the loop of Henle) primarily via active secretion by the organic anion transport system of proximal tubular cells. As stronger organic acids than thiazide diuretics (e.g., pK_a of furosemide 5 4.7), loop diuretics are good substrates for secretion. Extensive plasma protein binding by these drugs limits their access to the lumina of nephrons via filtration. Thus, a marked reduction in GFR does not limit access of loop diuretics to tubular lumina or markedly alter the therapeutic efficacy of these drugs. As a result, a loop diuretic would still be a preferred choice for treating BD if his CHF had been mild but his renal function reduced.

Following 6 weeks on his low-salt diet and drug therapy, BD's condition seems to be greatly improved. His serum potassium levels, however, have decreased from 4.2 to 3.1 mEq/L (normal value, 3.8–5.6 mEq/L). What caused his serum potassium levels to decrease over time? Why is this change a concern? What can be done to remedy this problem?

Answer

One of the major side effects of using a loop diuretic is excessive excretion of electrolytes, including potassium ions. Loss of potassium can eventually lead to hypokalemia (low blood potassium), and hypokalemia alone can lead to the development of cardiac arrhythmias. Potassium loss, however, also potentiates the actions of digitalis (cardiac sodium–potassium–adenosine triphosphatase inhibition) and can lead to digitalis-induced cardiac arrhythmias as well. Hypokalemia can be treated/prevented by the use of potassium supplements or the use of a potassium-sparing diuretic (e.g., triamterene and amiloride). Because potassium-sparing diuretics are weakly basic drugs, they do not alter the active secretion of loop diuretics.

Case Study

Victoria F. Roche

S. William Zito

You often eat lunch with your favorite grandma, who is 85 years old and generally in good health except for infrequent bouts of gout. During the last few years when you meet with her, you have noticed that she has been gaining weight around her middle and that her legs and ankle seem to be puffy. During your most recent lunch date, grandma shares with you a problem she has been having at night. It doesn't happen every night, but every now and then she wakes gasping for air, which requires her to get out of bed and open the window to get relief. She has taken to propping herself up using two or three pillows to get back to sleep. The next day, you accompany grandma to the family doctor, who based on physical examination and a chest radiograph makes a diagnosis of mild (New York Heart Association [NYHA] Functional Classification of Class II) congestive heart failure (CHF). A recommendation is made to limit sodium intake, institute a regimen of exercise and initiate diuretic therapy to remove pulmonary and pedal edema fluid, and decrease the workload on grandma's heart. The doctor knows you are a pharmacy student who likes medicinal chemistry and asks you to make an appropriate choice from structures 1 to 4.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.

Chapter 28

Angiotensin-Converting Enzyme Inhibitors, Antagonists and Calcium Blockers

Marc Harrold

The Renin-Angiotensin Pathway

The renin-angiotensin system is a complex, highly regulated pathway that is integral in the regulation of blood volume, electrolyte balance, and arterial blood pressure. It consists of two main enzymes, renin and angiotensin-converting enzyme (ACE), the primary purpose of which is to release angiotensin II from its endogenous precursor, angiotensinogen (Fig. 28.1). Angiotensin II is a potent vasoconstrictor that affects peripheral resistance, renal function, and cardiovascular structure (1).

History and Overview of Pathway

Historically, the renin-angiotensin system dates back to 1898, when Tiegerstedt and Bergman demonstrated the existence of a pressor substance in crude kidney extracts. A little over 40 years later, two independent research groups discovered that this pressor substance, which had previously been named renin, actually was an enzyme and that the true pressor substance was a peptide formed by the catalytic action of renin. This peptide pressor substance initially was assigned two different names, angiotonin and hypertensin; however, these names eventually were combined to produce the current designation, angiotensin. In the 1950s, it was discovered that angiotensin exists as both an inactive decapeptide, angiotensin I, and an active octapeptide, angiotensin II, and that the conversion of angiotensin I to angiotensin II is catalyzed by an enzyme distinct from renin (3).

Angiotensinogen is an α_2-globulin with a molecular weight of 58,000 to 61,000 daltons. It contains 452 amino acids, is abundant in the plasma, and is continually synthesized and secreted by the liver. A number of hormones, including glucocorticoids, thyroid hormone, and angiotensin II, stimulate its synthesis. The most important portion of this compound is the N-terminus, specifically

the Leu_{10}-Val_{11} bond. This bond is cleaved by renin and produces the decapeptide angiotensin I. The Phe_8-His_9 peptide bond of angiotensin I is then cleaved by ACE to produce the octapeptide angiotensin II. Aminopeptidase can further convert angiotensin II to the active heptapeptide angiotensin III by removing the N-terminal arginine residue. Further actions of carboxypeptidases, aminopeptidases, and endopeptidases result in the formation of inactive peptide fragments. An additional compound can be formed by the action of a prolyl-endopeptidase on angiotensin I. Cleavage of the Pro_7-Phe_8 bond of angiotensin I produces a heptapeptide known as angiotensin 1-7. The actions of all of these compounds are discussed below.

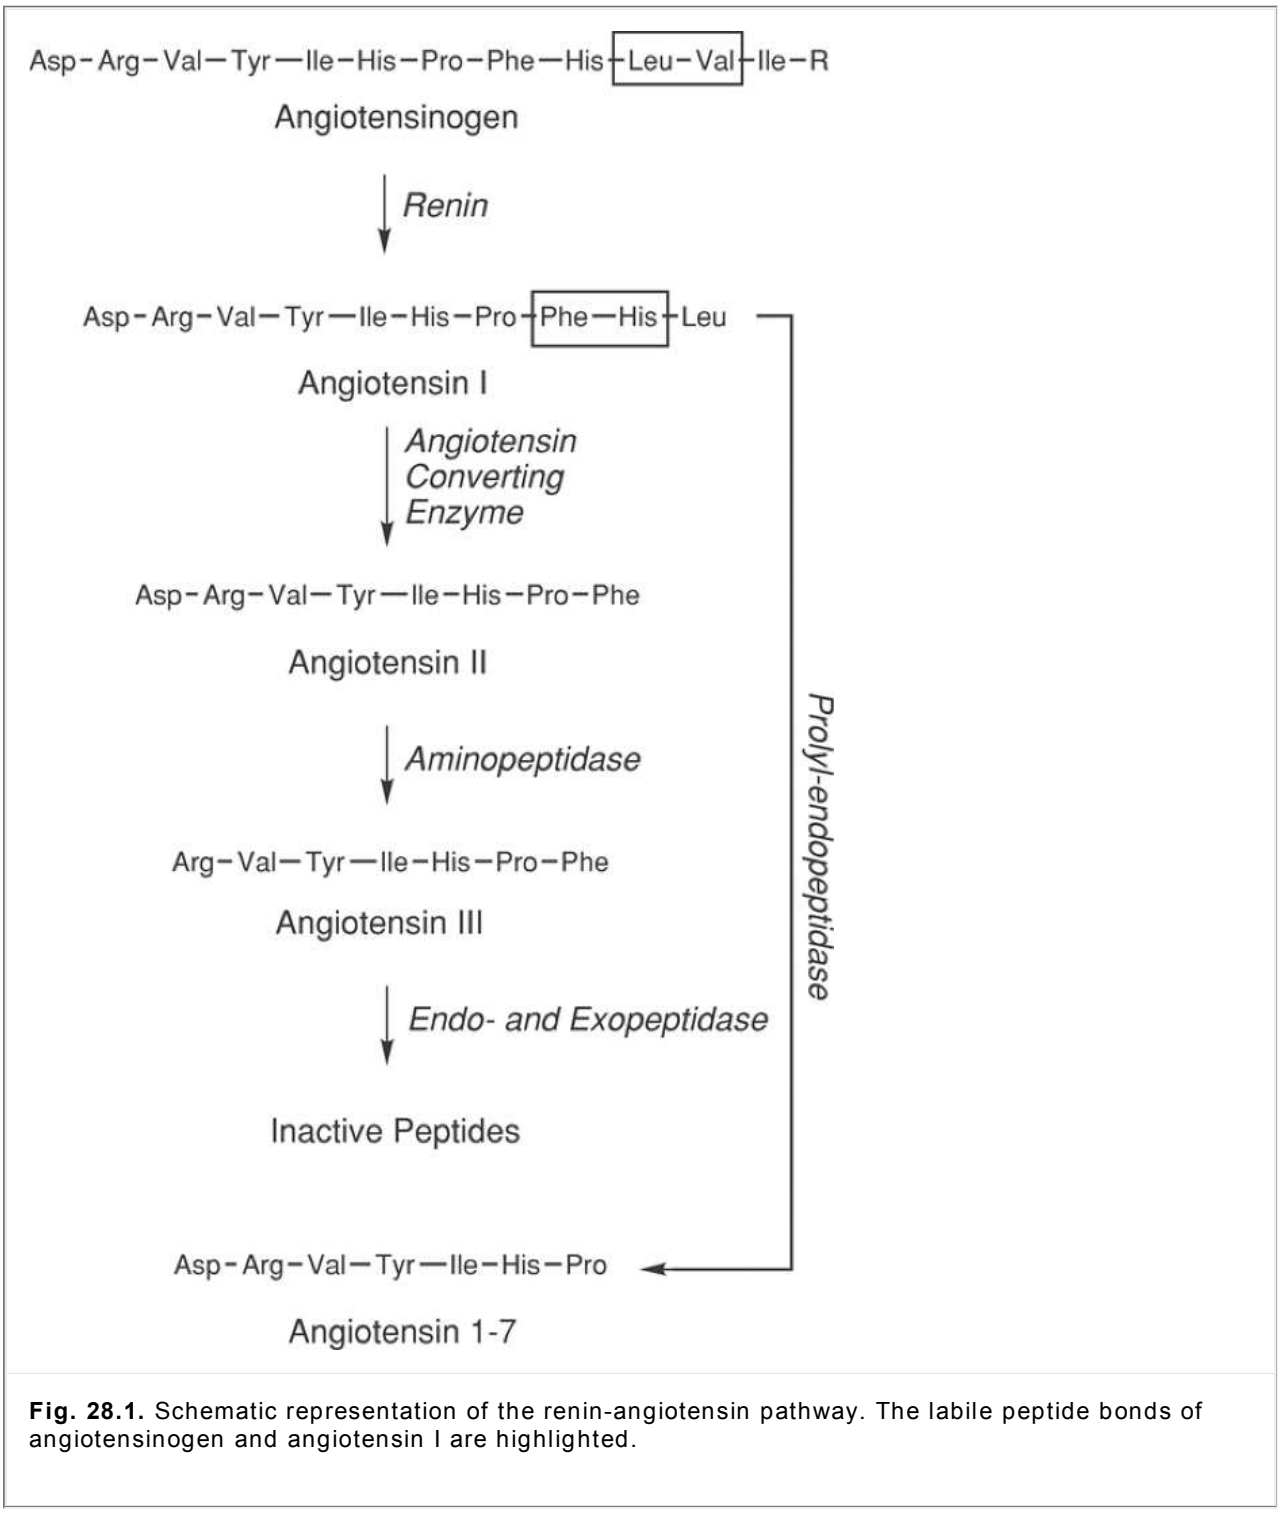

Fig. 28.1. Schematic representation of the renin-angiotensin pathway. The labile peptide bonds of angiotensinogen and angiotensin I are highlighted.

Clinical Significance

The treatment of hypertension and congestive heart failure (CHF) has improved significantly with the introduction of angiotensin-converting enzyme (ACE) inhibitors, angiotensin receptor blockers, and calcium channel blockers. The SARs and structural modifications of these agents have produced major therapeutic advances. These drugs have become cornerstones of therapy today. For example, more than 25 years ago, captopril was the first ACE inhibitor to be developed. Subsequent molecular modifications led to the development of newer agents, such as lisinopril. Although lisinopril exerts comparable ACE inhibition, it possesses a superior pharmacokinetic profile. Instead of having to administer captopril three times daily, lisinopril can be administered once daily.

Medication compliance is notoriously poor in cardiovascular patients. Administering an ACE inhibitor such as lisinopril once daily results in greatly enhanced medication compliance. The therapeutic outcomes of patients with hypertension and CHF have improved

immensely as a result. Similar molecular enhancements have been made with angiotensin receptor blockers and calcium channel blockers.

The application of basic science in modifying the chemical structure of these agents has ultimately resulted in patients living longer and suffering fewer cardiovascular events, such as myocardial infarction or worsening CHF. Importantly, their day-to-day quality of life is preserved as well.

Actions and Properties of Renin-Angiotensin Pathway Components

Renin is an aspartyl protease that determines the rate of angiotensin II production. It is a much more specific enzyme than ACE. Its primary function is to cleave the leucine-valine bond at residues 10 and 11 of angiotensinogen. The stimulation of renin release is controlled very closely by hemodynamic, neurogenic, and humoral signals (Fig. 28.2). Hemodynamic signals involve the renal juxtaglomerular cells. These cells are sensitive to the hemodynamic stretch of the afferent glomerular arteriole. An increase in the stretch implies a raised blood pressure and results in a reduced release of renin, whereas a decrease in the stretch increases renin secretion. Additionally, these cells also are sensitive to NaCl flux across the adjacent macula densa. Increases in NaCl flux across the macula densa inhibit renin release, but decreases in the flux stimulate release. Further, neurogenic enhancement of renin release occurs via activation of β_1 receptors. Finally, a variety of hormonal signals influence the release of renin. Somatostatin, atrial natriuretic factor, and angiotensin II inhibit renin release, whereas vasoactive intestinal peptide, parathyroid hormone, and glucagon stimulate renin release (4).

In contrast, ACE, also known as kininase II, is a zinc protease that is under minimal physiological control. It is not a rate-limiting step in the generation of angiotensin II and is a relatively nonspecific dipeptidyl carboxypeptidase that requires only a tripeptide sequence as a

substrate. The only structural feature required by ACE is that the penultimate amino acid in the peptide substrate cannot be proline. For this reason, angiotensin II, which contains a proline in the penultimate position, is not further metabolized by ACE. The lack of specificity and control exhibited by ACE results in its involvement in the bradykinin pathway (Fig. 28.3). Bradykinin is a nonapeptide that acts locally to produce pain, cause vasodilation, increase vascular permeability, stimulate prostaglandin synthesis, and cause bronchoconstriction. Similar to angiotensin II, bradykinin is produced by proteolytic cleavage of a precursor peptide. Cleavage of kininogens by the protease kallikrein produces a decapeptide known as either kallidin or lysyl-bradykinin. Subsequent cleavage of the N-terminal lysine by aminopeptidase produces bradykinin. The degradation of bradykinin to inactive peptides occurs through the actions of ACE. Thus, ACE not only produces a potent vasoconstrictor but also inactivates a potent vasodilator (1,4,5).

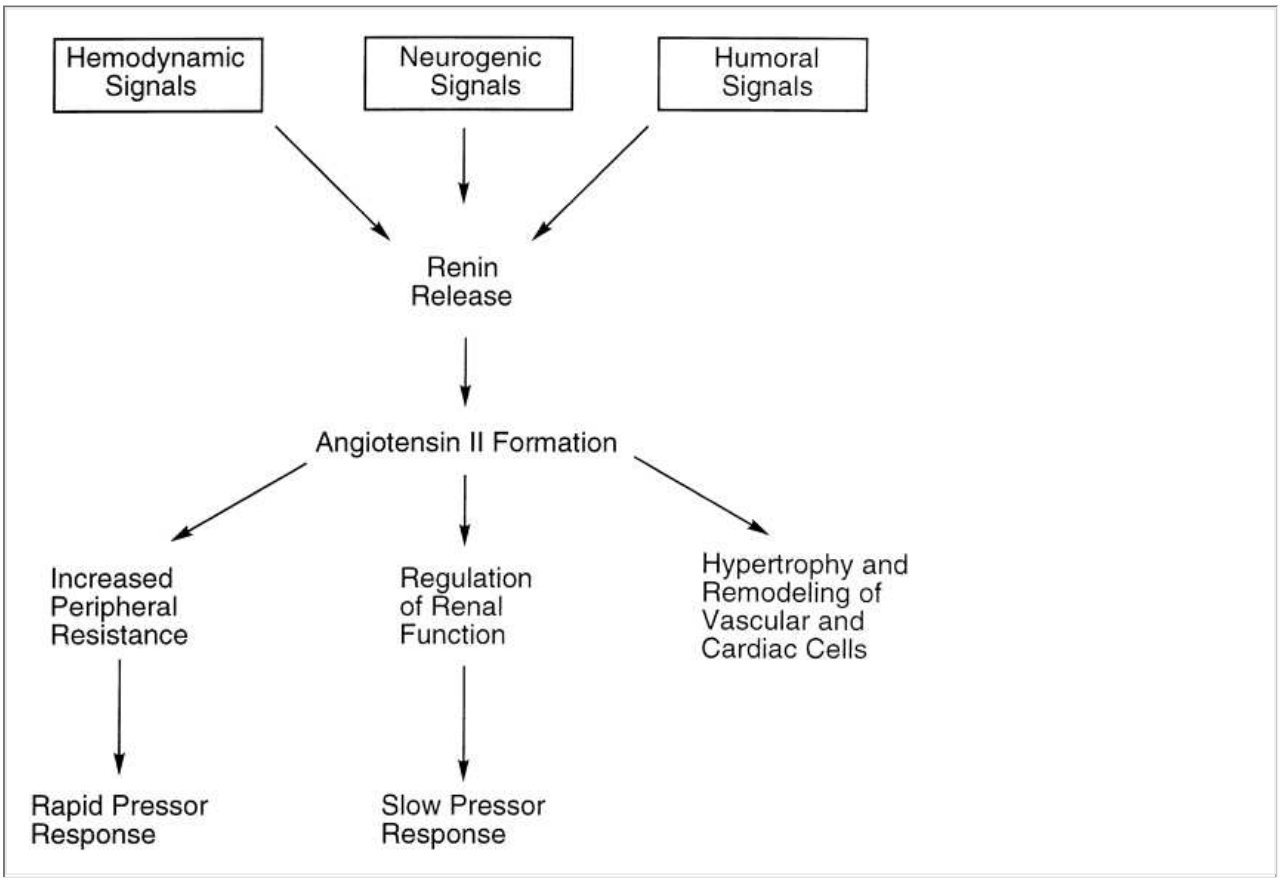

Fig. 28.2. Summary of the factors involved in renin release and the effects medicated by angiotensin II.

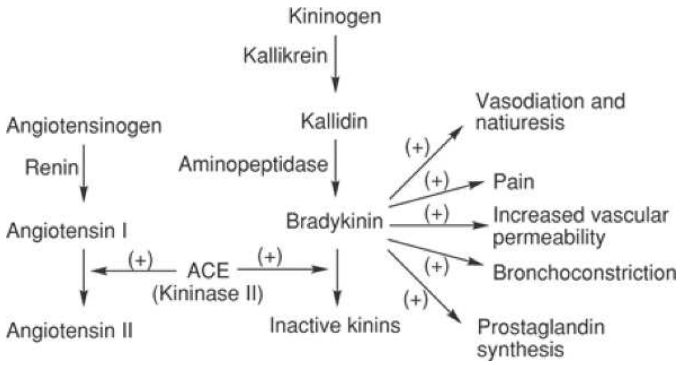

Fig. 28.3. Schematic representation of the bradykinin pathway and its relationship to ACE and the renin-angiotensin pathway.

Angiotensin II is the dominant peptide produced by the renin-angiotensin pathway (Fig. 28.2). It is a potent vasoconstrictor that increases total peripheral resistance through a variety of mechanisms: direct vasoconstriction, enhancement of both catecholamine release and neurotransmission within the peripheral nervous system, and increased sympathetic discharge. The result of all these actions is a rapid pressor response. Additionally, angiotensin II causes a slow pressor response, resulting in a long term stabilization of arterial blood pressure. This long-term effect is accomplished by the regulation of renal function. Angiotensin II directly increases sodium reabsorption in the proximal tubule. It also alters renal hemodynamics and causes the release of aldosterone from the adrenal cortex. Finally, angiotensin II causes the hypertrophy and remodeling of both vascular and cardiac cells through a variety of hemodynamic and nonhemodynamic effects (1).

Although secondary peptides, angiotensin III and angiotensin 1-7, also are thought to contribute to the overall effects of the renin-angiotensin pathway, angiotensin III is equipotent with angiotensin II in stimulating aldosterone secretion; however, it is only 10 to 25% as potent in increasing blood pressure. In contrast, angiotensin 1-7 does not cause either aldosterone secretion or vasoconstriction, but it does have potent effects that are distinct from those of angiotensin II. Similar to angiotensin II, angiotensin 1-7 causes neuronal excitation and vasopressin release. Additionally, it enhances the production of prostaglandins via a receptor-mediated process that does not involve an increase in intracellular calcium levels. It has been proposed to be important in the modulation of cell-to-cell interactions in cardiovascular and neural tissues (6).

Role of The Renin-Angiotensin Pathway in Cardiovascular Disorders

Because the renin-angiotensin pathway is central to the maintenance of blood volume, arterial blood pressure, and electrolyte balance, abnormalities in this pathway (e.g., excessive release of renin and overproduction of angiotensin II) can contribute to a variety of cardiovascular disorders. Specifically, overactivity of this pathway can result in hypertension or heart failure via the mechanisms previously described. Abnormally high levels of angiotensin II can contribute to hypertension through both rapid and slow pressor responses. Additionally, high levels of angiotensin II can cause cellular hypertrophy and increase both afterload and wall tension. All of these events can cause or exacerbate heart failure.

High blood pressure is a relatively common disorder, affecting more than 50 million Americans. It is more prevalent in males than in females and in blacks than in Caucasians. Onset usually begins during the third, fourth, and fifth decades of life, and the incidence of the disorder increases with age. Hypertension is classified as either primary or secondary. Primary hypertension, also known as essential hypertension, is the most prevalent form of the disorder and is defined as high blood pressure of an unknown etiology. Most cases of primary hypertension are thought to result from a variety of underlying pathophysiological mechanisms and not from a single, specific cause. Additionally, genetic factors appear to be important in the development of primary hypertension. Secondary hypertension is associated with a specific disorder (e.g., chronic renal disease, pheochromocytoma, and Cushing's syndrome), is present in approximately 5% of individuals with high blood pressure and, in some instances, is potentially curable. Secondary hypertension is much more common in children than in adults (7).

Heart failure (previously designated as congestive heart failure) affects approximately 5 million Americans and is the most common hospital discharge diagnosis in patients older than 65 years. The overall 5-year survival rate is approximately 50% for all patients, with women having an overall lower mortality rate than men. The disease results from conditions in which the heart is unable

to supply blood at a rate sufficient to meet the demands of the body. Similar to hypertension, this pathophysiological state can occur via a variety of mechanisms. Any pathophysiological event that causes either systolic or diastolic dysfunction will result in heart failure. Systolic dysfunction, or decreased contractility, can be caused by dilated cardiomyopathies, ventricular hypertrophy, or a reduction in muscle mass. Diastolic dysfunction, or restriction in ventricular filling, can be caused by increased ventricular stiffness, mitral or tricuspid valve stenosis, or pericardial disease. Both ventricular hypertrophy and myocardial ischemia can contribute to increased ventricular stiffness. Angiotensin II causes and/or exacerbates heart failure by increasing systemic vascular resistance, promoting sodium retention,

stimulating aldosterone release, and stimulating ventricular hypertrophy and remodeling (8).

Overview of Drug Therapy Affecting The Renin-Angiotensin Pathway

Because angiotensin II produces the majority of the effects attributed to the renin-angiotensin pathway, compounds that can block either the synthesis of angiotensin II or the binding of angiotensin II to its receptor should attenuate the actions of this pathway. Indeed, enzyme inhibitors of both renin and ACE, as well as receptor antagonists of angiotensin II, have all been shown to produce beneficial effects in decreasing the actions of angiotensin II. Inhibitors of ACE were the

first class of compounds to be marketed. This occurred in 1981 with the approval by the U.S. Food and Drug Administration of captopril. Fourteen years later, losartan was approved as the first angiotensin II receptor blocker (previous referred to as an angiotensin II receptor antagonist). The development, structure–activity relationship (SAR), physicochemical properties, interactions, and indications of these classes of drugs are discussed below.

Development of Orally Active Renin Inhibitors

Renin is a very specific enzyme. The octapeptide, His-Pro-Phe-His-Leu-Leu-Val-Tyr, is the smallest substrate recognized by the enzyme and is similar to the eight-amino-acid sequence, His_6-Pro_7-Phe_8-His_9-Leu_{10}-Val_{11}-Ile_{12}-His_{13}, which is found in angiotensinogen. Using this octapeptide, Boger (9) replaced the labile Leu-Leu bond with the stable dipeptide mimic statine and replaced the two C-terminal residues (Val–Tyr) with similar hydrophobic amino acids (Leu-Phe).

Statine

The resulting compound, N-isovaleryl-His-Pro-Phe-His-Sta-Leu-Phe-NH_2 (SCRIP), showed effective, although short-lived, inhibition of renin when given intravenously (IV). Infusion experiments with SCRIP were the first to demonstrate that a small molecule renin inhibitor could maintain a lowered blood pressure for an extended period of time. Susceptibility to proteolytic cleavage, however, limited the therapeutic utility of SCRIP and other analogous peptides.

Structure–activity studies with SCRIP revealed that the N-terminal His-Pro-Phe sequence could be replaced with an acylated phenylalanine or tyrosine without any significant loss in inhibitor activity. Additional changes to SCRIP resulted in the clinical drug candidate enalkiren, also known as A-64662 (Fig. 28.4). The histidine residue (His_6), which is present in angiotensinogen and all previous inhibitors, was thought to be essential for enzyme recognition and was left unchanged. The acylated tyrosine protects the compound from aminopeptidase enzymes and also contributes to enzyme active-site recognition. The remainder of the molecule is a stable dipeptide isostere. The cyclohexylmethylene and iso-butyl side chains are lipophilic and approximate the lipophilic side chains present in Leu_{10} and Val_{11} of angiotensinogen. Additionally, the use of a C-terminal alcohol instead of a C-terminal carboxylate protects enalkiren from carboxypeptidase enzymes (10,11).

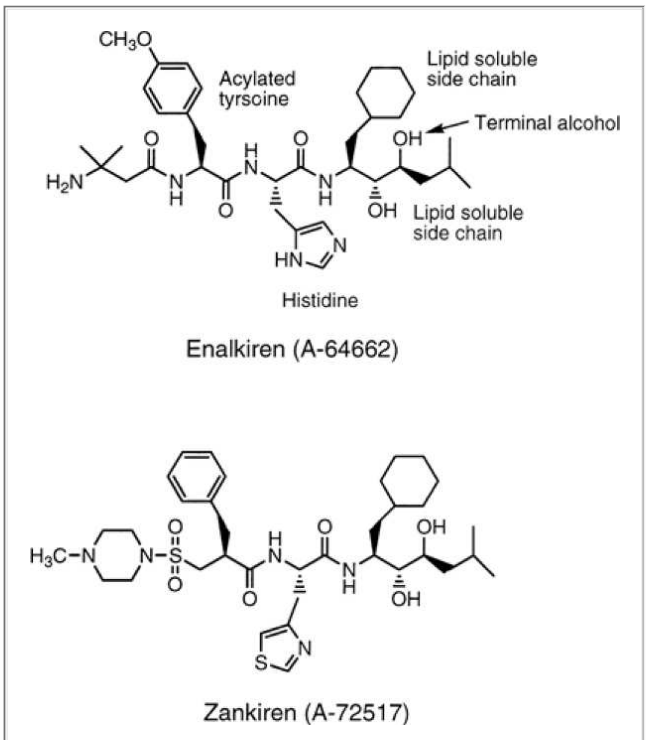

Fig. 28.4. Structures of enalkiren and zankiren.

Enalkiren has been extensively studied in preclinical and clinical trials and has been shown to be efficacious if given IV. It lacks significant bioavailability, however, mainly because of a lack of lipid solubility. A more lipophilic analogue, zankiren (A-72517) (Fig. 28.4), has demonstrated increased oral bioavailability and efficacy. Preclinical and clinical trials with orally administered zankiren showed good bioavailability and significant reduction in blood pressure (11,12). Zankiren has since been withdrawn from clinical trials for undisclosed reasons; however, the FDA recently approved Aliskiren (Tektournan), the first, non-peptidic orally active renin inhibitor. It is approved for the treatment of hypertension and will be available for use in 2007. See Drug update: http://thepoint./www.com/foyebe.

Attempts to develop orally active, bioavailable renin inhibitors actually predate the development of ACE inhibitors. Research in this area continues today; however, one of the main attractions of renin inhibitors, specificity, has proven to be a significant hurdle to the clinical development (9) of these agents.

Angiotensin-Converting Enzyme Inhibitors

Currently, there are 11 ACE inhibitors approved for therapeutic use in the United States. These compounds can be subclassified into three groups based on their chemical composition: sulfhydryl-containing inhibitors (exemplified by captopril), dicarboxylate-containing inhibitors (exemplified by enalapril), and phosphonate-containing inhibitors (exemplified by fosinopril). Captopril and fosinopril are the lone representatives of their respective chemical subclassifications, whereas the majority of the inhibitors contain the dicarboxylate functionality. All of these compounds effectively block the conversion of angiotensin I to angiotensin II and have similar therapeutic and physiological effects. The compounds differ primarily in their potency and pharmacokinetic profiles (1). Additionally, the sulfhydryl group in captopril is responsible for certain effects not seen with the other agents. Detailed descriptions of the rationale for the development of captopril, enalapril, and fosinopril are provided below.

Sulfhydryl-Containing Inhibitors: Development of Captopril

In 1965, Ferreira et al. (13) reported that the venom of the South American pit viper (*Bothrops jararaca*) contained factors that potentiated the action of bradykinin. These factors, originally designated as bradykinin-potentiating factors (BPFs), were isolated and found to be a family of peptides containing 5 to 13 amino acid residues. Their actions in potentiating bradykinin were subsequently linked to their ability to inhibit the enzymatic degradation of bradykinin. Soon thereafter, Bakhle et al. (14) reported that these same peptides also inhibited the enzymatic conversion of angiotensin I to angiotensin II. This latter enzyme, ACE, is now known to be identical with the former bradykininase enzyme (kininase II). Even at the time of these initial discoveries, however, BPFs were seen as lead compounds for the development of new antihypertensive agents, because they possessed dual activities—inhibition of the degradation of bradykinin, a potent vasodilator, and inhibition of the biosynthesis of angiotensin II, a potent vasoconstrictor (15).

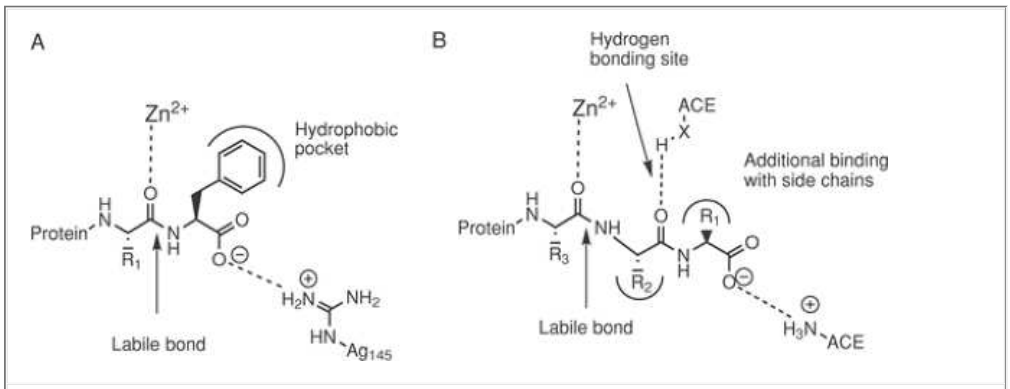

Fig. 28.5. A model of substrate binding to carboxypeptidase A (A) and ACE (B).

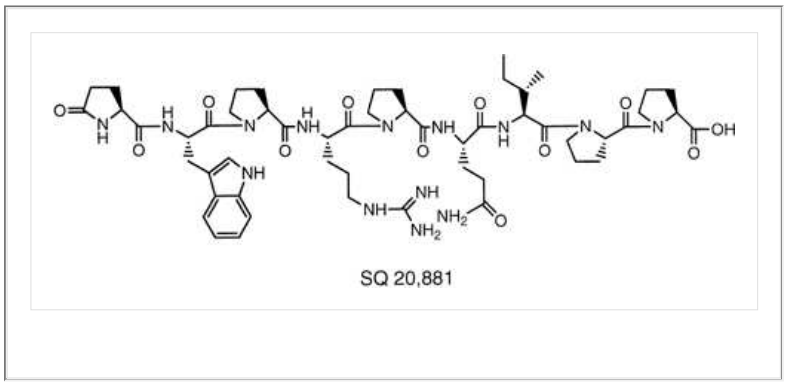
A nonapeptide, SQ 20,881 (teprotide), isolated from the original BPFs had the greatest in vivo potency in inhibiting ACE and was shown to consistently lower blood pressure in patients with essential hypertension. It also exerted beneficial effects in patients with heart failure; however, because of its peptide nature and lack of oral activity, teprotide had limited activity in the therapeutic treatment of these diseases (15,16).



Cushman, Ondetti, and coworkers (17,18,19) used SQ 20,881 and other peptide analogues to provide an enhanced understanding of the enzymatic properties of ACE. Using knowledge of substrate-binding specificities and the fact that ACE has properties similar to those of pancreatic carboxypeptidases, these researchers developed a hypothetical model of the enzyme active site. Carboxypeptidase A, like ACE, is a zinc-containing exopeptidase. The binding of a substrate to carboxypeptidase A involves three major interactions (Fig. 28.5A).

First, the negatively charged carboxylate terminus of the amino acid substrate binds to the positively charged Arg-145 on the enzyme. Second, a hydrophobic pocket in the enzyme provides specificity for a C-terminal aromatic or nonpolar residue. Third, the zinc atom is located close to the labile peptide bond and serves to stabilize the negatively charged tetrahedral intermediate, which results when a molecule of water attacks the carbonyl bond between the C-terminal and penultimate amino acid residues (20). Similarly, the binding of substrates to ACE was proposed to involve three or four major interactions (Fig. 28.5B). First, the negatively charged carboxylate terminus of angiotensin I and other substrates was assumed to occur via an ionic bond with a positively charged amine on ACE. Second, the role of the zinc atom in the mechanism of ACE hydrolysis was assumed to be similar to that of carboxypeptidase A. Because ACE cleaves dipeptides instead of single amino acids, the position of the zinc atom was assumed to be located two amino acids away from the cationic center for it to be adjacent to the labile peptide bond. Third, the side-chains R_1 and R_2 could contribute to the overall binding affinity; however, ACE, unlike carboxypeptidase A, does not show specificity for C-terminal hydrophobic amino acids and was not expected to have a hydrophobic binding pocket. Finally, the terminal peptide bond is nonlabile and was assumed to provide hydrogen bonding between the substrate and ACE.

The development of captopril and other orally active ACE inhibitors began with the observation that D-2-benzylsuccinic acid was an extremely potent inhibitor of carboxypeptidase A (17,18,19). The binding of this compound to carboxypeptidase A (Fig. 28.6A) is very similar to that seen for substrates with the exception that the zinc ion binds to a carboxylate group instead of the labile peptide bond. Byers and Wolfenden (21) proposed that this compound is a by-product analogue that contains structural features of both products of peptide hydrolysis. Most of the structural features of the compound are identical to the terminal amino acid of the substrate (Fig. 28.5A), whereas the additional carboxylate group is able to mimic the carboxylate group that would be produced during peptide hydrolysis (21). Applying this concept to the hypothetical model of ACE described above resulted in the synthesis and evaluation of a series of succinic acid derivatives (Fig. 28.6B). Because proline was present as the C-terminal amino acid in SQ 20,881 as well as in other potent, inhibitory snake venom peptides, it was included in the structure of newly designed inhibitors. The first inhibitor to be synthesized and tested was succinyl-L-proline (Fig. 28.7). This compound proved to be somewhat disappointing. Although it provided reasonable specificity for ACE, it was only approximately 1/500 as potent as SQ 20,881.

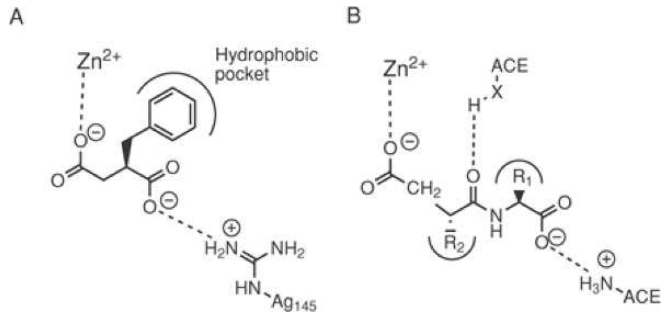


Fig. 28.6. Inhibitor binding models of (A) D-2-benzylsuccinic acid to carboxypeptidase A and (B) succinic acid derivatives to ACE.

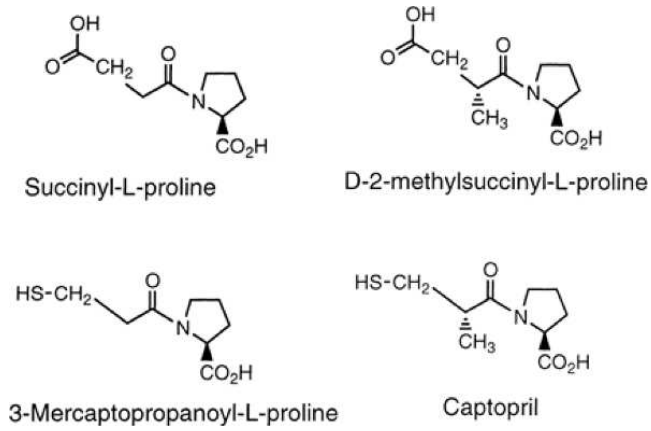

Fig. 28.7. Compounds prepared in the development of captopril.

Substitution of other amino acids in place of proline produced compounds that were even less potent; hence, all subsequent SAR studies were conducted using analogues of L-proline (Fig. 28.7). The addition of a methyl group to the 2 position of succinyl-L-proline to mimic the amino acid side chain, R_2, of the substrate enhanced activity but only marginally. D-2-Methylsuccinyl-L-proline had effects similar to SQ 20,881 but was still only 1/300 as potent. The D-isomer, rather than the L-isomer normally seen for amino acids, was necessary because of the isosteric replacement of an NH_2 with a CH_2 present in succinyl-L-proline. A comparison of the R_2 group of the substrate (Fig. 28.5B) with the methyl group of D-2-methylsuccinyl-L-proline, illustrates that this methyl group occupies the same binding site as the side chain of an L-amino group.

One of the most important alterations to succinyl-L-proline was the replacement of the succinyl carboxylate with other groups having enhanced affinity for the zinc atom bound to ACE. Replacement of this carboxylate with a sulfhydryl group produced 3-mercaptopropanoyl-L-proline. This compound has an IC_{50} value of 200 nM and is greater than 1000-fold more potent than succinyl-L-proline (Fig. 28.7). Additionally, it is 10- to 20-fold more potent than SQ 20,881 in inhibiting contractile and vasopressor responses to angiotensin I. Addition of a 2-D-methyl group further enhanced activity. The resulting compound, captopril (Fig. 28.7), is a competitive inhibitor of ACE with a K_i value of 1.7 nM and was the first ACE inhibitor to be marketed.

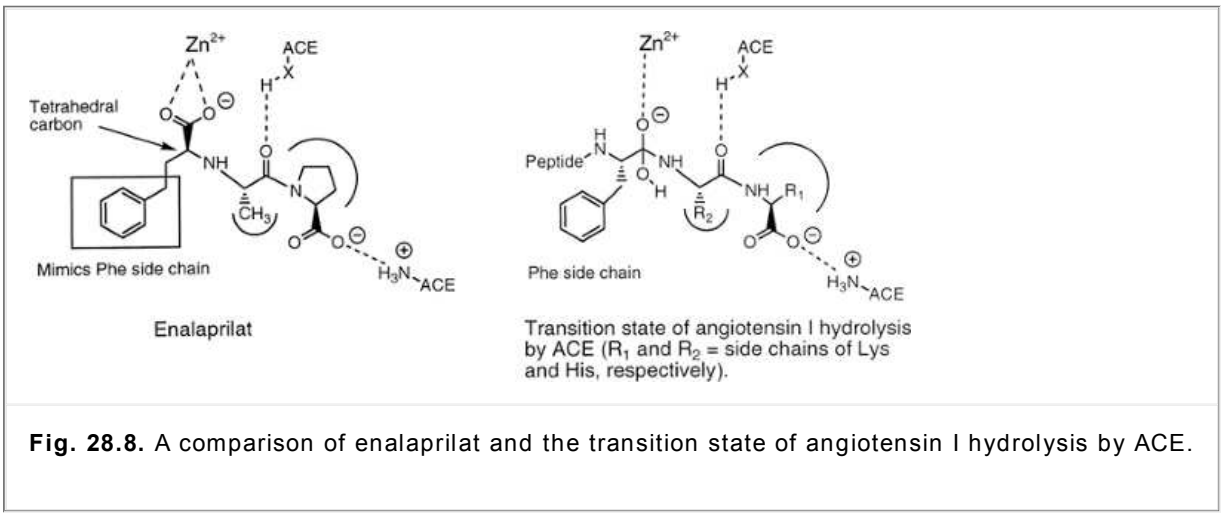

Fig. 28.8. A comparison of enalaprilat and the transition state of angiotensin I hydrolysis by ACE.

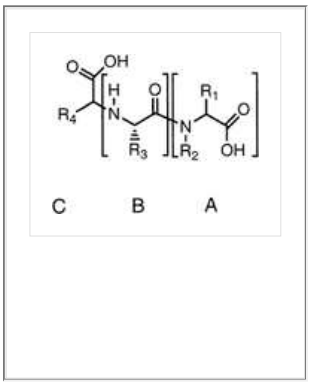
The sulfhydryl group of captopril proved to be responsible not only for the excellent inhibitory activity of the compound but also for the two most common side effects, skin rashes and taste disturbances (e.g., metallic taste and loss of taste). These side effects usually subsided on dosage reduction or discontinuation of captopril. They were attributed to the presence of the sulfhydryl group, because similar effects had been observed with penicillamine, a sulfhydryl containing agent used to treat Wilson's disease and rheumatoid arthritis (22,23).

Dicarboxylate-Containing Inhibitors

Development of Enalapril

Researchers at Merck (24) sought to develop compounds that lacked the sulfhydryl group of captopril yet maintained some ability to chelate zinc. Compounds having the general structure shown below were designed to meet this objective.



These compounds are tripeptide substrate analogues in which the C-terminal (A) and penultimate (B) amino acids are retained but the third amino acid is isosterically replaced by a substituted N-carboxymethyl group (C). Similar to the results seen in the development of captopril, C-terminal proline analogues provided optimum activity. The use of a methyl group at R_3 (i.e., B = Ala) and a phenylethyl group at R_4 resulted in enalaprilat (Fig. 28.8). In comparing the activity of captopril and enalaprilat, it was found that enalaprilat, with a K_i of 0.2 nM, was approximately 10-fold more potent than captopril. Studies investigating the binding of enalaprilat revealed that its ability to chelate the enzyme-bound zinc atom was significantly less than that of captopril. The enhanced binding was proposed to be caused by the ability to mimic the transition state of angiotensin I hydrolysis. As shown in Figure 28.8, enalaprilat possess a tetrahedral carbon in place of the labile peptide bond. The secondary amine, the carboxylic acid, and phenylethyl groups all contribute to the overall binding of the compound to ACE. The secondary amine is located at the same position as the labile amide nitrogen, the ionized carboxylic acid can form an ionic bond with the zinc atom, and the phenylethyl group mimics the hydrophobic side chain of the Phe amino acid, which is present in angiotensin I.

Despite excellent IV activity, enalaprilat has very poor oral bioavailability. Esterification of enalaprilat produced enalapril (Fig. 28.9), a compound with superior oral bioavailability. The combination of structural features in enalaprilat, especially the two carboxylate groups and the secondary amine, are responsible for its overall low lipophilicity and poor oral bioavailability. Zwitterion formation also has been suggested to contribute to the low oral activity (25), and a comparison of the pK_a values for the secondary amine of enalaprilat and enalapril supports this explanation. Ionization of the adjacent carboxylate in enalaprilat greatly enhances the basicity of the secondary amine such that the pK_a of the amine in this compound is 8.02, whereas in enalapril, it is only 5.49. Thus, in the small intestine, the amine in enalaprilat will be primarily ionized and form a zwitterion with the adjacent carboxylate, but the amine in enalapril will be primarily un-ionized (26).

Intravenous administration of either enalapril or enalaprilat produced similar effects on angiotensin II production

despite the fact that enalapril showed a 1,000-fold decrease in in vitro activity. Subsequent studies showed that enalapril undergoes

bioactivation and, thus, is a pro-drug of enalaprilat. Because human plasma was reported to lack enalapril esterolytic activity, bioactivation by hepatic esterases (Fig. 28.9) has been suggested as the most probable mechanism for enalaprilat formation (27,28).

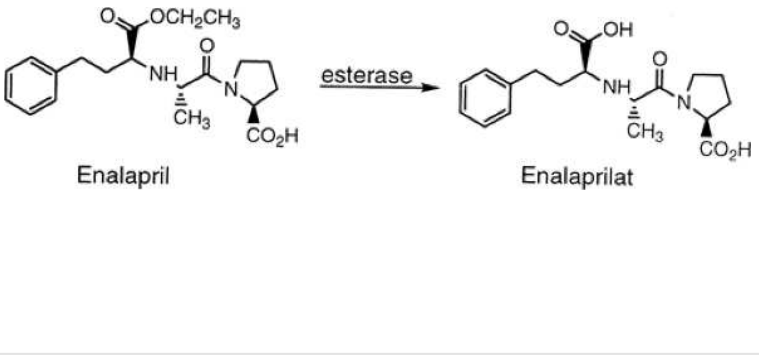


Fig. 28.9. Bioactivation of enalapril.

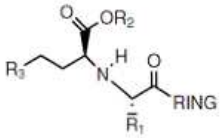
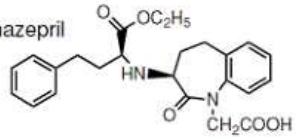
General structure:



Benazepril



Compounds	Ring	R_1	R_2	R_3
Lisinopril		$(CH_2)_4NH_2$	H	
Moexipril		CH_3	CH_2CH_3	
Perindopril		CH_3	CH_2CH_3	CH_3
Quinapril		CH_3	CH_2CH_3	
Ramipril		CH_3	CH_2CH_3	
Spirapril		CH_3	CH_2CH_3	
Trandolapril		CH_3	CH_2CH_3	

Table 28.1. Additional Dicarboxylate-containing Angiotensin Converting Enzyme Inhibitors

Additional Dicarboxylate Inhibitors

Eight other dicarboxylate inhibitors (Table 28.1) have been approved for various therapeutic indications; however, spirapril has never been marketed. Lisinopril is chemically unique in two respects. First, it contains the basic amino acid lysine ($R_1 = CH_2CH_2CH_2CH_2NH_2$) instead of the standard nonpolar alanine ($R = CH_3$)

residue. Second, it does not require bioactivation, because neither of the carboxylic acid groups are esterified (i.e., $R_2 = H$). Lisinopril was developed at the same time as enalapril. Despite the addition of another ionizable group, the oral absorption of lisinopril was found to be superior to that of enalaprilat but less than that of enalapril. In vitro studies of enalaprilat and lisinopril showed lisinopril to be slightly more potent than enalaprilat (27,28). Lisinopril, along with captopril, currently are the only two ACE inhibitors that are not pro-drugs.

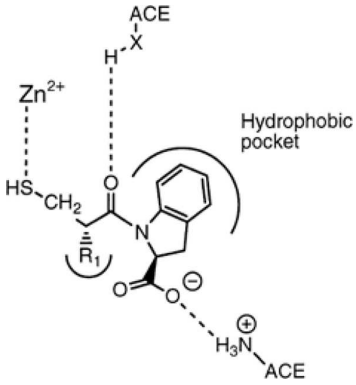


Fig. 28.10. A modified model of ACE inhibitor binding.

The major structural difference among the remaining ACE inhibitors is in the ring of the C-terminal amino acid. Lisinopril, like enalapril and captopril, contains the pyrrolidine ring of proline, whereas all the other compounds contain larger bicyclic or spiro ring systems. Studies of indoline analogues of captopril indicated that a hydrophobic pocket similar to that seen in carboxypeptidase A also was present in ACE. This led to a modification (Fig. 28.10) of Ondetti and Cushman's original model and the development of inhibitors that contained larger hydrophobic ring systems (29). Although this modified model was proposed for captopril analogues, it is readily adaptable to include enalaprilat analogues. In general, the varied ring systems seen in benazepril, moexipril, perindopril, quinapril, ramipril, spirapril, and trandolapril provide enhanced binding and potency. They also lead to differences in absorption, plasma protein binding, elimination, onset of action, duration of action, and dosing among the drugs. These differences are discussed in more detail in *Pharmacokinetic Properties* below.

Phosphonate-containing Inhibitors: the Development of Fosinopril

The search for ACE inhibitors that lacked the sulfhydryl group also lead to the investigation of phosphorous-containing compounds (30). The phosphinic acid shown in Figure 28.11 is capable of binding to ACE in a manner similar to enalapril. The interaction of the zinc atom with the phosphinic acid is similar to that seen with sulfhydryl and carboxylate groups. Additionally, this compound is capable of forming the ionic, hydrogen, and hydrophobic bonds similar to those seen with enalapril and other dicarboxylate analogues. A feature unique to this compound is the ability of the phosphinic acid to more truly mimic the ionized, tetrahedral intermediate of peptide hydrolysis. Unlike enalapril and other dicarboxylate analogues, however, the spacing of this tetrahedral species is shorter, being only two atoms removed from the proline nitrogen. Additionally, the spacing between the proline nitrogen and the hydrophobic phenyl ring is one atom longer than that seen in the dicarboxylates.

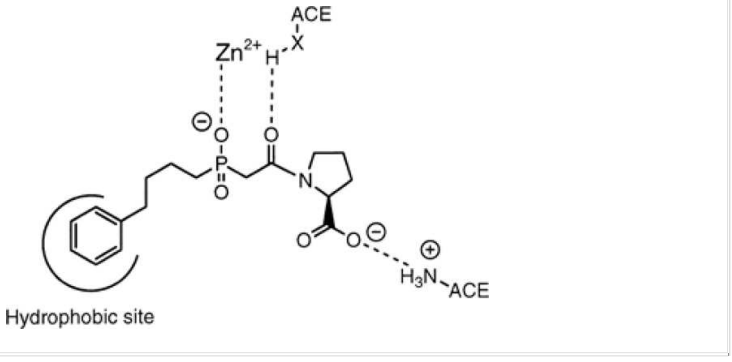

Fig. 28.11. The binding of phosphinate analogues to ACE.

Structural modification to investigate more hydrophobic, C-terminal ring systems, similar to that described above for the dicarboxylate compounds, lead to a 4-cyclohexylproline analogue of the original phosphinic acid. This compound, fosinoprilat (Fig. 28.12), was more potent than captopril but less potent than enalaprilat. The above-mentioned differences in the spacing of the phosphinic acid and phenyl groups may be responsible for this latter difference in potency. Similar to the dicarboxylates, fosinoprilat was too hydrophilic and exhibited poor oral activity. The pro-drug fosinopril contains an (acyloxy)alkyl group that allows better lipid solubility and improved bioavailability (30). Bioactivation via esterase activity in the intestinal wall and liver produces fosinopril (Fig. 28.12).

Mechanism of Action

The ACE inhibitors attenuate the effects of the renin-angiotensin system by inhibiting the conversion of angiotensin I to angiotensin II (Fig. 28.1). They also inhibit the conversion of [des-Asp^1]angiotensin I to angiotensin III; however, this action has only a minor role in the overall cardiovascular effects of these drugs. They are selective in that they do not directly interfere with any other components of the renin-angiotensin system; however, they do cause other effects that are unrelated to the decrease in angiotensin II concentration. Inhibitors of ACE increase bradykinin levels that, in turn, stimulate prostaglandin biosynthesis (Fig. 28.3). Both of these compounds have been proposed to contribute to the overall action of ACE inhibitors. Additionally, decreased angiotensin II levels increase the release of renin and the production of angiotensin I. Because ACE is inhibited,

angiotensin I is shunted toward the production of angiotensin 1-7 and other peptides. The contribution of these peptides to the overall effect of ACE inhibitors is unknown (1).

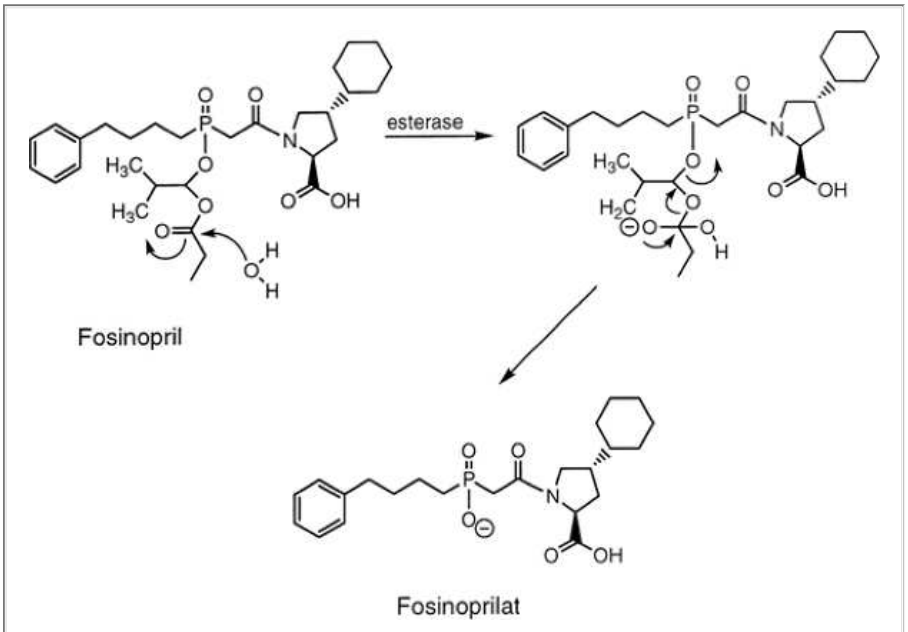

Fig. 28.12. Bioactivation of fosinopril.

Structure–Activity Relationships

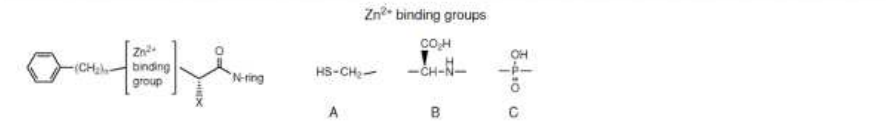
The structural characteristics for ACE inhibitory activity are given in Table 28.2. Angiotensin-converting enzyme is a stereoselective drug target. Because currently approved ACE inhibitors act as either di- or tripeptide substrate analogues, they must contain a stereochemistry that is consistent with the L-amino acids present in the natural substrates. This was established very early in the development of ACE inhibitors when compounds with carboxyl-terminal D-amino acids were discovered to be very poor inhibitors (31). Later work by Patchett et al. (24) reinforced this idea. They reported a 100- to 1,000-fold loss in inhibitor activity whenever the configuration of either the carboxylate or the R_1 substituent (Table 28.1) was altered. The *S,S,S*-configuration seen in enalapril and other dicarboxylate inhibitors meets the above-stated criteria and provides for optimum enzyme inhibition.

Physicochemical Properties

Captopril and fosinopril are acidic drugs, but all other ACE inhibitors are amphoteric. The carboxylic acid attached to the N-ring is a common structural feature in all ACE inhibitors. It has a pK_a in the range of 2.5 to 3.5 and will be ionized primarily at physiological pH. As discussed above

with enalapril, the pK_a and ionization of the secondary amine in the dicarboxylate series depends on whether the adjacent functional group is in the pro-drug or active form. In the pro-drug form, the amine is adjacent to an ester, is less basic, and is primarily un-ionized at

physiological pH. Following bioactivation, the amine is adjacent to an ionized carboxylic acid that enhances both the basicity and ionization of the amine. Similarly, the basic nitrogen enhances the acidity of the adjacent carboxylic acid such that it usually has a lower pK_a than the carboxylic acid attached to the N-ring. As an example, the pK_a values of enalapril are 3.39 and 2.30. These values correspond to the carboxylic acid on the N-ring and the carboxylic acid adjacent to the amine, respectively. The analogous values for these functional groups in lisinopril are 3.3 and 1.7 (26).



a. The N-ring must contain a carboxylic acid to mimic the C-terminal carboxylate of ACE substrates.
b. Large hydrophobic heterocyclic rings (i.e., the N-ring) increase potency and alter pharmacokinetic parameters.
c. The zinc binding groups can be either sulfhydryl (A), a carboxylic acid (B), or a phosphinic acid (C).
d. The sulfhydryl group shows superior binding to zinc (the side chain mimicking Phe in carboxylate and phosphinic acid compounds compensates for the lack of a sulfhydryl group).
e. Sulfhydryl-containing compounds produce high incidence of skin rash and taste disturbances.
f. Sulfhydryl-containing compounds can form dimers and disulfides which may shorten duration of action.
g. Compounds which bind to zinc through either a carboxylate or phosphinate mimic the peptide hydrolysis transition state.
h. Esterification of the carboxylate or phosphinate produces an orally bioavailable prodrug.
i. X is usually methyl to mimic the side chain of alanine. Within the dicarboxylate series, when X equals n-butylamine (lysine side chain) this produces a compound which does not require prodrug for oral activity.
j. Optimum activity occurs when stereochemistry of inhibitor is consistent with L-amino acid stereochemisty present in normal substrates.

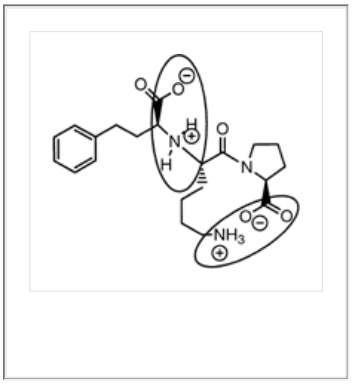
NA, not applicable, —, data not available.

The calculated log P values (26) along with other pharmacokinetic parameters for the ACE inhibitors are shown in Table 28.3. With three notable exceptions, captopril, enalaprilat, and lisinopril, all of the compounds possess good lipid solubility. Compounds that contain hydrophobic bicyclic ring systems are more lipid soluble than those that contain proline. A comparison of the log P values of benazepril, fosinopril, moexipril, perindopril, quinapril, ramipril, spiropril, and trandolapril to those for captopril and enalapril illustrates this fact. As previously discussed, enalaprilat is much more hydrophilic than its ester pro-drug and is currently the only ACE inhibitor marked for IV administration. In terms of solubility, lisinopril probably is the most interesting compound in that it is the most hydrophilic inhibitor, yet unlike enalaprilat, it is orally active. One possible explanation for this phenomenon is that in the duodenum, lisinopril will exist as a di-zwitterion in which the ionized groups can internally bind to one another. In this manner, lisinopril may be able to pass through the lipid bilayer with an overall net neutral charge.



Metabolism

Lisinopril and enalaprilat are excreted unchanged, whereas all other ACE inhibitors undergo some degree of metabolic transformation (1,32,33,34). As previously discussed and illustrated (Figs. 28.9 and 28.12), all dicarboxylate and phosphonate pro-drugs must undergo bioactivation via hepatic esterases. Additionally, based on their structural features, specific compounds can undergo metabolic inactivation via various pathways (Fig. 28.13). Because of its sulfhydryl group, captopril is subject to oxidative dimerization or conjugation. Approximately 40 to 50% of a dose of captopril is excreted unchanged, whereas the remainder is excreted as either a disulfide dimer or a captopril-cysteine disulfide. Glucuronide conjugation has been reported for benazepril, fosinopril, quinapril, and ramipril. This conjugation can occur either with the parent pro-drug or with the activated drug. Benazepril, with the N-substituted glycine, is especially susceptible to this reaction because of a difference in steric hindrance. For all ACE inhibitors, except

benazepril, the carbon atom directly adjacent to the carboxylic acid is part of a ring system and provides some steric hindrance to conjugation. The unsubstituted methylene group (i.e., $–CH_2–$) of benazepril provides less steric hindrance and, thus, facilitates conjugation. Moexipril, perindopril, and ramipril can undergo cyclization to produce diketopiperazines. This cyclization can occur with either the parent or active forms of the drugs.

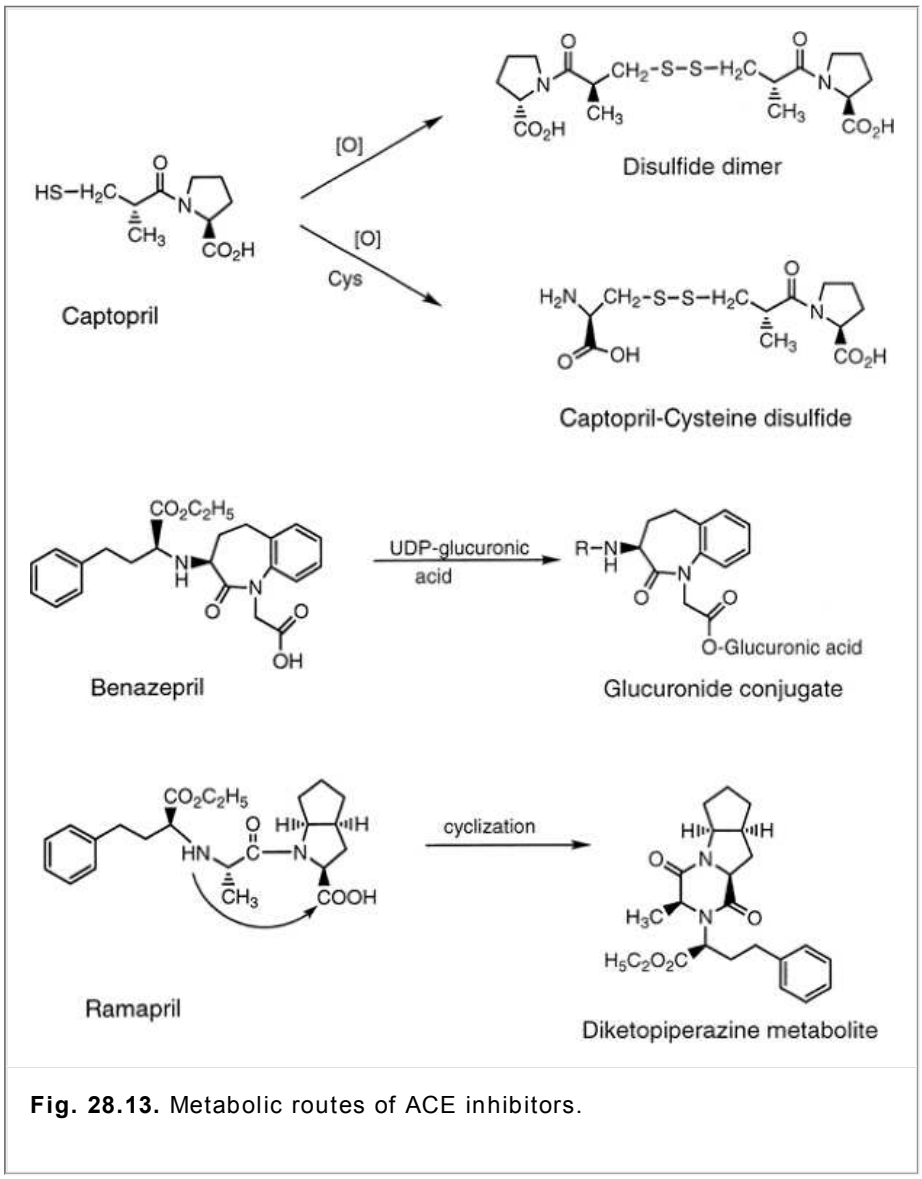


Fig. 28.13. Metabolic routes of ACE inhibitors.

A comparative study of the metabolism and biliary excretion of lisinopril, enalapril, perindopril, and ramipril revealed that whereas neither lisinopril nor enalapril underwent any appreciable metabolism beyond bioactivation of enalapril to enalaprilat, both perindopril and ramipril were extensively metabolized beyond the initial bioactivation. It was proposed that these differences in hepatic metabolism could be explained, in part, by the larger, more hydrophobic rings present on perindopril and ramipril (35).

Pharmacokinetic Parameters

The pharmacokinetic parameters and dosing information for ACE inhibitors are summarized in Tables 28.3 and 28.4, respectively (1,32,33,34). The oral bioavailability of this class of drugs ranges from 13 to 95%. Differences in both lipid solubility and first-pass metabolism are most likely responsible for this wide variation. Both parameters should be considered when comparing any two or more compounds. With the exceptions of enalapril and lisinopril, the concurrent administration of food adversely affects the oral absorption of ACE inhibitors. Product literature specifically instructs that captopril should be taken 1 hour before meals and that moexipril should be taken in the fasting state. Although not specifically stated, similar instructions also should benefit patients taking an ACE inhibitor whose absorption is affected by food.

The extent of protein binding also exhibits wide variability among the different compounds. The data suggests that this variation has some correlation with the calculated log P values for the compounds (Table 28.3). Three of the more lipophilic compounds—fosinopril, quinapril, and benazepril—exhibit protein binding of greater than 90%, whereas three of the least lipophilic compounds—lisinopril, enalapril, and captopril—

exhibit much lower protein binding. The lack of a protein binding value for spirapril prevents a more definitive statement on this correlation.

Renal elimination is the primary route of elimination for most ACE inhibitors. With the exceptions of fosinopril and spirapril, altered renal function significantly diminishes the plasma clearance of ACE inhibitors, including those that are eliminated primarily by the feces. Therefore, the dosage of most ACE inhibitors should be reduced in patients with renal impairment (1). Studies of fosinopril in patients with heart failure demonstrated that it is eliminated by both renal and hepatic pathways and does not require a dosage reduction in

patients with renal dysfunction (36). Spirapril also exhibits similar properties; however, it is not currently available for use. It should be noted that the literature data for routes of elimination are not always consistent. The designation of renal elimination is quite clear, but it is difficult to correlate what some sources call renal/hepatic elimination with what others call renal/fecal elimination. Additionally, it is uncertain whether the designation of fecal elimination also includes unabsorbed drug. As a result, there is some variability for major routes of elimination listed in Table 28.3.

With one exception, all ACE inhibitors have a similar onset of action, duration of action, and dosing interval. Captopril has a more rapid onset of action; however, it also has a shorter duration and requires a more frequent dosing interval than any of the other compounds. When oral dosing is inappropriate, enalaprilat can be used IV. The normal dose administered to hypertensive patients is 0.625 to 1.25 mg every 6 hours. The dose usually is administered over 5 minutes and may be titrated up to 5 mg IV every 6 hours.

Chemical/Pharmacological Classes Used to Treat Hypertension

Diuretics (see Chapter 27), ACE inhibitors, angiotensin II blockers, calcium channel blockers (see Chapter 28), central α_2-agonists, peripheral α_1-antagonists, β-blockers, ganglionic blockers, and vasodilators (see Chapter 29).

Therapeutic Applications

The ACE inhibitors have been approved for the treatment of hypertension, heart failure, left ventricular dysfunction (either post–myocardial infarction [MI] or asymptomatic), improved survival post-MI, diabetic nephropathy, and reduction of the risk of MI, stroke, and death from cardiovascular causes. Although all ACE inhibitors possess the same physiological actions and, thus, should produce similar therapeutic effects, the approved indications differ among the currently available agents (Table 28.4).

P.751

Inhibitors of ACE have been designated as first-line agents for the treatment of hypertension (37) and are effective for a variety of cardiovascular disorders. They can be used either individually or with other classes of compounds. They are especially useful in treating patients with hypertension who also suffer from heart failure, left ventricular dysfunction, or diabetes. Arterial and venous dilation seen with ACE inhibitors not only lowers blood pressure but also has favorable effects on both preload and afterload in patients with heart failure. Additionally, the ability of ACE inhibitors to cause regression of left ventricular hypertrophy has been demonstrated to reduce the incidence of further heart disease in patients with hypertension. The use of ACE inhibitors in patients with MI is similarly based on the ability of ACE inhibitors to decrease mortality by preventing postinfarction left ventricular hypertrophy and heart failure. Current recommendations to give ACE inhibitors to all patients with impaired left ventricular

P.752

systolic impairment regardless of the presence of observable symptoms also are based on the ability of these inhibitors to block the vascular and cardiac hypertrophy and remodeling caused by angiotensin II. Inhibitors of ACE also have been reported to slow the progression of diabetic nephropathy and, thus, are preferred agents in the treatment of hypertension in a patients with diabetes. It also has been suggested that ACE inhibitors be used in patients with diabetic nephropathy regardless of the presence or absence or hypertension (1,7,8,33).

Table 28.4. Dosing Information for Orally Available ACE Inhibitors

Generic Name	Trade Name(s)	Approved Indications	Dosing Range (Treatment of Hypertension)	Maximum Daily Dose	Dose Reduction with Renal Dysfunction	Available Tablet Strengths (mg)
Benazepril	Lotensin	Hypertension	10–40 mg q.d. or b.i.d.	80 mg	Yes	5, 10, 20, 40
Captopril	Capoten	Hypertension, heart failure, left ventricular dysfunction (post-MI), diabetic nephropathy	25–150 mg b.i.d. or t.i.d.	450 mg	Yes	12.5, 25, 50, 100
Enalapril	Vasotec	Hypertension, heart failure, left ventricular dysfunction (asymptomatic)	2.5–40 mg q.d. or b.i.d.	40 mg	Yes	2.5, 5, 10, 20
Fosinopril	Monopril	Hypertension, heart failure	10–40 mg q.d.	80 mg	No	10, 20, 40
Lisinopril	Prinivil,	Hypertension,	10–40 mg	40 mg	Yes	2.5, 5,

	Zestril	heart failure, Improve survival post-MI	q.d.			10, 20, 30, 40
Moexipril	Univasc	Hypertension	7.5–30 mg q.d. or b.i.d.	30 mg	Yes	7.5, 15
Perindopril	Aceon	Hypertension	4–8 mg q.d. or b.i.d.	16 mg	Yes	2, 4, 8
Quinapril	Accupril	Hypertension, heart failure	10–80 mg q.d. or b.i.d.	80 mg	Yes	5, 10, 20, 40
Ramipril	Altace	Hypertension, heart failure, reduce risk of MI, stroke, and death from cardiovascular causes	2.5–20 mg q.d. or b.i.d.	20 mg	Yes	1.25, 2.5, 5, 10
Trandolapril	Mavik	Hypertension, heart failure, left ventricular dysfunction (post-MI)	1–4 mg q.d.	8 mg	Yes	1, 2, 4

MI, myocardial infarction.

Combination Products That Include an ACE Inhibitor

ACE Inhibitor/Diuretic: benazepril/hydrochlorothiazide, captopril/hydrochlorothiazide, enalapril/hydrochlorothiazide, fosinopril/hydrochlorothiazide, lisinopril/hydrochlorothiazide, moexipril/hydrochlorothiazide, and quinapril/hydrochlorothiazide

ACE Inhibitor/Calcium Channel Blocker: benazepril/amlodipine, enalapril/felodipine, trandolapril/verapamil

Unlabeled Uses

Hypertensive crises, renovascular hypertension, neonatal and childhood hypertension, stroke prevention, migraine prophylaxis, nondiabetic nephropathy, chronic kidney disease, diagnosis of scleroderma renal crisis, and Bartter's syndrome (32,33)

Peptide Mimetics: Design of Agonists/Antagonists

Peptide mimetics have been defined as molecules that mimic the action of peptides, have no peptide bonds (i.e., no amide bonds between amino acids), and a molecular weight of less than 700 Daltons. In comparison with peptide drugs, peptide mimetics have numerous pharmaceutical advantages. Foremost among these are increased bioavailability and increased duration of action. The majority of known peptide mimetics have been discovered by random screening techniques; however, this process is costly, labor intensive, and unpredictable.

A more logical and rational approach is de novo peptide mimetic design (40), and an example of this approach is illustrated in Figure 28.14. In this example, the overall process is divided into three steps (A–C). Initially, the amino acids that comprise the pharmacophore of the peptide must be identified. Thus, a knowledge of the SARs for the peptide under consideration is essential. In Figure 28.14A, the side chains present on amino acid residues 1, 3, and 5 of a hypothetical heptapeptide are assumed to comprise the pharmacophore, and the remainder of the peptide is assumed to provide the proper structural support for these key groups. In the second step of this de novo design process, the proper spatial arrangement of the pharmacophoric groups must be elucidated. Nuclear magnetic resonance spectroscopy, x-ray diffraction studies, and molecular modeling programs that allow energy-minimization procedures and molecular dynamics simulation can be used to construct a model of the biologically active conformation. Returning to the example, the side chains representing the pharmacophore are assumed to be located on the inside of the peptide, whereas the remaining residues are assumed to be located on the outside of the peptide (Fig. 28.14B). In the final step of the process, the pharmacophoric groups must be mounted on a nonpeptide template in such a manner that they retain the proper spatial arrangement found in the original peptide. This is shown in Figure 28.14C, where side

chains 1, 3, and 5 of the original peptide are connected to a rigid template (represented by the polygon). A variety of aromatic ring systems (e.g., benzene, biphenyl, phenanthrene, and benzodiazepine) can be used to provide the rigid template, and appropriately placed alkyl groups can be used to enhance spacing and increase flexibility. Additionally, isosteres of the original pharmacophoric groups may be used to circumvent specific synthetic problems (41).

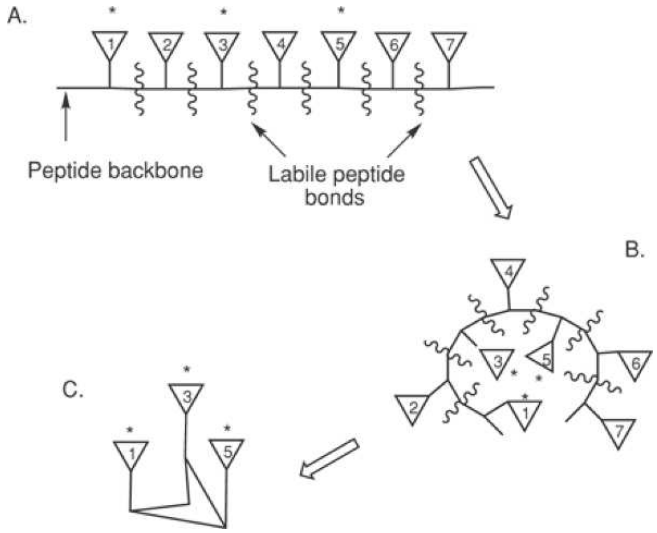

Fig. 28.14. A general process for the rational design of peptide mimetics: (A) identification of crucial pharmacophoric groups, (B) determination of the spatial arrangement of these groups, and (C) use of a template to mount the key functional groups in their proper conformation. Groups highlighted with an asterisk comprise the pharmacophore of the heptapeptide. (From Harrold MW. Preparing students for future therapies: the development of novel agents to control the renin-angiotensin system. Am J Pharm Educ 1997;61:173–178; with permission.)

Adverse Effects and Drug Interactions

The most prevalent or significant side effects of ACE inhibitors are listed below while drug interactions for ACE inhibitors are listed in Table 28.5 (1,32,33). Some adverse effects can be attributed to specific functional groups within individual agents, whereas others can be directly related to the mechanism of action of this class of compounds. The higher incidence of maculopapular rashes and taste disturbances observed for captopril have been linked to the presence of the sulfhydryl group in this compound. All ACE inhibitors can cause hypotension, hyperkalemia, and a dry cough. Hypotension results from an extension of the desired physiological effect, whereas hyperkalemia results from a decrease in aldosterone secretion secondary to a decrease in angiotensin II production. Cough is by far the most prevalent and bothersome side effect seen with the use of ACE inhibitors. It is seen in 5 to 20% of patients, usually is not dose related, and apparently results from the lack of selectivity of this class of drugs. As previously discussed, ACE inhibitors also prevent the breakdown of bradykinin (Fig. 28.3), and because bradykinin stimulates prostaglandin synthesis, prostaglandin levels also increase. The increased levels of both bradykinin and prostaglandin have been proposed to be responsible for the cough (38).

The use of ACE inhibitors during pregnancy is contraindicated. This class of compounds is not teratogenic during the first trimester, but administration during the second and third trimester is associated with an increased incidence of fetal morbidity and mortality. Inhibitors of ACE can be used in women of childbearing age; however, they should be discontinued as soon as pregnancy is confirmed.

Adverse Effects of ACE Inhibitors

Hypotension, hyperkalemia, cough, rash, taste disturbances, headache, dizziness, fatigue, nausea, vomiting, diarrhea, acute renal failure, neutropenia, proteinuria, and angioedema

Table 28.5. Drug Interactions for ACE Inhibitors

Drug	ACE Inhibitor	Result of Interaction
Allopurinol	Captopril	Increased risk of hypersensitivity
Antacids	All	Decreased bioavailability of ACE inhibitor (more likely with captopril and fosinopril)

Capsaicin	All	Exacerbation of cough
Digoxin	All	Either increased or decreased plasma digoxin levels
Diuretics	All	Potential excessive reduction in blood pressure; the effects of loop diuretics may be reduced.
Iron Salts	Captopril	Reduction of captopril levels unless administration is separated by at least 2 hours
K^+ preparations or K^+-sparing diuretics	All	Elevated serum potassium levels
Lithium	All	Increased serum lithium levels
NSAIDs	All	Decreased hypotensive effects
Phenothiazides	All	Increased pharmacological effects of ACE inhibitor
Probenecid	Captopril	Decreased clearance and increased blood levels of captopril
Rifampin	Enalapril	Decreased pharmacological effects of enalapril
Tetracycline	Quinapril	Decreased absorption of tetracycline (may result from high magnesium content of quinapril tablets)

NSAIDs, nonsteroidal anti-inflammatory agents.

Angiotensin II Receptor Blockers

From an historical perspective, the angiotensin II receptor was the initial target for developing compounds that could inhibit the renin-angiotensin pathway. Efforts to develop angiotensin II receptor antagonists began in the early 1970s and focused on peptide-based analogues of the natural agonist. The prototypical compound that resulted from these studies was saralasin, an octapeptide in which the Asp_1 and Phe_8 residues of angiotensin II were replaced with Sar (sarcosine, N-methylglycine) and Ile, respectively. Saralasin as well as other peptide analogues demonstrated the ability to reduce blood pressure; however, these compounds lacked oral bioavailability and expressed unwanted partial agonist activity. More recent efforts have used peptide mimetics to circumvent these inherent problems with peptide-based antagonists. The culmination of these efforts was the 1995 approval of losartan, a nonpeptide angiotensin II receptor blocker (ARB) (1,39).

Development of Losartan

The development of losartan can be traced back to two 1982 patent publications (42), which described the antihypertensive effects of a series of imidazole-5-acetic acid analogues. These compounds are exemplified by S-8308

(Fig. 28.15) and were later found to block the angiotensin II receptor specifically. Although these compounds were relatively weak antagonists, they did not possess the unwanted agonist activity previously seen in peptide analogues. A computerized molecular modeling overlap of angiotensin II with the structure of S-8308 revealed three common structural features: The ionized carboxylate of S-8308 correlated with the C-terminal carboxylate of angiotensin II, the imidazole ring of S-8308 correlated with the imidazole side chain of the His_6 residue, and the n-butyl group of S-8308 correlated with the hydrocarbon side chain of the Ile_5 residue (Fig. 28.15). The benzyl group of S-8308 was proposed to lie in the direction of the N-terminus of angiotensin II; however, it was not believed to have any significant receptor interactions.

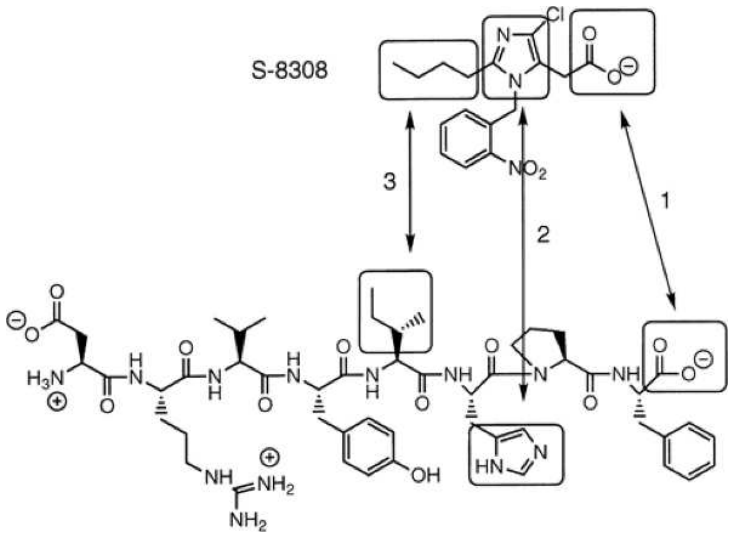

Fig. 28.15. Structural comparison of S-8308, an imidazole-5-acetic acid analogue, with angiotensin II. (Adapted from Timmermans PB, Wong PC, Chiu AT, et al. Angiotensin II receptors and angiotensin II receptor antagonists. Pharmacol Rev 1993;45:205–213; with permission.)

From S-8308, a number of molecular modifications were carried out in an attempt to improve receptor binding and lipid solubility, with the latter being important to assure adequate oral absorption. These changes resulted in the preparation of losartan, a compound with high receptor affinity (IC_{50}, 0.019 M) and oral activity (Fig. 28.16).

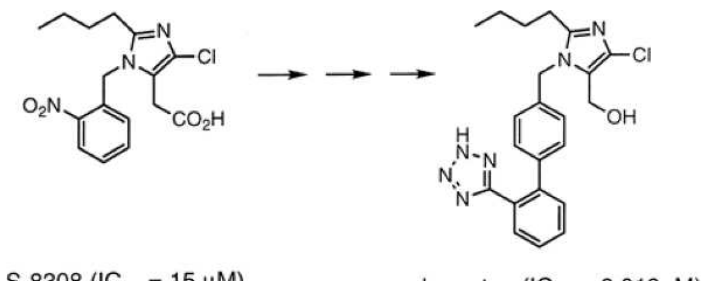

Fig. 28.16. The development of losartan from S-8308.

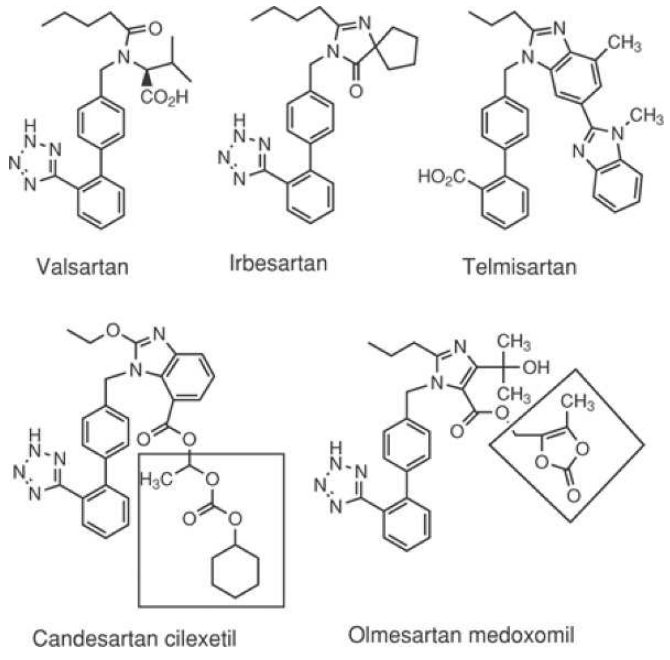

Fig. 28.17. Structures of losartan analogues. The highlighted portions of candesartan cilexitil and olmesartan medoxomil are hydrolyzed via esterases to produce their respective active, carboxylate metabolites.

Additional Angiotensin II Receptor Blockers

Valsartan, irbesartan, telmisartan, candesartan, and olmesartan are biphenyl analogues of losartan (Fig. 28.17). These compounds possess structural features that are similar to those seen in losartan. Valsartan, named for the valine portion of the compound, is the first nonimidazole-containing ARB and is slightly more potent (IC_{50}, 0.0089 μM) than losartan. The amide carbonyl of valsartan is isosteric with the imidazole nitrogen of losartan and can serve as a hydrogen bond acceptor similar to the imidazole nitrogen. Irbesartan is a spiro-compound that lacks the primary alcohol of losartan but that has a 10-fold greater binding affinity (IC_{50}, 0.0013 μM) for the angiotensin II receptor. Hydrogen bonding, or ion–dipole binding, of the carbonyl group can mimic the interaction of the primary alcohol of losartan, whereas the spirocyclopentane can provide enhanced hydrophobic binding. Both candesartan cilexitil and telmisartan contain benzimidazole rings that provide some enhanced hydrophobic binding, similar to that seen with the spirocyclopentane ring of irbesartan. Both candesartan cilexitil and olmesartan medoxomil are pro-drugs that are rapidly and completely hydrolyzed during absorption from the gastrointestinal tract to their active carboxylic acid metabolites, candesartan and olmesartan, respectively. These carboxylic acids lie in exactly the same locations as the hydroxyl group of losartan, the carboxylic acid of valsartan, and the ketone of irbesartan and can participate in both ionic and dipole interactions.

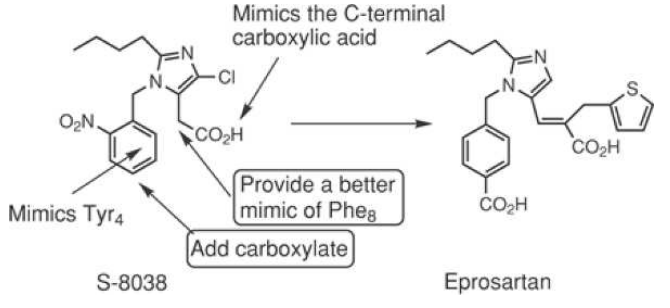

Fig. 28.18. The development of eprosartan from S-8308. The Phe_8 residue of angiotensin II contains the C-terminal carboxylic acid.

Eprosartan was developed using a different hypothesis than that for losartan (Fig. 28.18). Similar to the rationale for losartan, the carboxylic acid of S-8308 was thought to mimic the Phe_8 (i.e., *C-terminal) carboxylate of angiotensin II. The benzyl group of S-8308 was*

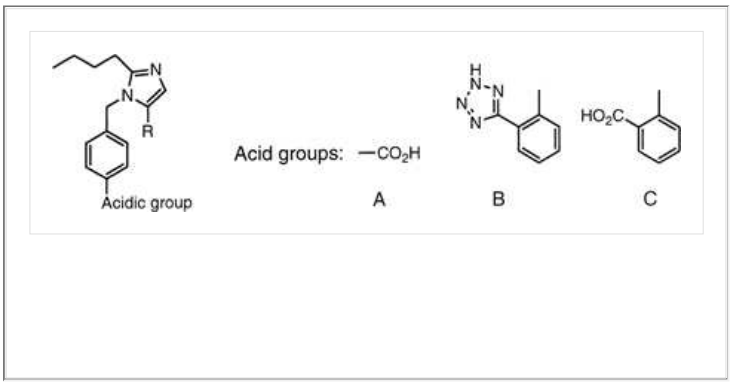
*proposed to be an important structural feature that mimicked the aromatic side chain of Tyr_4 present in the agonist. Thus, the major structural change was not an extension of the N-benzyl group but, rather, an enhancement of the compound's ability to mimic the C-terminal end of angiotensin II. This was accomplished by substituting the 5-acetic acid group with an α-thienylacrylic acid. In addition, a para-carboxylate (a functional group investigated during the development of losartan) also was added. The thienyl ring isosterically mimics the Phe_8 phenyl ring of angiotensin II and, along with the para-carboxylate, is responsible for the excellent potency (IC_{50} = 0.0015 μM) of this compound (*39*).*

Mechanism of Action

The angiotensin II receptor exists in at least two subtypes, type 1 (AT_1) and type 2 (AT_2). The AT_1 receptors are located in brain, neuronal, vascular, renal, hepatic, adrenal, and myocardial tissues and mediate the cardiovascular, renal, and central nervous system (CNS) effects of angiotensin II. All currently available ARBs are 10,000-fold more selective for the AT_1 receptor subtype and act as competitive antagonists at this site. In terms of relative affinity for the AT_1 receptor, candesartan and olmesartan have the greatest affinity; irbesartan and eprosartan have a somewhat lower affinity; and telmisartan, valsartan, and losartan have the lowest affinity. All ARBs prevent and reverse all of the known effects of angiotensin II, including rapid and slow pressor responses, stimulatory effects on the peripheral sympathetic nervous system, CNS effects, release of catecholamines, secretion of aldosterone, direct and indirect renal effects, and all growth-promoting effects. The function of the AT_2 receptors is not as well characterized; however, they have been proposed to mediate a variety of growth, development, and differentiation processes. Some concern has arisen that unopposed stimulation of the AT_2 receptor in conjunction with AT_1 receptor antagonism may cause long-term adverse effects. As a result, compounds that exhibit balanced antagonism at both receptor subtypes are currently being sought (1,43).

Structure–Activity Relationships

All commercially available ARBs are analogues of the following general structure:



1. The “acidic group” is thought to mimic either the Tyr_4 phenol or the Asp_1 carboxylate of angiotensin II. Groups capable of such a role include the carboxylic acid (A), a phenyl tetrazole (B), or a phenyl carboxylate (C).
2. In the biphenyl series, the tetrazole and carboxylate groups must be in the ortho position for optimal activity (the tetrazole group is superior in terms of metabolic stability, lipophilicity, and oral bioavailability).
3. The n-butyl group of the model compound provides hydrophobic binding and, most likely, mimics the side chain of Ile_5 of angiotensin II. As seen with candesartan, telmisartan, and olmesartan, this n-butyl group can be replaced with either an ethyl ether or an n-propyl group.
4. The imidazole ring or an isosteric equivalent is required to mimic the His_6 side chain of angiotensin II.
5. Substitution can vary at the “R” position. A variety of R groups, including a carboxylic acid, a hydroxymethyl group, a ketone, or a benzimidazole ring, are present in currently available ARBs and are thought to interact with the AT_1 receptor through either ionic, ion–dipole, or dipole–dipole bonds.

Physicochemical Properties

All ARBs are acidic drugs. The tetrazole ring found in losartan, valsartan, irbesartan, candesartan, and olmesartan has a pK_a of approximately 6 and will be at least 90% ionized at physiological pH. The carboxylic acids found on valsartan, candesartan, olmesartan, telmisartan, and eprosartan have pK_a values in the range 3–4 and also will be primarily ionized. Currently, available agents have adequate, but not excellent, lipid solubility. As previously mentioned, the tetrazole group is more lipophilic than a carboxylic. Additionally, the four nitrogen atoms present in the tetrazole ring can create a greater charge distribution than that available for a carboxylic acid. These properties have been proposed to be responsible for the enhanced binding and bioavailability of the tetrazole-containing compounds (44). Similar to ACE inhibitors,

the stereochemistry of valsartan is consistent with the L-amino acids in the natural agonist.

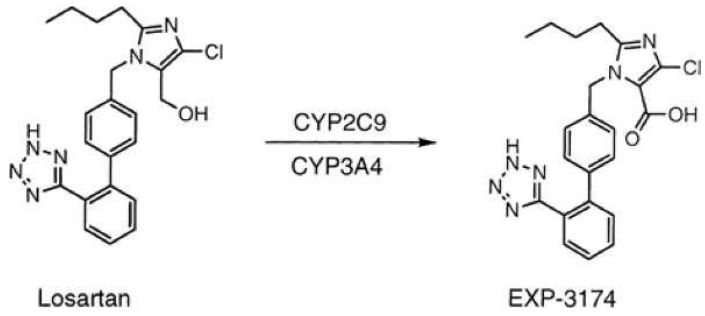


Fig. 28.19. The metabolic conversion of losartan to EXP-3174 by cytochrome P450 isozymes.

Metabolism

Approximately 14% of a dose of losartan is oxidized by the isozymes CYP2C9 and CYP3A4 to produce EXP-3174, a noncompetitive AT_1 receptor antagonist that is 10- to 40-fold more potent than losartan (Fig. 28.19). The overall cardiovascular effects seen with losartan result from the combined actions of the parent drug and the active metabolite; thus, losartan should not be considered to be a pro-drug (1). As previously mentioned, candesartan cilexetil and olmesartan medoxomil are rapidly and completely hydrolyzed to candesartan and olmesartan, respectively, in the intestinal wall.

None of the other compounds are converted to active metabolites. All of these compounds are primarily (80%) excreted unchanged. Approximately 20% of valsartan is metabolized to inactive compounds via mechanisms that do not appear to involve the CYP450 system. The primary circulating metabolites for irbesartan, telmisartan and eprosartan, are inactive glucuronide conjugates. A small amount of irbesartan is oxidized by CYP2CP; however, irbesartan does not substantially induce or inhibit the CYP450 enzymes normally involved in drug metabolism (1,32,33,34).

Pharmacokinetic Parameters

The pharmacokinetic parameters and dosing information for angiotensin receptor antagonists are summarized in Tables 28.6 and 28.7, respectively (32,33,34). With the exception of irbesartan (60–80%) and, possibly, telmisartan (42–58%), all of the compounds have low, but adequate, oral bioavailability (15–33%). Given the fact that most of the compounds are excreted unchanged, the most probable reasons for the low bioavailability are poor lipid solubility and incomplete absorption. Effects of food on the absorption of losartan, eprosartan, valsartan, and eprosartan is to reduce absorption; however, these effects have been deemed to be clinically insignificant; thus, the compounds can be taken either with or without food. All of the compounds have similar onsets, are highly protein bound, have elimination half-lives that allow once- or twice-daily dosing, and with the exception of olmesartan, are primarily eliminated via the fecal route. Candesartan and telmisartan appear to require a slightly longer time to reach peak plasma concentrations. As with ACE inhibitors, literature designation of fecal elimination is unclear regarding whether it includes unabsorbed drug.

Candesartan cilexetil, losartan, and olmesartan differ from the other compounds in several respects. They are the only compounds with active metabolites, and they have the highest renal elimination of all of the agents. Product labeling indicates that renal impairment does not require a dosage reduction for losartan, but area under the curve values are increased by 50% in patients with

a creatinine clearance of less than 30 mL/min and are doubled in hemodialysis patients. These increases are not seen for the other agents. Losartan and telmisartan are the only two agents that require initial dose reductions in patients with hepatic impairment. Because of significantly increased plasma concentration, patients with impaired hepatic function or biliary obstructive disorders should avoid the use of telmisartan.

Table 28.6. Pharmacokinetic Parameters of Angiotensin II Receptor Blockers

Drug	Oral Bioavailability (%)	Active Metabolite	Protein Binding (%)	Time to Peak Plasma Concentration (hours)	Elimination Half-Life (hours)	Major Route(s) of Elimination
Candesartan Cilexetil	15	Candesartan	99	3–4	9	Fecal (67%) Renal (33%)
Eprosartan	15	None	98	1–2	5–9	Fecal (90%) Renal

						(10%)
Irbesartan	60–80	None	90	1.5–2.0	11–15	Fecal (80%) Renal (20%)
Losartan	33	EXP-3174	98.7 (losartan) 99.8 (EXP-3174)	1 (losartan) 3–4 (EXP-3174)	1.5–2.0 (losartan) 6–9 (EXP-3174)	Fecal (60%) Renal (35%)
Olmesartan Medoxomil	26	Olmesartan	99	1.5–3.0	10–15	Fecal (35–50%) Renal (50–65%)
Telmisartan	42–58	None	100	5	24	Fecal (97%)
Valsartan	25	None	95	2–4	6	Fecal (83%) Renal (13%)

Table 28.7. Dosing Information for Angiotensin II Receptor Blockers

Generic Name	Trade Name(s)	Approved Indications	Dosing Range (Treatment of Hypertension)	Maximum Daily Dose	Initial Dose Reduction with Hepatic Dysfunction	Dose Reduction with Renal Dysfunction	Available Tablet Strengths (mg)
Candesartan Cilexetil	Atacand	Hypertension, heart failure	8–32 mg q.d.	32 mg	No	Only with severe impairment	4, 8, 16, 32
Eprosartan	Teveten	Hypertension	400–800 mg q.d. or b.i.d.	900 mg	No	Decrease maximum daily dose to 600 mg	400, 600
Irbesartan	Avapro	Hypertension, nephropathy in type II diabetics	150–300 mg q.d.	300 mg	No	No	75, 150, 300
Losartan	Cozaar	Hypertension, nephropathy in type II diabetics, hypertension with left ventricular hypertrophy	25–100 mg q.d. or b.i.d.	100 mg	Yes	Adults, no Children, yes	25, 50, 100
Olmesartan	Benicar	Hypertension	20–40 mg	40	No	No	5, 20,

Medoxomil			q.d.	mg			40
Telmisartan	Micardis	Hypertension	40–80 mg q.d.	80 mg	Yes (avoid)	No	20, 40, 80
Valsartan	Diovan	Hypertension heart failure	80–320 q.d.	320 mg	No	No	40, 80, 160, 320

Therapeutic Applications

All ARBs are currently approved for the treatment of hypertension and, along with ACE inhibitors, diuretics, β-blockers, and calcium channel blockers, have been designated as first-line agents either alone or in combination with other antihypertensive agents (37). All ARBs are available as single agents and as combination products with hydrochlorthiazide. Additionally, irbesartan and losartan have been approved for the treatment of nephropathy in type II diabetes, losartan for the treatment of hypertension with left ventricular hypertrophy, and candesartan and valsartan for the treatment of heart failure. Based on their ability to attenuate the renin-angiotensin system, one should expect a gradual increase in the number of uses and approved indications for this class of agents.

Adverse Effects

The most prevalent side effects of ARBs are listed above and discussed below. (1,32,33,34). Overall, this class of agents is well tolerated, with CNS effects being the most commonly reported complaint. Similar to ACE inhibitors, some of the adverse effects are directly related to attenuation of the renin-angiotensin pathway. Notably absent are the dry cough and angioedema seen with ACE inhibitors. Because ARBs are specific in their actions, this class of drugs does not affect the levels of bradykinin or prostaglandins and, thus, does not cause these bothersome side effects. Like ACE inhibitors, the use of ARBs during pregnancy is contraindicated, especially during the second and third trimesters. The use of ARBs should be discontinued as soon as pregnancy is confirmed unless the benefits outweigh the potential risks.

Chapter 29

Central and Peripheral Sympatholytics and Vasodilators

David A. Williams

Cardiovascular Hypertension

Hypertension is the most common cardiovascular disease and is the major risk factor for coronary artery disease, heart failure, stroke, and renal failure. Approximately 50 million Americans have a systolic or diastolic blood pressure above 140/90 mm Hg. The onset of hypertension is defined as having a blood pressure of 140/90 mm Hg or greater and most commonly appears during the fourth, fifth, and sixth decades of life (1).

The importance of controlling blood pressure is well documented (1), although the rates of awareness, treatment, and control of hypertension have not risen as expected in the National Health and Nutrition Examination Survey (2). This survey showed that 68% of Americans are aware that they have high blood pressure but that only 53% are receiving treatment and only 27% have their blood pressure under control. Since 1976, there had been a significant improvement in the rates of awareness, treatment, and control of hypertension, but since 1990, whatever progress had been achieved has now reached a plateau (2). Although the age-adjusted death rates from stroke and coronary heart disease during this period have fallen by 59 and 53%, respectively, these rates of decline also appear to have reached a plateau (2). These troubling trends should awaken clinicians to be more aggressive in the treatment of patients with hypertension.

When the decision to initiate hypertensive therapy is made, physicians often are presented with the dilemma of which of more than 80 antihypertensive products, representing more than 8 different drug classes, to use for their patients (Table 29.1) (1,3). Those factors that can affect the outcomes from the treatment of hypertension include potential adverse effects, clinically significant drug–drug interactions (especially when so many different drug classes are involved), patient compliance, affordability (especially for the elderly and those on fixed incomes), risk/benefit ratios, and dosing frequency must be considered (3). Having considered these factors, the health care provider (clinician or pharmacist) arrives at an appropriate choice of antihypertensive drug (3). Once the patient is stabilized on a antihypertensive medication, some of these issues need to be reevaluated. Patients should be continually asked about side effects, because many of the antihypertensive drugs possess side effects that the patient may not tolerate (1). This problem and the cost of drug therapy can affect compliance to drug therapy especially for the elderly and those on fixed incomes (4).

Drug therapy in the management of hypertension must be individualized and adjusted based on coexisting risk factors, including the degree of blood pressure elevation, severity of the disease (e.g., presence of target organ damage), presence of underlying cardiovascular or other risk factors, response to therapy (single or multiple

drugs), and tolerance to drug-induced adverse effects (1,3). Antihypertensive therapy generally is reserved for patients who fail to respond to nondrug therapies along with lifestyle modifications, such as diet including sodium restriction and adequate potassium intake, regular aerobic physical activity, moderation of alcohol consumption, and weight reduction (3).

Clinical Significance

Understanding the pathophysiology of hypertension and the medicinal chemistry of the treatment options allows the clinician to tailor pharmacotherapy to each individual patient. The patient with hypertension may start on a single oral agent but, eventually, will need a combination of medications from different drug classes, especially if the patient has diabetes, heart failure, or renal disease. A through understanding of the basic chemical properties of the drugs and their respective mechanism of action will be invaluable to making appropriate clinical decisions. The therapy for patients with hypertension must be “fine-tuned” as the clinical presentation of the hypertension changes or the patient's ability to metabolize and eliminate the medications changes. The therapeutic benefits can be maximized, and the side effects or other toxicities can be minimized. The ultimate goal for these patients would be to maximize the quality of life by controlling blood pressure and preventing long-term complications.

The astute clinician understands the differences between the medications in the individual medication classes. All β-blockers are not considered to be equally safe and effective in treating patients with peripheral arterial disease, reactive airway disease, heart failure, or a cocaine overdose. Not all calcium channel blockers and β-blockers may be safely combined for angina treatment, and only certain antihypertensive agents may be used safely during

pregnancy.

The study of medicinal chemistry gives us hope for future treatment options for hypertension. Knowledge of structure–activity relationships and mechanisms of action foster the development of new medications and administration techniques. Clinicians will have to stay up to date with the new developments in the etiology of the disease state, the molecular bases of the drugs' actions, and the pharmacokinetic properties of the drugs to provide the best therapeutic outcomes for patients.

Kimberly Birtcher, Pharm.D.

Clinical Assistant Professor

University of Houston College of Pharmacy

It is not surprising that compliance with antihypertensive therapy may be as low as 40% when one considers that the patient, if he or she has other chronic diseases, may be taking as many as 10 different drugs and up to 40 tablets or capsules per day (4). To achieve better compliance requires educating the patient and simplification of the drug regimen by reducing the number of drugs being taken.

Hypertension in pregnancy presents a formidable therapeutic challenge and requires comprehensive management with close monitoring for both maternal and fetal welfare (5). Mechanisms involved with pregnancy-related hypertension include an hyperadrenergic state, plasma volume reduction, reduction in uteroplacental perfusion, hormonal control of vascular reactivity, and prostacyclin deficiency may result from or activate the mechanisms that elevate blood pressure. Effective blood pressure control for pregnancy-related hypertension often can be achieved with methyldopa (recommended), β-blockers, or mixed α/β-blockers (combinations of β-blockers with α-blockers). The vasodilating agent hydralazine is used to treat hypertensive emergencies associated with eclampsia (1,6). The presence or development of proteinuria (preeclampsia) in a hypertensive pregnant woman implies a major increase in risk to the fetus and warrants immediate admission to a hospital for specialist management (5).

Combination Antihypertensive Therapy

It is well-documented that monotherapy adequately controls hypertension only in approximately 50% of patients (7,8). Therefore, a large percentage of patients will require at least two drugs to control their blood pressure and symptoms of hypertension. By combining different antihypertensive drug classes in low doses, their different mechanisms of action result in synergistic blood pressure lowering as well as in minimizing the adverse effects and improving compliance issues (1,8). For example, the addition of a low-dose thiazide diuretic dramatically increases the response rates to methyldopa, angiotensin-converting

enzyme (ACE) inhibitors, and β-blockers without producing the undesirable side effects. In the latest guidelines for treatment of hypertension, the Joint National Committee for Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI), clinicians are encouraged to use either diuretics or mixed α/β blockers or β_1-blockers for initial monotherapy in patients with uncomplicated hypertension, because both of these drug classes have been shown

to decrease morbidity and mortality in long-term clinical trials (2). In the presence of other cardiovascular diseases, however, the other antihypertensive classes that could be used as first-line agents include ACE inhibitors, calcium-channel blockers, α_1-blockers, or mixed α/β-blockers. In patients with risk factors for heart disease or with clinical manifestations of cardiovascular disease (Table 29.2), treatment should be more aggressive, with the goal of reducing blood pressure to less than 140/90 mm Hg (1). These recommendations reflect the current awareness of the importance of addressing other cardiovascular conditions aside from just lowering the blood pressure.

Table 29.2. Risk Factors for Cardiovascular Disease

Correctable	Noncorrectable
Cigarette smoking	Age > 60 years
Hypertension	Sex (men and postmenopausal women)
Elevated cholesterol	Family history of cardiovascular disease or stroke (women <65 years, men <55 years)
Reduced HDL cholesterol Diabetes mellitus	
Obesity	Target oral damage

HDL, high-density lipoprotein.

Arterial pressure is the product of cardiac output and peripheral vascular resistance and, therefore, can be lowered by decreasing or inhibiting either or both of these physiologic responses with the drug classes represented in Table 29.1 and summarized in Figure 29.1. This chapter will discuss those antihypertensives that are classified as either sympatholytics (i.e., having a central or peripheral mechanism of action) or vasodilators. These classes of drugs are less commonly used today because of the higher incidence of side effects associated with inhibition of the sympathetic nervous system (sympathoinhibition) or vasodilation. In many instances, they have been replaced because of availability of newer and more effective antihypertensive drugs with fewer side effects, such as ACE inhibitors.

Overview of Vascular Tone (1)

Before beginning the discussion of the sympatholytics and vasodilators, it is important to review the nature of vascular tone. The term “vascular tone” refers to the degree of constriction experienced by a blood vessel relative to its maximally dilated state. All resistance (arteries) and capacitance (venous) vessels under basal conditions exhibit some degree of smooth muscle contraction, which determines the diameter and, hence, the tone of the vessel.

Basal vascular tone varies among organs. Those organs having a large vasodilatory capacity (e.g., myocardium, skeletal muscle, skin, and splanchnic circulation) have high vascular tone, whereas organs having relatively low vasodilatory capacity (e.g., cerebral and renal circulations) have low vascular tone. Vascular tone is determined by

many different competing vasoconstrictor and vasodilator influences acting on the blood vessel. Influences such as sympathetic nerves and circulating angiotensin II regulate arterial blood pressure by increasing vascular tone (i.e., cause vasoconstriction). On the other hand, mechanisms for local blood flow regulation within an organ include endothelial factors (e.g., nitric oxide [NO] and endothelin) or local hormones/chemical substances (e.g., prostanoids, thromboxanes, histamine, and bradykinin) that can either increase or decrease tone. The mechanisms by which the above influences either constrict or relax blood vessels involve a variety of signal transduction mechanisms that, ultimately, influence the interaction between actin and myosin in the smooth muscle.

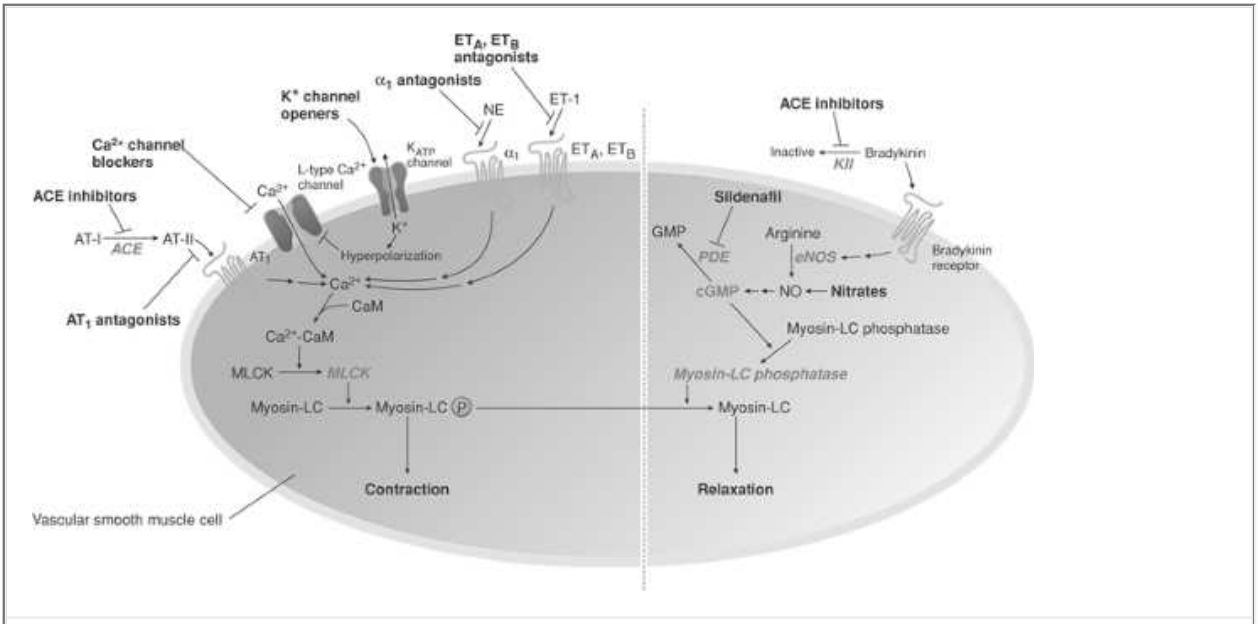

Fig. 29.1. Calcium second messenger mechanism of vascular smooth muscle contraction and relaxation and sites of action of the peripheral and centrally acting sympatholytics and vasodilators. (From Yeh DC, Michel T. Pharmacology of Vascular Tone. In: Golan DE, Tashjian A, Armstrong E, et al., eds. Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004; 317–330; with permission.)

Overview of the Regulation of Vascular Smooth Muscle Contraction and Relaxation (1)

The contractile characteristics and the mechanisms that cause contraction of vascular smooth muscle (VSM) are very different from those of cardiac muscle. The VSM undergoes slow, sustained, tonic contractions, whereas cardiac muscle contractions are rapid and of relatively short duration (a few hundred milliseconds). Whereas VSM contains actin and myosin, it does not have the regulatory protein troponin, as is found in the heart. Furthermore, the arrangement of actin and myosin in VSM is not organized into distinct bands, it is in cardiac muscle. This is not to imply that the contractile proteins of VSM are disorganized and not well-developed. Actually, they are highly organized and well-suited for their role in maintaining tonic contractions and reducing lumen diameter.

Contraction of the VSM can be initiated by mechanical, electrical, and chemical stimuli. Passive stretching of VSM can cause contraction that originates from the smooth muscle itself and, therefore, is termed a "myogenic response." Electrical depolarization of the VSM cell membrane also elicits contraction, most likely by opening voltage-dependent calcium channels (L-type calcium channels) and causing an influx (increase) in the intracellular concentration of calcium. Finally, a number of chemical stimuli, such as norepinephrine, angiotensin II, vasopressin, endothelin-1, and thromboxane A_2, can cause contraction. Each of these substances bind to specific receptors on the VSM cell (or to receptors on the endothelium adjacent to the VSM), which then leads to VSM contraction. The mechanism of contraction involves different signal transduction pathways, all of which converge to increase intracellular calcium.

The mechanism by which an increase in intracellular calcium stimulates VSM contraction is illustrated in the left panel of Figure 29.1 An increase in free intracellular calcium results from either increased flux of calcium into the cell through calcium channels or by release of calcium from intracellular stores, such as the sarcoplasmic reticulum. The free calcium binds to a special calcium binding protein called calmodulin. Calcium–calmodulin activates myosin light-chain kinase (MLCK), an enzyme that is capable of phosphorylating myosin light chains in the presence of adenosine triphosphate (ATP). Myosin light-chain phosphorylation leads to actin–myosin cross-bridge formation between the myosin heads and the actin filaments and, hence, VSM contraction. Dephosphorylation of myosin light-chain phosphorylation by myosin light-chain phosphorylase yields myosin light chain which results in relaxation. The concentration of intracellular calcium depends on the balance between the calcium that enters the cells, the calcium that is released by intracellular storage sites (e.g., sarcoplasmic reticulum), and the removal of calcium either back into storage sites or out of the cell. Calcium is resequestered by the sarcoplasmic reticulum by an ATP-dependent calcium pump. Calcium is removed from the cell to the external environment either by an ATP-dependent calcium pump

or by the sodium-calcium exchanger.

The activation of the calcium second messenger system by hormones, neurotransmitters, local mediators, and sensory stimuli is very important in regulating VSM contraction. Several signal transduction mechanisms modulate intracellular calcium concentration and, therefore, the state of vascular tone. These calcium second messenger systems are the phosphatidylinositol (PIP_2)/G_q protein–coupled pathway, the cyclic adenosine monophosphate (cAMP)/G_s protein–coupled pathway, and the NO/cyclic guanosine monophosphate (cGMP) pathway.

The PIP_2 pathway in VSM is similar to that found in the heart (Fig. 29.2). The VSM membrane is lined with specific

receptors for norepinephrine (α_1-adrenoceptors), angiotensin II (AT-II), or endothelin-1 (ET_A receptors) that stimulate G_q protein, activating phospholipase C and resulting in the formation of inositol triphosphate (IP_3) from PIP_2 in the membrane. Then, IP_3 stimulates the sarcoplasmic reticulum to release calcium, which in turn activates the phosphorylation of myosin light chain, causing contraction. The formation of diacylglycerol activates protein kinase C, which also contributes to VSM contraction via protein phosphorylation.

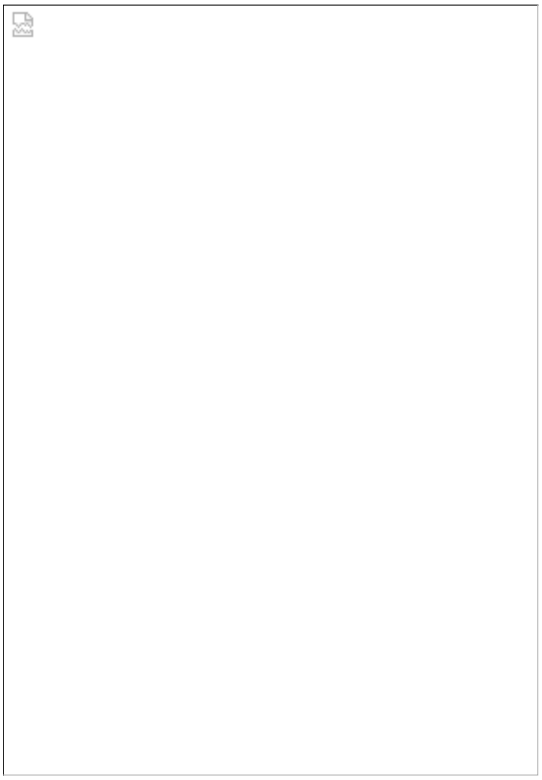

Fig. 29.2. The mechanism of activation of the cyclic adenosine monophosphate (cAMP)/G_s protein–coupled pathway and the phospholipase C/phosphatidylinositol (PIP_2) pathway in vascular smooth muscle. (From Yeh DC, Michel T. Pharmacology of Vascular Tone. In: Golan DE, Tashjian A, Armstrong E, et al., eds. Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004; 317–330; with permission.)

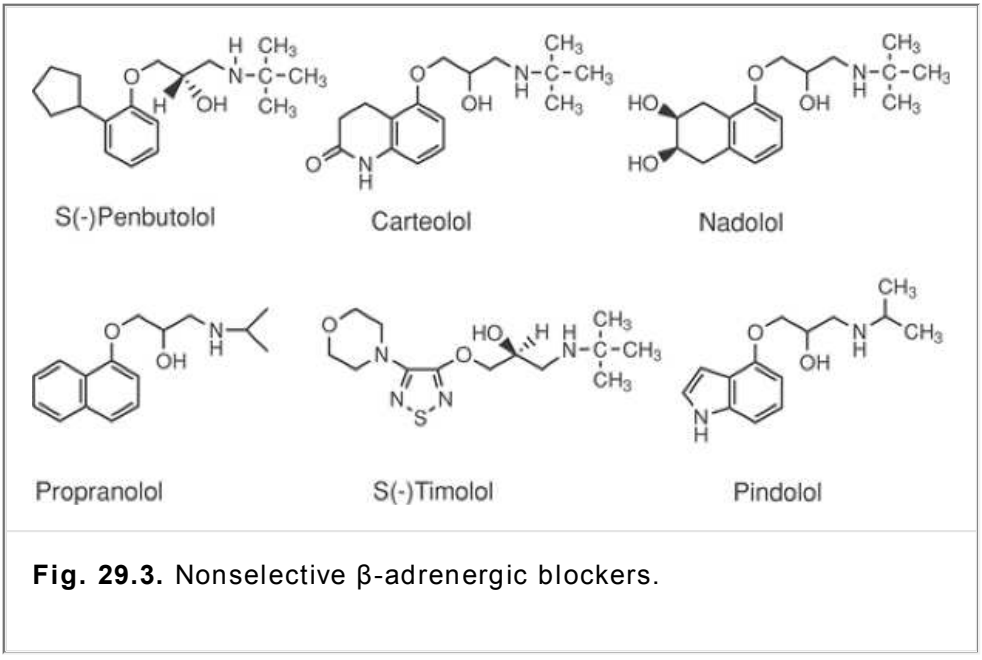

Fig. 29.3. Nonselective β-adrenergic blockers.

The cAMP/G_s protein–coupled pathway stimulates adenylate (also known as adenylyl) cyclase, which catalyzes the formation of cAMP (Fig. 29.2). In VSM, unlike the heart, an increase in intracellular cAMP concentrations stimulated by a β_2-adrenoceptor agonist, such as epinephrine or isoproterenol, binding to the β-receptor inhibits myosin light-chain phosphorylation, causing VSM relaxation. Therefore, drugs that increase cAMP (e.g., β_2-adrenoceptor agonists, PDE3 phosphodiesterase inhibitors) cause vasodilation. On the other hand, stimulation of G_i protein inhibits adenylyl cyclase.

A third mechanism that is also very important in regulating VSM tone is the NO/cGMP Pathway (Fig. 29.1, right). The formation of NO in the endothelium activates guanylate (also known as guanylyl) cyclase, which causes increased formation of cGMP and vasodilation. The precise mechanisms by which cGMP relaxes VSM is unclear; however, cGMP can activate a cGMP-dependent protein kinase, inhibit calcium entry into the VSM, activate K^+ channels, and decrease IP_3.

Drug Therapy of Hypertension

Peripherally Acting Sympatholytics

β-Adrenergic receptor blockers

β-blockers are drugs that bind to β-adrenoceptors and, thereby, block the binding of norepinephrine and epinephrine to these receptors, causing inhibition of normal sympathetic effects. Therefore, β-blockers are sympatholytic drugs. Some β-blockers, when they bind to the β-adrenoceptor, partially activate the receptor while preventing norepinephrine from binding to the receptor. These partial agonists therefore provide some “background” of sympathetic activity while preventing normal and enhanced sympathetic activity. These particular β-blockers (partial agonists) are said to possess intrinsic sympathomimetic activity (ISA). Some β-blockers also possess what is referred to as membrane-stabilizing activity. This effect is similar to the membrane-stabilizing activity of sodium channel blockers that represent Class I antiarrhythmics.

The first generation of β-blockers were nonselective, meaning that they blocked both β_1- and β_2-adrenoceptors (Fig. 29.3). Second-generation β-blockers are more cardioselective, because they are relatively selective for β_1-adrenoceptors (Fig. 29.4). Note that this relative selectivity can be lost at higher drug doses. Finally, the third-generation β-blockers are drugs that also possess vasodilator actions through blockade of vascular α-adrenoceptors (mixed α_1/β_1-adrenergic blockers) (see Fig. 29.7). Their structure–activity relationship, pharmacokinetics, and metabolism are discussed in Chapter 13 and also presented in Table 29.3. In addition to uncomplicated hypertension, they also may be used as monotherapy in the treatment of angina, arrhythmias, mitral valve prolapse, myocardial infarction, migraine headaches, performance anxiety, excessive sympathetic tone, or “thyroid storm” in hyperthyroidism (6).

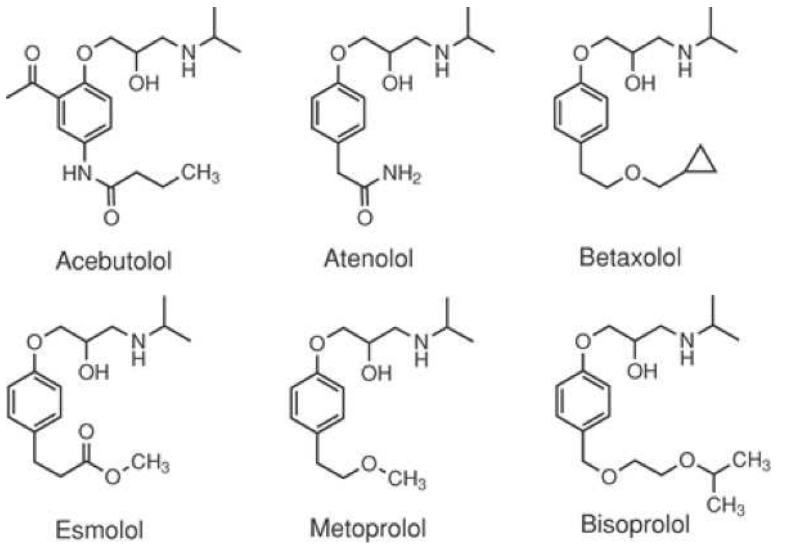

Fig. 29.4. β_1-selective adrenergic blockers.

Table 29.3. Pharmacologic/Pharmacokinetic Properties of Antihypertensive β-Adr

Drug	Adrenergic Receptor Blocking Activity	Membrane Stabilizing Activity	Intrinsic Sympatho-mimetic activity	Lipid Solubility	Extent of Absorption (%)	Absolute Oral Bioavailability (%)	Half-li (hours
Acebutolol (Sectral)	β_1a	+	+	Low	90	20–60	3–4
Atenolol (Tenormin)	$\beta_1{}^{\alpha}$	0	0	Low	50	50–60	6–9
Betaxolol (Kerlone)	$\beta_1{}^{\alpha}$	%	0	Low	~100	89	14–2
Bisoprolol (Zebeta)	$\beta_1{}^{\alpha}$	0	0	Low	≥0	80	9–12
Esmolol (Brevibloc)	$\beta_1{}^{\alpha}$	0	0	Low	NA	NA	0.15

Metoprolol (Lopressor) Metoprolol, LA	β_1[a]	0b	0	Moderate	95	40–50	3–7
Carteolol (Cartrol)	β	0	11	Low	80	85	6
Nadolol (Corgard)	β_1 β_2	0	0	Low	30	30–50	20–2
Penbutolol (Levatol)	β_1 β_2	0	+	High	~100	>90	5
Pindolol (Visken)	β_1 β_2	+	111	Moderate	95	>90	3–4c
Propranolol (Inderal)	β_1 β_2	11	0	High	90	30	3–5
Propranolol, LA						9–18	8–11
Timolol (Blocadren)	β_1 β_2	0	0	Low to moderate	90	75	4
Labetalold (Normodyne)	β_1 β_2 α_1	0	0	Moderate	100	30–40	5.5–8
Carvedilol (Coreg)	β_1 β_2 α_1	0	0	Moderate to high	>90	25–35	7–10

[a]Inhibits β_2-receptors (bronchial and vascular) at higher doses.

[b]Detectable only at doses much greater than required for β-blockade.

[c]In elderly hypertensive patients with normal renal function; half-life variable, 7–15 hours.

[d]Not labetalol monograph.

Adapted from Drug Facts and Comparison 2000; with permission.
NA, not applicable (available as intravenous only); 0, none; +, low; 11, moderate; 111, high.

Mechanism of Action

The VSM are lined with β_2-adrenoceptors that normally are activated by norepinephrine released from sympathetic adrenergic nerves or by circulating epinephrine. These receptors, like those in the heart, are coupled to a G_s protein, which stimulates the formation of cAMP. Although increased cAMP enhances cardiac contraction, with VSM an increase in cAMP leads to smooth muscle relaxation (Fig. 29.2). Therefore, increases in intracellular cAMP caused by β_2-agonists inhibits MLCK, thereby producing less contractile force (i.e., promoting relaxation). Inhibition of cardiac β_1- and β_2-adrenoceptors reduce the contractility of the myocardium (negative inotropic), decreasing heart rate (negative chronotropic), blocking sympathetic outflow from the central nervous system (CNS), and suppressing renin release (9). The antianginal and antiarrhythmic effects of the β-blockers are discussed in Chapter 26.

Therapeutic Applications (1,6,10)

β-Blockers decrease arterial blood pressure by reducing cardiac output. Many forms of hypertension are associated with an increase in blood volume and cardiac output. Therefore, reducing cardiac output by β-blockade can be an effective treatment for hypertension, especially when used in conjunction with a diuretic. Hypertension in some patients is caused by emotional stress, which causes enhanced sympathetic activity. β-Blockers are very effective in these patients and are especially useful in treating hypertension caused by a pheochromocytoma, which results in elevated circulating catecholamines. β-Blockers have an additional benefit as a treatment for hypertension in that they inhibit the release of renin by the kidneys (the release of which is partly regulated by a β_1-adrenoceptors in the kidney). Decreasing circulating plasma renin leads to a decrease in angiotensin II and aldosterone, which enhances renal loss of sodium and water and further diminishes arterial pressure. Acute treatment with a β-blocker is not very effective in reducing arterial pressure because of a compensatory increase in systemic vascular resistance. This may occur because of baroreceptor reflexes working in conjunction with the removal of β_2 vasodilatory influences that normally offset, to a small degree, α-adrenergic–mediated vascular tone. Chronic treatment with β-blockers lowers arterial pressure more than acute treatment, possibly because of reduced renin release and effects of β-blockade on central and peripheral nervous systems.

The selection of oral β-blockers as monotherapy for uncomplicated hypertension is based on several factors, including their cardioselectivity and preexisting conditions, ISA, lipophilicity, metabolism, and adverse effects (exception is esmolol) (Table 29.3). Esmolol is a very short-acting cardioselective β_1-blocker administered by infusion because of its rapid hydrolysis by plasma esterases to a rapidly excreted zwitterionic metabolite (plasma half-life, 9 minutes). Following the discontinuation of esmolol infusion, blood pressure returns to preexisting conditions in approximately 30 minutes. Oral β-blockers are recommended as initial therapy for uncomplicated hypertension or in the stepped-care approach to antihypertensive drug therapy (as step 1). The elderly hypertensive patient (age, >65 years) may not tolerate or respond to these drugs because of their mechanism of lowering cardiac output and increasing systemic vascular resistance (11).

Adverse Effects

Common adverse effects for the β-blockers include decreased exercise tolerance, cold extremities, depression, sleep disturbance, and impotence, although these side effects may be less severe with the β_1-selective blockers, such as metoprolol, atenolol, or bisoprolol (12). The use of lipid-soluble β-blockers, such as propranolol (Table 29.3), has been associated with more CNS side effects, such as dizziness, confusion, or depression (1,6). These side effects can be avoided, however, with the use of hydrophilic drugs, such as nadolol or atenolol. The use of β_1-selective drugs also helps to minimize adverse effects associated with β_2-blockade, including suppression of insulin release and increasing the chances for bronchospasms (asthma) (1,6). It is important to emphasize that none of the β-blockers, including the cardioselective ones, is cardiospecific. At high doses, these cardioselective agents can still adversely affect asthma, peripheral vascular disease, and diabetes (1,6). Nonselective β-blockers are contraindicated in patients with bronchospastic disease (asthma), and β_1-selective blockers should be used with caution in these patients. β-Blockers with ISA, such as acebutolol, pindolol, carteolol, or penbutolol (Table 29.3), partially stimulate the β-receptor while also blocking it (13). The proposed advantages of β-blockers with ISA over those without ISA include less cardiodepression and resting bradycardia as well as neutral effects on lipid and glucose metabolism. Neither cardioselectivity nor ISA, however, influences the efficacy of β-blockers in lowering blood pressure (6).

α_1-Adrenergic blockers

The structures for the available α_1-receptor blockers are shown in Figure 29.5. These include prazosin, doxazosin, and temazosin, the structure–activity relationships of which were previously discussed in Chapter 13, along with their pharmacokinetics and metabolism.

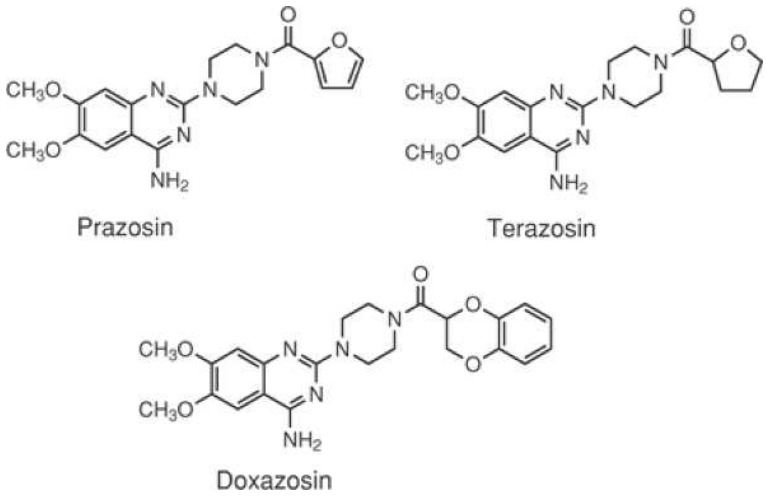

Fig. 29.5. α_1-Selective adrenergic blockers.

Mechanism of Action

These drugs block the effect of sympathetic nerves on blood vessels by selectively binding to α_1-adrenoceptors located on the VSM (Fig. 29.1), stimulating G_q protein, and activates smooth muscle contraction through the IP_3 signal transduction pathway. Most of these drugs act as competitive antagonists by competing with the binding of norepinephrine to α_1-adrenergic receptors on VSM. Some α-blockers are noncompetitive (e.g., phenoxybenzamine) (see Chapter 12), which greatly prolongs their action. Prejunctional α_2-adrenoceptors located on the sympathetic nerve terminals serve as a negative feedback mechanism for norepinephrine release.

α-Blockers dilate both arteries and veins, because both vessel types are innervated by sympathetic adrenergic nerves. The vasodilator effect is more pronounced, however, in the arterial resistance vessels. Because most blood vessels have some degree of sympathetic tone under basal conditions, these drugs are effective dilators. They are even more effective under conditions of elevated sympathetic activity (e.g., during stress) or during pathologic increases in circulating catecholamines caused by an adrenal gland tumor (pheochromocytoma) (9). α_2-Adrenoceptors also are abundant in the smooth muscle of the bladder neck and prostate and, when inhibited, cause relaxation of the bladder muscle increasing urinary flow rates and the relief.

Therapeutic Applications (6,14)

α_1-Blockers are effective agents for the initial management of hypertension and are especially advantageous for older men who also suffer from symptomatic benign prostatic hyperplasia. In the stepped-care approach to antihypertensive drug therapy, α_1-blockers are suggested as a step 1 drug. They have been shown to be as effective as other major classes of antihypertensives in lowering blood pressure in equivalent doses. α_1-Blockers possess a characteristic "first-dose" effect, which means that orthostatic hypotension frequently occurs with the first few doses of the drug. This side effect can be minimized by slowly increasing the dose and by administering the first few doses at bedtime.

Side Effects and Contraindications

The most common side effects are related directly to α_1-adrenoceptor blockade. These side effects include dizziness, orthostatic hypotension (because of loss of reflex vasoconstriction on standing), nasal congestion (because of dilation of nasal mucosal arterioles), headache, and reflex tachycardia (especially with nonselective α-blockers). Fluid retention also is a problem that can be rectified by use of a diuretic in conjunction with the α_1-blocker. α-Blockers have not been shown to be beneficial in heart failure or angina and should not be used in these conditions.

Mixed α/β-blockers

The two available mixed α/β-receptor blockers are carvedilol (15) and labetalol (16) (pK_a = 9.3) (Fig. 29.6), and their

structure–activity relationships were previously discussed in Chapter 13 along with their pharmacokinetics and metabolism (Table 29.3). The α-methyl substituent attached to the N-arylalkyl group appears to be responsible for the α-adrenergic blocking effect. Carvedilol is administered as its racemate. Its *S*-(–)-enantiomer is both an α- and nonselective β-blocker, whereas its *R*-(+)-enantiomer is an α_1-blocker. Labetalol possesses two chiral centers and, therefore, is administered as a mixture of four stereoisomers, of which *R*(CH_3),*R*(OH) is the active β-blocker diastereomer with minimal α_1-blocking activity and the *S*(CH_3),*R*(OH) diastereomer is predominantly an α_1-blocker. The *R,R* diastereomer is also known as dilevalol. The *S*(CH_3),*S*(OH) and *R*(CH_3),*S*(OH) diastereomers are both inactive. The comparative potency for labetalol reflects the fact that 25% of the diastereomeric mixture is the active *R,R*-diastereomer.

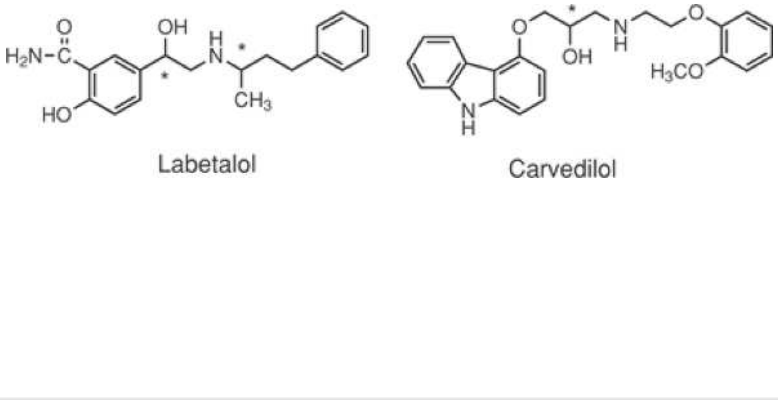

Fig. 29.6. Mixed α/β-selective adrenergic blockers.

Mechanism of Action

The mixed α/β-receptor blocking properties in the same molecule confer some advantages in the lowering of blood pressure. Vasodilation via α_1-blockade lowers peripheral vascular resistance to maintain cardiac output, thus preventing bradycardia more effectively when compared to β-blockers (17). β-Blockade helps to avoid the reflex tachycardia sometimes observed with the other vasodilators listed below.

Therapeutic Applications

Monotherapy with these mixed-acting antihypertensive drugs reduces blood pressure as effectively as other major antihypertensives and their combinations (15,16,17). In the stepped-care approach to antihypertensive drug therapy, mixed α/β-blockers are recommended for initial management of mild to moderate hypertension (step 1). Both drugs effectively lower blood pressure in essential and renal hypertension. Carvedilol also is effective in ischemic heart disease.

Adverse Effects

Any adverse effects usually are related to β_1- or α_1-blockade. The β-effects usually are less bothersome, because the α_1-blockade reduces the effects of β-blockade.

Centrally Acting Sympatholytics

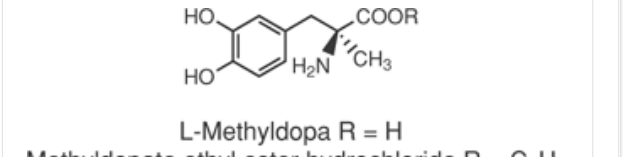
The sympathetic adrenergic nervous system plays a major role in the regulation of arterial pressure. Activation of these nerves to the heart increases the heart rate (positive chronotropy), contractility (positive inotropy), and velocity of electrical impulse conduction (positive dromotropy). Within the medulla are located preganglionic sympathetic excitatory neurons, which travel from the spinal cord to the ganglia. They have significant basal activity, which generates a level of sympathetic tone to the heart and vasculature even under basal conditions. The sympathetic

neurons within the medulla receive input from other neurons within the medulla and together, these neuronal systems regulate sympathetic (and parasympathetic) outflow to the heart and vasculature. Sympatholytic drugs can block this sympathetic adrenergic system are three different levels. First, peripheral sympatholytic drugs, such as α-adrenoceptor and β-adrenoceptor antagonists, block the influence of norepinephrine at the effector organ (heart or blood vessel). Second, there are ganglionic blockers that block impulse transmission at the sympathetic ganglia. Third, there are drugs that block sympathetic activity within the brain, centrally acting sympatholytic drugs. Centrally acting

sympatholytics block sympathetic activity by binding to and activating α_2-adrenoceptors, which reduces sympathetic outflow to the heart, thereby decreasing cardiac output by decreasing heart rate and contractility. Reduced sympathetic output to the vasculature decreases sympathetic vascular tone, which causes vasodilation and reduced systemic vascular resistance, which in turn decreases arterial pressure.

Specific drug

Methyldopa and Methyldopate Ester Hydrochloride



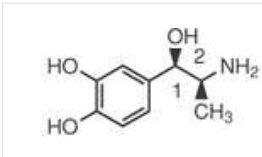
L-Methyldopa R = H
Methyldopate ethyl ester hydrochloride R = C_2H_5

Physicochemical Properties

Methyldopa is structurally and chemically related to L-DOPA and the catecholamines. To increase its water solubility for parenteral administration, the zwitterion methyldopa is esterified and converted to its hydrochloride salt, methyldopate ethyl ester hydrochloride (referred to as methyldopate). Methyldopate ester hydrochloride is used to prepare parenteral solutions of methyldopa, having a pH in the range of 3.5 to 6.0. Methyldopa is unstable in the presence of oxidizing agents (i.e., air), alkaline pH, and light. Being related to the catecholamines, which are subject to air oxidation, metabisulfite/sulfite may be added to dosage formulations to prevent oxidation. Some patients, especially those with asthma, may exhibit sulfite-related hypersensitivity reactions. Methyldopate hydrochloride injection has been reported to be physically incompatible with drugs that are poorly soluble in an acidic medium (e.g., sodium salts of barbiturates and sulfonamides) and with drugs that are acid labile. Incompatibility depends on several factors (e.g., concentrations of the drugs, specific diluents used, resulting pH, and temperature).

Mechanism of Action

As discussed in Chapter 12, the central mechanism for the antihypertensive activity of the pro-drug methyldopa is not caused by its inhibition of norepinephrine biosynthesis but, rather, by its metabolism in the CNS to α-methylnorepinephrine, an α_2-adrenergic agonist (9). Other more powerful inhibitors of aromatic L-amino acid decarboxylase (e.g., carbidopa) have proven to be clinically useful, but not as antihypertensives. Rather, these agents are used to inhibit the metabolism of exogenous L-DOPA administered in the treatment of Parkinson's disease (see Chapter 24).



α–Methylnorepinephrine
direct acting stereoisomer

The mechanism of the central hypotensive action for methyldopa is attributed to its transport into the CNS via an aromatic amino acid transport mechanism, where it is decarboxylated and hydroxylated into α-methylnorepinephrine

(9). This active metabolite of methyldopa decreases total peripheral resistance, with little change in cardiac output and heart rate, through its stimulation of central inhibitory α_2-adrenoceptors. A reduction of plasma renin activity also may contribute to the hypotensive action of methyldopa. Postural hypotension and sodium and water retention also are effects related to a reduction in blood pressure. If a diuretic is not administered concurrently with methyldopa, tolerance to the antihypertensive effect of the methyldopa during prolonged therapy can result.

Pharmacokinetics (18)

The oral bioavailability of methyldopa ranges from 20 to 50% and varies among individuals. Optimum blood pressure response occurs in 12 to 24 hours in most patients. After withdrawal of the drug, blood pressure returns to pretreatment levels within 24 to 48 hours. Methyldopa and its metabolites are weakly bound to plasma proteins. Although 95% of a dose of methyldopa is eliminated in hypertensive patients with normal renal function, with a plasma half-life of approximately 2 hours, in patients with impaired renal function the half-life is doubled to approximately 3 to 4 hours, with about 50% of it excreted. Orally administered methyldopa undergoes presystemic first-pass metabolism in the gastrointestinal (GI) tract to its 3-O-monosulfate metabolite. Sulfate conjugation occurs to a greater extent when the drug is given orally than when it is given intravenously (IV). Its rate of sulfate conjugation is decreased in patients with renal insufficiency. Methyldopa is excreted in urine as its mono-O-sulfate conjugate. Any peripherally decarboxylated α-methylnorepinephrine is metabolized by catecho-o-methyltransferase (COMT) and monoamine oxidase (MAO).

Methyldopate is slowly hydrolyzed in the body to form methyldopa. The hypotensive effect of IV methyldopate begins in 4 to 6 hours and lasts 10 to 16 hours.

Therapeutic Applications (1,6)

Methyldopa is used in the management of moderate to severe hypertension and is considered to be a step 2 drug reserved for patients who fail to respond to therapy with step 1 drugs. Methyldopa

also is coadministered with diuretics and other classes of antihypertensive drugs, permitting a reduction in the dosage of each drug and minimizing adverse effects while maintaining blood pressure control. Methyldopa has been used in the management of hypertension during pregnancy without apparent substantial adverse effects on the fetus and also for the management of pregnancy-induced hypertension (i.e., preeclampsia) (5).

Intravenous methyldopate may be used for the management of hypertension when parenteral hypotensive therapy is necessary. Because of its slow onset of action, however, other agents, such as sodium nitroprusside, are preferred when a parenteral hypotensive agent is employed for hypertensive emergencies.

Adverse Effects (6)

The most common adverse effect for methyldopa is drowsiness, which occurs within the first 48 to 72 hours of therapy and may disappear with continued administration of the drug. Sedation commonly recurs when its dosage is increased. A decrease in mental acuity, including impaired ability to concentrate, lapses of memory, and difficulty in performing simple calculations, may occur and usually necessitates withdrawal of the drug. Patients should be warned that methyldopa may impair their ability to perform activities requiring mental alertness or physical coordination (e.g., operating machinery or driving a motor vehicle). Nightmares, mental depression, orthostatic hypotension, and symptoms of cerebrovascular insufficiency may occur during methyldopa therapy and is an indication for dosage reduction. Orthostatic hypotension may be less pronounced with methyldopa than with guanethidine but may be more severe than with reserpine, clonidine, hydralazine, propranolol, or thiazide diuretics. Nasal congestion commonly occurs in patients receiving methyldopa. Positive direct antiglobulin (Coombs') test results have been reported in approximately 10 to 20% of patients receiving methyldopa, usually after 6 to 12 months of therapy. This phenomenon is dose related. Methyldopa should be used with caution in patients with a history of previous liver disease or dysfunction, and it should be stopped if unexplained drug-induced fever and jaundice occurs. These effects commonly occur within 3 weeks after initiation of treatment.

Dosage forms of methyldopa and methyldopate may contain sulfites, which can cause allergic-type reactions, including anaphylaxis and life-threatening or less severe asthmatic episodes. These allergic reactions are observed more frequently in asthmatic than in nonasthmatic individuals. Methyldopa is contraindicated in patients receiving MAO inhibitors.

α_2-Adrenergic agonists

The mechanism of action, therapeutic applications, and adverse effects common to the α_2-adrenergic agonists clonidine, guanabenz, and guanfacine (Fig. 29.7) will be discussed together, but any significant differences between these specific agents will be included in the discussions of the individual drugs.

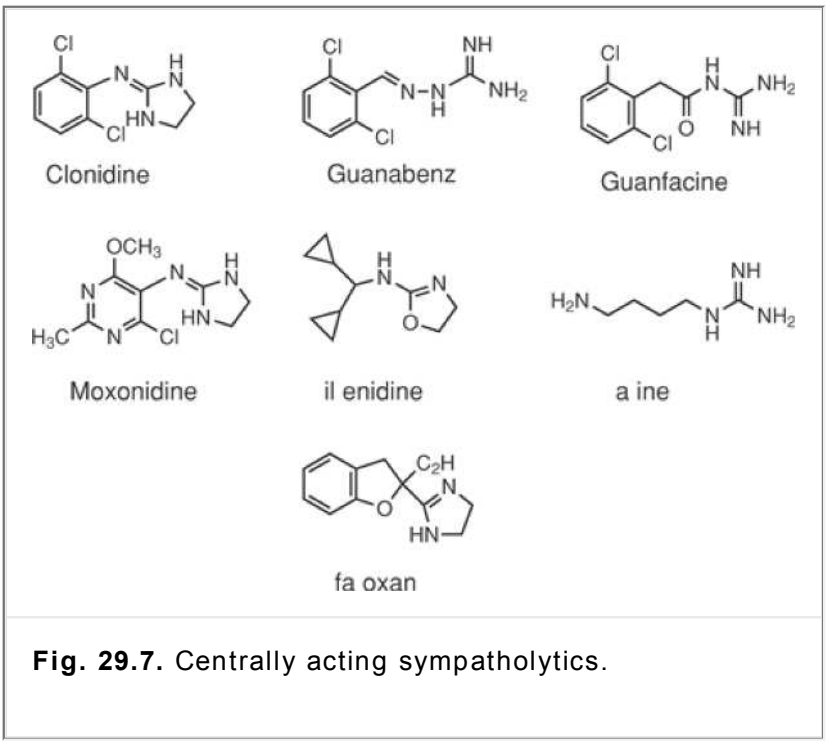


Fig. 29.7. Centrally acting sympatholytics.

Mechanism of Action

The overall mechanism of action for the centrally active sympatholytics, clonidine, guanabenz, and guanfacine, appears to be stimulation of α_2-adrenoceptors and specific binding to nonadrenergic imidazoline binding sites (I_1-IBS) in the CNS (mainly in the medulla oblongata), causing inhibition of sympathetic output (sympathoinhibition) (19,20). This effect results in reduced peripheral and renovascular resistance and leads to a decrease in systolic and diastolic blood pressure. Through the use of imidazoline and α_2-adrenergic antagonists, specific I_1-IBS have recently been characterized in CNS control of blood pressure (21). Specific I_1-IBS are G protein-coupled receptors, with agmatine being the endogenous ligand for IBS. Specific I_1-IBS are pharmacologically distinct from α_2-receptors, because they are not activated by catecholamines but characterized by their high affinity for 2-iminoimidazolines (or 2-aminoimidazolines) and low affinity for guanidines (21). Thus, the central hypotensive action for clonidine, other 2-aminoimidazolines, and structurally related compounds need both the I_1-IBS and α_2-adrenoceptors to produce their central sympatholytic response (20). As a result of this discovery, a new generation of centrally acting antihypertensive agents selective for the I_1-IBS receptor has been developed, moxonidine (a pyrimidinyl aminoimidazoline) and rilmenidine (an alkylaminooxazoline) (Fig. 29.7). Rilmenidine and moxonidine are both highly selective for the I_1-IBS while having low affinity for α_2-adrenoceptors, and both control blood pressure effectively without the adverse effects associated with binding to α_2-receptors (e.g., sedation, bradycardia, and mental depression) (20). Clonidine appears to be more selective for α_2-adrenoceptors than for I_1-IBS. Another antihypertensive is efaroxan which exhibits good affinity for I_1-IBS but is an antagonist at α_2-receptors.

Pharmacokinetics

The effective oral dose range for rilmenidine is 1 to 3 mg, with a dose-dependent duration of action of 10 to 20 hours. Moxonidine is administered once a day at a dose range of 0.2 to 0.4 mg. The oral bioavailability of

moxonidine in humans is greater than 90%, with approximately 40 to 50% of the oral dose excreted unmetabolized in the urine (22,23). The principal route of metabolism for moxonidine is oxidation of the 2-methyl group in the pyrimidine ring to 2-hydroxymethyl and 2-carboxylic acid derivative as well as the formation of corresponding glucuronides. Following an oral dose of monoxidine, peak hypotensive effects occur within 2 hours, with an elimination half-life of greater than 8 hours (23,24). Rilmenidine is readily absorbed from the GI tract, with an oral bioavailability greater than 95%. It is poorly metabolized and is excreted unchanged in the urine, with an elimination half-life of 8 hours (25,26).

Following IV or oral administration of these drugs in normotensive patients, an initial hypertensive response to the drug occurs that is caused by activation of the peripheral α_2-adrenoceptors and the resulting vasoconstriction. This response is not observed, however, in patients with hypertension.

Therapeutic Applications (1,6)

The selection of these drugs for monotherapy or in the stepped-care approach is based on several factors, including their similar mechanism of action, preexisting conditions, pharmacokinetics, distribution, and metabolism. The α_2-adrenergic antagonists show a similarity in adverse effects.

Clonidine, guanabenz, and guanfacine are used in the management of mild to moderate hypertension (1,6). They have been used as monotherapy or to achieve lower dosages in combination with other classes of antihypertensive agents. In the stepped-care approach to antihypertensive drug therapy, centrally acting sympatholytics generally are step 2 drugs and reserved for patients who fail to respond to therapy with a step 1 drug (e.g., diuretics, β-adrenergic blocking agents, ACE inhibitors, and α_1-blockers). Clonidine, guanabenz, and guanfacine have been used in conjunction with diuretics and other hypotensive agents, permitting a reduction in the dosage of each drug, minimizing adverse effects while maintaining blood pressure control. Geriatric patients, however, may not tolerate the adverse cognitive effects of these sympatholytics. All three drugs reduce blood pressure to essentially the same extent in both supine and standing patients; thus, orthostatic effects are mild and infrequently encountered. Exercise does not appear to affect the blood pressure response to guanabenz and guanfacine in patients with hypertension. Plasma renin activity may be unchanged or reduced during long-term therapy with these drugs.

Adverse Effects (6)

Overall, the frequency of adverse effects produced by clonidine, guanabenz, and guanfacine are similar and appear to be dose related. Drowsiness, tiredness, dizziness, weakness, bradycardia, headache, and dry mouth are common adverse effects for patients receiving clonidine, guanabenz, and guanfacine. The sedative effect for these centrally acting sympatholytics may result from their central α_2-agonist activity. The dry mouth induced by these drugs may result from a combination of central and peripheral α_2-adrenoceptor mechanisms, and the decreased salivation may involve inhibition of cholinergic transmission via stimulation of peripheral α_2-adrenoceptors. Orthostatic hypotension does not appear to be a significant problem with these drugs, because there appears to be little difference between supine and standing systolic and diastolic blood pressures in most patients. Other adverse effects include urinary frequency and sexual dysfunction (e.g., decreased libido and impotence), nasal congestion, tinnitus, blurred vision, and dry eyes. These symptoms most often occur within the first few weeks of therapy and tend to diminish with continued therapy, or they may be relieved by a reduction in dosage. Although adverse effects of the drug generally are not severe, discontinuance of therapy has been necessary in some patients because of intolerable sedation or dry mouth. Sodium and fluid retention may be avoided or relieved by administration of a diuretic.

Drug Interactions (6)

The hypotensive actions for clonidine, guanabenz, and guanfacine may be additive with, or may potentiate the action of, other CNS depressants, such as opiates or other analgesics, barbiturates or other sedatives, anesthetics, or alcohol. Coadministration of opiate analgesics with clonidine also may potentiate the hypotensive effects of clonidine. Tricyclic antidepressants (i.e., imipramine and desipramine) have reportedly inhibited the hypotensive effect of clonidine, guanabenz, and guanfacine, and the increase in blood pressure usually occurs during the second week of tricyclic antidepressant therapy. Dosage should be increased to adequately control hypertension if necessary. Sudden withdrawal of clonidine, guanabenz, and guanfacine may result in an excess of circulating catecholamines; therefore, caution should be exercised in concomitant use of drugs that affect the metabolism or tissue uptake of these amines (MAO inhibitors or tricyclic antidepressants, respectively). Because clonidine, guanabenz, and guanfacine may produce bradycardia, the possibility of additive effects should be considered if these drugs are given concomitantly with other drugs, such as hypotensive drugs or cardiac glycosides.

Specific Drugs

Clonidine

Clonidine is an aryl-2-aminoimidazoline that is more selective for α_2-adrenoceptors than for I_1-IBS (Fig. 29.7) in producing its hypotensive effect. It is available as oral tablets, injection, or a transdermal system.

Mechanism of Action

In addition to its central stimulation of I_1-IBS and α_2-adrenoceptors (20,21), clonidine (as well as other α_2-adrenergic agonists), when administered epidurally, produces analgesia by stimulation of spinal α_2-adrenoceptors, inhibiting sympathetically mediated pain pathways that are activated by nociceptive stimuli, thus preventing transmission of pain signals to the brain (9). Activation of α_2-adrenoceptors also apparently stimulates acetylcholine release and inhibits the release of substance

P, an inflammatory neuropeptide. Analgesia resulting from clonidine therapy is not antagonized by opiate antagonists.

Pharmacokinetics

Clonidine has an oral bioavailability of more than 90%, with a pK_a of 8.3 and a log P(exp) of 1.56 (6). It also is absorbed when applied topically to the eye. Clonidine is well absorbed percutaneously following topical application of a transdermal system to the arm or chest (27,28,29). Following application of a clonidine transdermal patch, therapeutic plasma concentrations are attained within 2 to 3 days. Studies have indicated that release of clonidine from the patch averages from 50 to 70% after 7 days of wear. Plasma clonidine concentrations attained with the transdermal systems generally are similar to twice-daily oral dosing regimens of the drug. Percutaneous absorption of the drug from the upper arm or chest is similar, but less drug is absorbed from the thigh (29). Replacement of the transdermal system at a different site at weekly intervals continuously maintains therapeutic plasma clonidine concentrations. Following discontinuance of transdermal therapy, therapeutic plasma drug concentrations persist for approximately 8 hours and then decline slowly over several days; over this time period, blood pressure returns gradually to pretreatment levels.

Blood pressure begins to decrease within 30 to 60 minutes after an oral dose of clonidine, with the maximum decrease in approximately 2 to 4 hours (6). The hypotensive effect lasts up to 8 hours. Following epidural administration of a single bolus dose of clonidine, it is rapidly absorbed into the systemic circulation and into cerebrospinal fluid (CSF), with maximal analgesia within 30 to 60 minutes. Although the CSF is not the presumed site of action of clonidine-mediated analgesia, the drug appears to diffuse rapidly from the CSF to the dorsal horn. After oral administration, clonidine appears to be well distributed throughout the body, with the lowest concentration in the brain. Clonidine is approximately 20 to 40% bound to plasma proteins, and it crosses the placenta. The plasma half-life of clonidine is 6 to 20 hours in patients with normal renal function and 18 to 41 hours in patients with impaired renal function. Clonidine is metabolized in the liver to its inactive major metabolite, 4-hydroxyclonidine, and its glucuronide and sulfate conjugates (10–20%) (Fig. 29.8). In humans, 40 to 60% of an oral or IV dose of clonidine is excreted in urine as unchanged drug within 24 hours. Approximately 85% of a single dose is excreted within 72 hours, with 20% of the dose excreted in feces, probably via enterohepatic circulation.

Therapeutic Applications (6)

Clonidine is administered twice a day for the management of mild to moderate hypertension (6). Transdermal clonidine also has been successfully substituted for oral clonidine in some patients with mild to moderate hypertension whose compliance with a daily dosing regimen may be a problem (28).

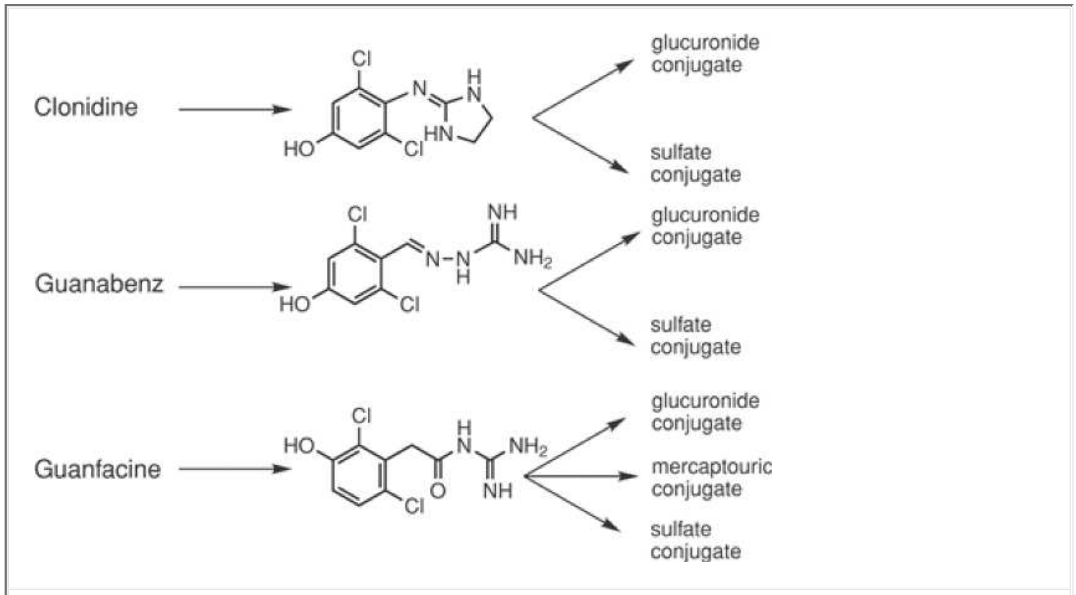

Fig. 29.8. Metabolites formed from clonidine, guanabenz, and guanfacine.

When administered by epidural infusion, clonidine is used as adjunct therapy in combination with opiates for the management of severe cancer pain not relieved by opiate analgesics alone. Other nonhypertensive uses for clonidine include the prophylaxis of migraine headaches, the treatment of severe dysmenorrhea, menopausal flushing, rapid detoxification in the management of opiate withdrawal in opiate-dependent individuals, in conjunction with benzodiazepines for the management of alcohol withdrawal, and for the treatment of tremors associated with the adverse effects of methylphenidate in patients with attention-deficit disorder. Clonidine has been used to reduce intraocular pressure in the treatment of open-angle and secondary glaucoma.

Adverse Effects (6)

Adverse effects occurring with transdermal clonidine generally appear to be similar to those occurring with oral therapy (28,29). They have been mild and have tended to diminish with continued treatment. Hypotension has occurred in patients receiving clonidine by epidural infusion as adjunct therapy with epidural morphine for the treatment of cancer pain. With the transdermal system, localized skin reactions, such as erythema and pruritus, have occurred in some patients.

Within 2 to 3 hours following the abrupt withdrawal of oral clonidine therapy, a rapid increase in systolic and diastolic blood pressures occurs, and blood pressures may exceed pretreatment levels. Associated with the clonidine withdrawal syndrome, the symptoms observed include nervousness, agitation, restlessness, anxiety, insomnia, headache, sweating, palpitation, increased heart rate, tremor, and increased salivation. The exact mechanism of the withdrawal syndrome following discontinuance of α_2-adrenergic agonists has not been determined but may involve increased concentrations of circulating catecholamines, increased sensitivity of adrenoceptors, enhanced renin-angiotensin system activity, decreased

vagal function, failure of autoregulation of cerebral blood flow, and failure of central α_2-adrenoceptor mechanisms to regulate sympathetic outflow from the CNS (6). The clonidine withdrawal syndrome is more pronounced after abrupt cessation of long-term therapy and with administration of high oral dosages (>1.2 mg daily). Withdrawal symptoms have been reported following discontinuance of transdermal therapy or when absorption of the drug is impaired because of dermatologic changes (e.g., contact dermatitis) under the transdermal system. Epidural clonidine may prolong the duration of the pharmacologic effects, including both sensory and motor blockade, of epidural local anesthetics.

Guanabenz Acetate

Guanabenz, a centrally active hypotensive agent, is pharmacologically related to clonidine but differs structurally from clonidine by the presence of an aminoguanidine side chain rather than an aminoimidazoline ring (Fig. 29.7). At pH 7.4, guanabenz (pK_a = 8.1) is predominately (80%) in the nonionized, lipid-soluble base form. Guanabenz can be given as a single daily dose administered at bedtime to minimize adverse effects.

Pharmacokinetics (30)

The oral bioavailability of guanabenz is 70 to 80%. Following an oral dose, the hypotensive effect of guanabenz begins within 1 hour, peaks within 2 to 7 hours, and is diminished within 6 to 8 hours. It has an elimination half-life averaging 4 to 14 hours. The blood pressure response can persist for at least 12 hours. Following IV dosing, guanabenz is distributed into the CNS, with brain concentrations 3 to 70 times higher than concurrent plasma concentrations. Guanabenz is approximately 90% bound to plasma proteins. In patients with hepatic or renal impairment, its elimination half-life may be prolonged.

Guanabenz is metabolized principally by hydroxylation to its inactive metabolite, 4-hydroxyguanabenz, which is eliminated in the urine as its glucuronide (major) and sulfate conjugates (Fig. 29.8). Guanabenz and its inactive metabolites are excreted principally in urine, with approximately 70 to 80% of its oral dose excreted in urine within 24 hours and approximately 10–30% in feces via enterohepatic cycling. Approximately 40% of an oral dose of guanabenz is excreted in urine as 4-hydroxyguanabenz and its glucuronide, and less than 5% is excreted unchanged. The remainder is excreted as unidentified metabolites and their conjugates.

Therapeutic Applications (6,30)

Overall, the therapeutic applications for guanabenz are similar to those of clonidine and other α_2-adrenergic agonists. One advantage for guanabenz is its once-a-day dosing schedule. Guanabenz has been used in diabetic patients with hypertension without adverse effect on the control of or therapy for diabetes, and it has been effective in hypertensive patients with chronic obstructive pulmonary disease, including asthma, chronic bronchitis, or emphysema. Guanabenz has been used alone or in combination with naltrexone in the management of opiate withdrawal in patients physically dependent on opiates and undergoing detoxification. Guanabenz also has been used as an analgesic in a limited number of patients with chronic pain.

Adverse Effects (6,30)

Overall, the frequency of adverse effects produced by guanabenz is similar to that produced by clonidine and the other α_2-adrenergic agonists, but the incidence is lower. As with the other centrally active sympatholytics (e.g., clonidine), abrupt withdrawal of guanabenz may result in rebound hypertension, but the withdrawal syndrome symptoms appear to be less severe.

Guanfacine Hydrochloride

Guanfacine, a phenylacetyl guanidine derivative (pK_a = 7) (Fig. 29.7), is a centrally acting sympatholytic that is more selective for α_2-adrenoceptors than is clonidine. Its mechanism of action is similar to clonidine and is an effective alternative to that of the other centrally acting antihypertensive drugs. Although guanfacine is 5- to 20-fold less potent than clonidine on a weight basis, comparable blood pressure–lowering effects have been achieved when the two drugs were given in equipotent dosages. Its relatively long elimination half-life permits a once-a-day dosing schedule. Guanfacine activates peripheral α_2-adrenoceptors, because a transient increase in blood pressure is observed in normotensive, but not in hypertensive, patients.

Pharmacokinetics (31,32,33)

The pharmacokinetic properties for guanfacine differ from those of clonidine, guanabenz, and α-methyldopa. At pH 7.4, guanfacine is predominately (67%) in the nonionized, lipid-soluble base form, which accounts for its high oral bioavailability (>80%). Following an oral dose, peak plasma concentrations occur in 1 to 4 hours, with a relatively long elimination half-life of 14 to 23 hours. The maximum blood pressure response occurs in 8 to 12 hours after oral administration and is maintained up to 36 hours following its discontinuation. Following IV dosing, guanfacine achieves the highest concentrations in liver and kidney, with low concentrations in the brain. Guanfacine is 64% bound to plasma proteins. In patients with hepatic or renal impairment, its elimination half-life may be prolonged.

Guanfacine is metabolized principally by hepatic hydroxylation to its inactive metabolite, 3-hydroxyguanfacine (20%), which is eliminated in the urine as its glucuronide (30%), sulfate (8%), or mercapturic acid conjugate (10%), and 24 to 37% is excreted as unchanged guanfacine (Fig. 29.8). Its nearly complete bioavailability suggests no evidence of any first-pass effect. Guanfacine and its inactive metabolites are excreted principally in urine, with approximately 80% of its oral dose excreted in urine within 48 hours.

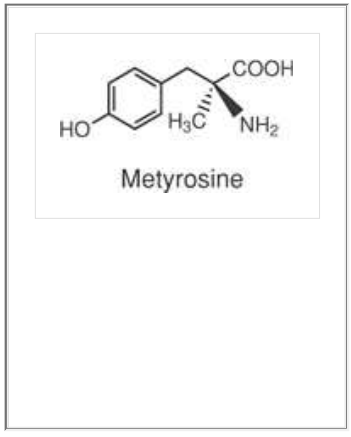
Therapeutic Applications (6,32)

Overall, the therapeutic applications for guanfacine are similar to those of the other centrally acting α_2-adrenergic agonists and methyldopa. It has been effective as monotherapy in the treatment of patients with mild to moderate hypertension. One advantage for guanfacine is its once-a-day dosing schedule. The use of diuretics to prevent accumulation of fluid may allow a reduction in the dosage for guanfacine.

Adverse Effects (6,32)

Overall, although the frequency of troublesome adverse effects produced by guanfacine is similar to that produced by clonidine and the other centrally acting sympatholytics, their incidence and severity are lower with guanfacine. Unlike clonidine, abrupt discontinuation of guanfacine rarely results in rebound hypertension. When a withdrawal syndrome has occurred, its onset was slower and its symptoms less severe than the syndrome observed with clonidine.

Metyrosine



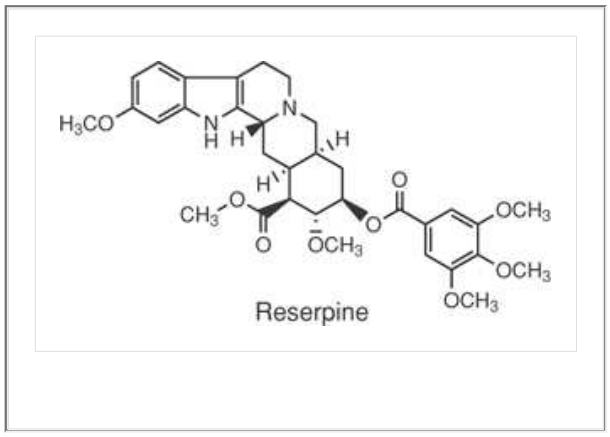
Hypothetically, inhibitors of any of the three enzymes involved in the conversion of L-tyrosine to norepinephrine (see Fig. 13.1) could be used as drugs to moderate adrenergic transmission. Inhibitors of the rate-limiting enzyme tyrosine hydroxylase would be the most logical choice. One inhibitor of tyrosine hydroxylase, metyrosine or α-methyl-L-tyrosine, a competitive inhibitor of tyrosine hydroxylase, is in limited clinical use to help control hypertensive episodes caused by excess catecholamine biosynthesis. The drug also can control other symptoms of catecholamine overproduction in patients with the rare adrenal tumor pheochromocytoma. Although metyrosine is useful in treating hypertension

associated with pheochromocytoma, it is not useful for treating essential hypertension. The drug metyrosine is the S-enantiomer of α-methyltyrosine. The R-enantiomer, R-α-methyltyrosine, does not bind to the active site of tyrosine hydroxylase and, thus, has no useful pharmacologic activity.

Adrenergic Neuron Blocking Agents

Bretylium, guanethidine, and guanadrel are three drugs with similar mechanisms of action involving norepinephrine storage granules. These drugs are transported into the adrenergic neurons by uptake-1, where they bind to the storage vesicles and prevent release of neurotransmitter in response to a neuronal impulse. Reserpine, guanethidine, and guanadrel are orally active antihypertensives that actually replace norepinephrine in the storage vesicles, resulting in a slow release in the amount of norepinephrine that is present. At usual doses, guanethidine and guanadrel act as "false neurotransmitters" in that they are released into the synapse but do not effectively stimulate the receptors. At higher acute doses, their principal mechanism is a poorly understood inhibition of neurotransmitter release. Bretylium is a quaternary ammonium salt and must be given IV, because it has poor oral absorption. Initially, it can cause a release of norepinephrine and a transient rise in blood pressure, but its clinical utility is limited to cardiac arrhythmias and so will not be discussed in this chapter (see Chapter 26).

Reserpine



An old and historically important drug that affects the storage and release of norepinephrine is reserpine. Reserpine is one of several indole alkaloids isolated from the roots of *Rauwolfia serpentina*; these roots were used in India for centuries both as a remedy for snake bites and as a sedative. The antihypertensive effects of the root extracts were first reported in India in 1918 and in the West in 1949. Shortly thereafter, reserpine was isolated and identified as the principal active agent. Reserpine was the first effective antihypertensive drug introduced into Western medicine, but it has largely been replaced in clinical use by agents with fewer side effects.

Mechanism of Action (9)

Reserpine acts to replace and deplete the adrenergic neurons of their stores of norepinephrine by inhibiting the active transport Mg-ATPase responsible for sequestering norepinephrine and dopamine within the storage vesicles. The norepinephrine and dopamine that are not sequestered in vesicles are destroyed by MAO. As a result, the storage vesicles contain little neurotransmitter, adrenergic transmission is dramatically inhibited, and sympathetic tone is decreased, leading to vasodilation. Reserpine has the same effect on epinephrine storage in the adrenal medulla. Reserpine readily enters the CNS, where it also depletes the stores of norepinephrine and serotonin. The CNS neurotransmitter depletion led to the use of reserpine in treating certain mental illnesses.

Pharmacokinetics (6,9)

Limited information is available regarding the pharmacokinetics of reserpine. Peak blood concentrations for reserpine occur within 2 hours following oral administration, and the full effects for reserpine usually are delayed for at least 2 to 3 weeks. Both CNS and cardiovascular effects may persist for several

days to several weeks after chronic oral therapy is discontinued. Reserpine appears to be widely distributed in body tissues, especially adipose tissue; crosses the blood-brain barrier and the placenta; and is distributed into milk. The elimination of reserpine appears to be biphasic, with a plasma half-life averaging 4.5 hours during the first phase and approximately 11.3 days during the second phase. Reserpine is metabolized to unidentified inactive compounds. Unchanged reserpine and its metabolites are excreted slowly in urine and feces, with an average of 60% reserpine recovered in feces within 96 hours after oral administration of 0.25 mg of radiolabeled reserpine.

Therapeutic Application (6)

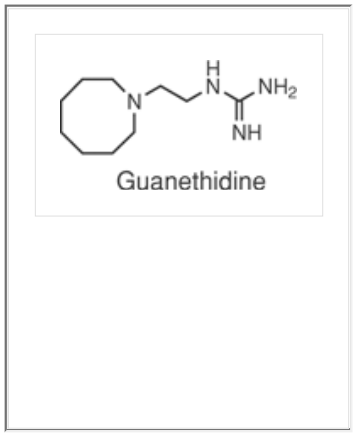
Reserpine has been used in the management of mild to moderate hypertension, but because of very significant CNS adverse effects and its cumulative action in the adrenergic neurons, reserpine is rarely used. Reserpine and related *Rauwolfia* alkaloids have been used in the symptomatic treatment of agitated psychotic states, such as schizophrenic disorders, although other antipsychotic agents generally have replaced reserpine and the alkaloids.

Adverse Effects (6)

The common adverse CNS effects for reserpine include drowsiness, fatigue, or lethargy. Mental depression is one of the most serious potential adverse effects for reserpine, which may be severe enough to require hospitalization or result in suicide attempts. Reserpine-induced depression may persist for several months after the drug is discontinued.

Guanethidine monosulfate

Guanethidine contains two basic nitrogen atoms with pK_a values of 9.0 and 12.0 and, therefore, can form guanethidine monosulfate ($C_{10}H_{22}N_4 \cdot H_2SO_4$) or guanethidine sulfate [$(C_{10}H_{22}N_4)_2 \cdot H_2SO_4$] salts. Caution should be exercised when interchanging between these sulfate forms, because the potency of guanethidine may be expressed in terms of guanethidine sulfate or guanethidine monosulfate, a significant difference in molecular weight.



Mechanism of Action

Guanethidine is an adrenergic neuronal blocking agent that produces a selective block of peripheral sympathetic pathways by replacing and depleting norepinephrine stores from adrenergic nerve endings, but not from the adrenal medulla (6,9). It prevents the release of norepinephrine from adrenergic nerve endings in response to sympathetic nerve stimulation. The chronic administration of guanethidine results in an increased sensitivity of these effector cells to catecholamines. Following the oral administration of usual doses of guanethidine, depletion of the catecholamine stores from adrenergic nerve endings occurs at a very slow rate, producing a more gradual and prolonged fall in systolic blood pressure than in diastolic pressure. Associated with the decrease in blood pressure is an increase in sodium and water retention and expansion of plasma volume (edema). If a diuretic is not administered concurrently with guanethidine, tolerance to the antihypertensive effect of the guanethidine during prolonged therapy can result.

Pharmacokinetics (6)

Guanethidine is incompletely absorbed from the GI tract and is metabolized in the liver to several metabolites, including guanethidine N-oxide (from flavin mononucleotide). These metabolites of guanethidine are excreted in the urine and have less than 10% of its hypotensive activity. The amount of drug that reaches the systemic circulation after oral administration is highly variable from patient to patient and may range from 3 to 50% of a dose. Guanethidine accumulates in the neurons with an elimination half-life of 5 days.

Therapeutic Applications (6)

Guanethidine is used in the management of moderate to severe hypertension and in the management of renal hypertension. In the stepped-care approach to antihypertensive drug therapy, guanethidine has been suggested as a step 2 or step 3 drug and generally is reserved for patients who fail to respond adequately to an antihypertensive regimen that includes a diuretic and other step 1 drugs, such as β-blockers, ACE inhibitors, or calcium-channel blocking agents. Its coadministration with other hypotensive agents permits a reduction in the dosage of each drug and a minimization of adverse effects while maintaining blood pressure control. It has been administered as ophthalmic drops in the treatment of chronic open-angle glaucoma and for endocrine ophthalmopathy, ophthalmoplegia, lid lag,

and lid retraction.

Adverse Effects (6)

Adverse effects of guanethidine frequently are dose related, including dizziness, weakness, lassitude, and syncope resulting from postural or postexercise hypotension. A hot environment (i.e., a hot bath) may aggravate postural hypotension. Patients should be warned about possible orthostatic hypotension and about the effect of rapid postural changes on blood pressure (e.g., arising in the morning) that may cause fainting, especially during the initial period of dosage adjustment. Sodium retention (edema) usually is controlled by the coadministration of a diuretic.

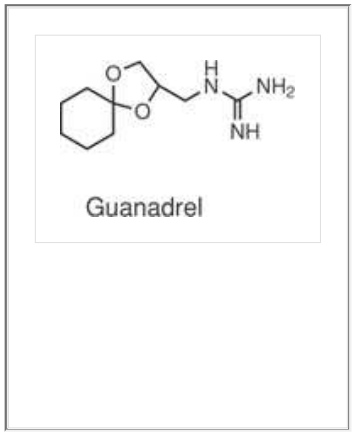
Drug Interactions (6)

Diuretics and other hypotensive drugs can potentiate the hypotensive effects of guanethidine. Reportedly, MAO inhibitors antagonize the hypotensive effect of guanethidine. Oral sympathomimetic, nasal decongestants, and other vasopressor agents should be used cautiously in patients receiving guanethidine, because guanethidine may potentiate their pressor effects. The mydriatic response to ophthalmic administration of phenylephrine is markedly increased in patients receiving guanethidine either ophthalmically or orally.

Tricyclic antidepressants and some phenothiazines block the uptake of guanethidine into adrenergic neurons and, thus, prevent the hypotensive activity of guanethidine. Orthostatic hypotension may be increased by concomitant administration of alcohol with guanethidine, and patients receiving guanethidine should be cautioned to limit alcohol intake.

Guanadrel sulfate

Guanadrel sulfate is a adrenergic neuronal blocking agent that is structurally and pharmacologically related to guanethidine: Both are guanidine derivatives. Guanadrel differs structurally from guanethidine by the presence of a dioxaspirodecyl ring system linked to guanidine by a methyl group rather than a hexahydroazocinyl ring linked by an ethyl group.



Mechanism of Action

Guanadrel, like guanethidine, produces a selective block of efferent, peripheral sympathetic pathways by replacing and depleting norepinephrine stores from adrenergic nerve endings, thus preventing the release of norepinephrine from adrenergic nerve endings in response to sympathetic nerve stimulation (9,34). Unlike guanethidine, it does not release norepinephrine from the adrenal medulla and reportedly depletes norepinephrine stores in the GI tract to a lesser extent than guanethidine does. Guanadrel decreases systolic blood pressure more than diastolic blood pressure.

Pharmacokinetics (34)

Guanadrel, unlike guanethidine, is rapidly and almost completely absorbed following oral administration. Following oral administration, its peak plasma concentrations usually are achieved in approximately 2 hours, and its hypotensive effect usually has an onset of 0.5 to 2.0 hours, with peak activity at 4 to 6 hours and a duration of action of 4 to 14 hours. Approximately 20% of guanadrel is bound to plasma proteins, and little, if any, of the drug crosses the blood-brain barrier or distributes into the eye. Guanadrel has a plasma half-life of approximately 2 hours and an elimination half-life of approximately 10 to 12 hours in patients with normal renal function. Approximately 40 to 50% of guanadrel is metabolized in the liver to 2,3-dihydroxypropylguanidine and several unidentified metabolites, which are excreted principally in the urine (Fig. 29.9). Unlike guanethidine, approximately 85% of an oral dose of the drug is excreted in the urine within 24 hours, with 40 to 50% of the dose excreted in the urine unchanged. In patients with

impaired renal function, the half-life of guanadrel is prolonged, and apparent total body clearance and renal clearances are decreased.

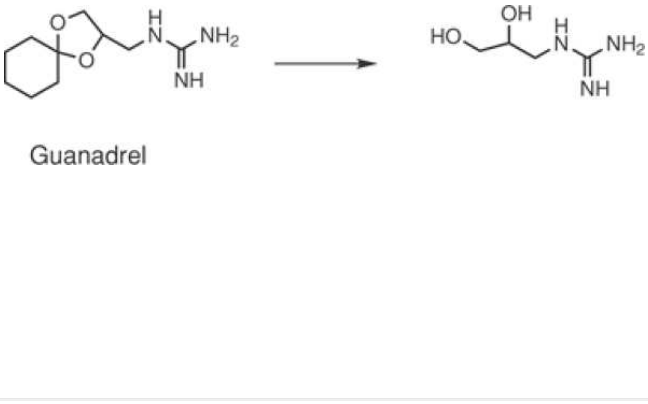


Fig. 29.9. Metabolism of guanadrel.

Therapeutic Application (6,34)

Guanadrel is used in the management of hypertension, and its efficacy is similar to that of guanethidine. Guanadrel generally is considered to be a step 2 drug and is reserved for patients who fail to respond to therapy with a step 1 drug or for cases requiring more prompt or aggressive therapy. Postural and postexercise hypotension is common in patients receiving guanadrel, and it also is likely that heat-induced vasodilation will augment its hypotensive effect. There is a possibility that geriatric patients may not tolerate the postural hypotensive effects of guanadrel. Being a peripheral adrenergic neuron blocking drug, guanadrel shares the toxic potentials of guanethidine, and the usual precautions of this drug should be observed.

Adverse Effects (6)

Overall, the frequency of adverse effects produced by guanadrel is similar or less than those produced by guanethidine and by methyldopa. In patients with impaired renal function, the elimination half-life of unmetabolized guanadrel is prolonged and its clearance decreased, thus increasing the incidence of adverse effects if the usual dosage is maintained in these patients.

Drug Interactions

Being a peripheral adrenergic neuron blocking drug, guanadrel shares the same potential for drug interactions as guanethidine, and the usual precautions of this drug should be observed.

Vasodilators

Vasodilator drugs relax the smooth muscle in blood vessels, which causes the vessels to dilate. Dilation of arterial vessels leads to a reduction in systemic vascular resistance, which leads to a fall in arterial blood pressure. Dilation of venous vessels decreases venous blood pressure.

Arterial dilator drugs commonly are used to treat systemic and pulmonary hypertension, heart failure, and angina. They reduce arterial pressure by decreasing systemic vascular resistance, thereby reducing the afterload on the left ventricle and enhancing stroke volume and cardiac output. They also decrease the oxygen demand of the heart and, thereby, improve the oxygen supply/demand ratio. The primary functions of venous dilators in treating cardiovascular hypertension include reduction in venous pressure, thus reducing preload on the heart and decreasing cardiac output and capillary fluid filtration and edema formation (a decrease in capillary hydrostatic pressure). Therefore, venous dilators sometimes are used in the treatment of heart failure along with other drugs, because they help to reduce pulmonary and/or systemic edema that results from heart failure.

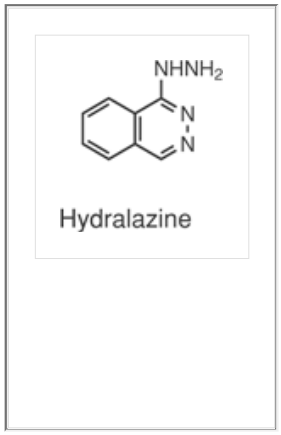
There are three potential drawbacks in the use of vasodilators: First, vasodilators can lead to a baroreceptor-mediated reflex stimulation of the heart (increased heart rate and inotropy) from systemic vasodilation and arterial pressure reduction. Second, they can impair the normal baroreceptor-mediated reflex vasoconstriction when a person stands up, which can lead to orthostatic hypotension and syncope on standing. Third, they can lead to renal retention of sodium

and water, increasing blood volume and cardiac output.

Vasodilator drugs are classified either based on their site of action (arterial vs. venous) or, more commonly, by their primary mechanism of action.

Direct-acting vasodilators

Hydralazine Hydrochloride



Mechanism of Action

The only drug in this group, hydralazine, does not fit neatly into the other mechanistic classes, in part because its mechanism of action is not entirely clear. It appears to have multiple, direct effects on the VSM. Hydralazine, a phthalazine-substituted hydrazine antihypertensive drug with a pK_a of 7.3, is highly specific for arterial vessels, producing its vasodilation by a couple of different mechanisms. First, it causes smooth muscle hyperpolarization, quite likely through the opening of K^+ channels. Activation therefore increases the efflux of potassium ions from the cells, causing hyperpolarization of VSM cells and, thus, prolonging the opening of the potassium channel and sustaining a greater vasodilation on arterioles than on veins (9). It also may inhibit the second messenger, IP_3-induced release of calcium from the smooth muscle sarcoplasmic reticulum (the PIP_2 signal transduction pathway) (Fig. 29.2). Finally, hydralazine stimulates the formation of NO by the vascular endothelium, leading to cGMP-mediated vasodilation (Fig. 29.1). The arterial vasodilator action of hydralazine reduces systemic vascular resistance and arterial pressure. Diastolic blood pressure usually is decreased more than systolic pressure is. The hydralazine-induced decrease in blood pressure and peripheral resistance causes a reflex response, which is accompanied by increased heart rate, cardiac output, stroke volume, and an increase in plasma renin activity. It has no direct effect on the heart (6). This reflex response could offset the hypotensive effect of arteriolar dilation, limiting its antihypertensive effectiveness. Hydralazine also causes sodium and water retention and expansion of plasma volume, which could develop tolerance to its antihypertensive effect during prolonged therapy. Thus, coadministration of a diuretic improves the therapeutic outcome.

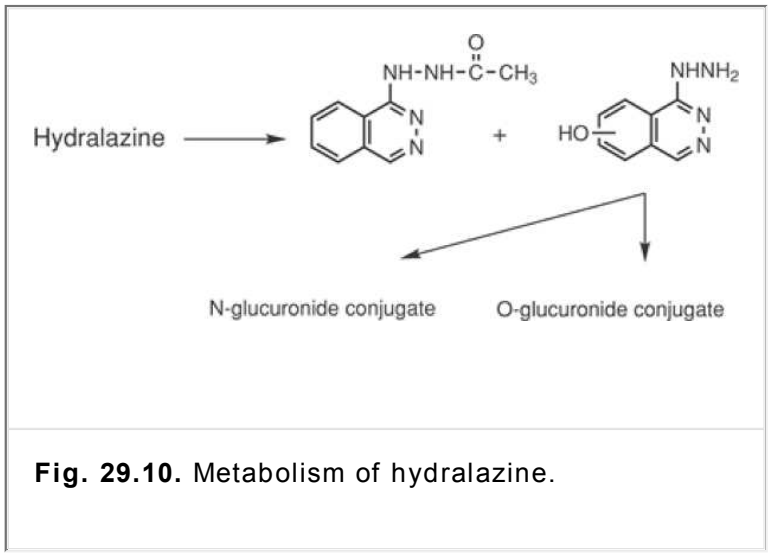


Fig. 29.10. Metabolism of hydralazine.

Pharmacokinetics (6,9)

Hydralazine is well absorbed from the GI tract and is metabolized in the GI mucosa (prehepatic systemic metabolism) and in the liver by acetylation, hydroxylation, and conjugation with glucuronic acid (Fig. 29.10; see Table 8.17). Little of the hydralazine dose is excreted unchanged in urine but mainly as metabolites, which are without significant therapeutic activity. A small amount of hydralazine is reportedly converted to a hydrazone, most likely with vitamin B_6 (pyridoxine), which may be responsible for some its neurotoxic effects. Following the oral administration of hydralazine, its antihypertensive effect begins in 20 to 30 minutes and lasts 2 to 4 hours. The plasma half-life of hydralazine generally is 2 to 4 hours but, in some patients, may be up to 8 hours (i.e., slow acetylators). In slow acetylator patients or those with impaired renal function, the plasma concentrations for hydralazine are increased and, possibly, prolonged. Approximately 85% of hydralazine in the blood is bound to plasma proteins following administration of usual doses.

First-pass acetylation in the GI mucosa and liver is related to genetic acetylator phenotype (8). Acetylation phenotype is an important determinant of the plasma concentrations of hydralazine when the same dose of hydralazine is administered orally. Slow acetylators have an autosomal recessive trait that results in a relative deficiency of the hepatic enzyme N-acetyl transferase, thus prolonging the elimination half-life of hydralazine (see Chapter 10). This population of hypertensive patients will require an adjustment in dose to reduce the increased overactive response. Approximately 50% of African Americans and Caucasians, and the majority of American Indians, Eskimos, and Orientals are rapid acetylators of hydralazine. This population of patients will have subtherapeutic plasma concentrations of hydralazine because of its rapid metabolism to inactive metabolites and shorter elimination times. Patients with hydralazine-induced systemic lupus erythematosus frequently are slow acetylators.

Therapeutic Applications (6)

Hydralazine is used in the management of moderate to severe hypertension. In the stepped-care approach to antihypertensive drug therapy, hydralazine has been suggested as a step 2 or step 3 drug

and generally is reserved for patients who fail to respond adequately to an antihypertensive regimen that includes a diuretic and other hypotensive drugs, such as β-blockers, ACE inhibitors, or calcium-channel blockers. Hydralazine is recommended for use in conjunction with a diuretic and another hypotensive drugs, such as β-adrenergic blockers, and has been effectively used in conjunction with cardiac glycosides, diuretics, and other vasodilators for the short-term treatment of severe congestive heart failure. Patients who engage in potentially hazardous activities, such as operating machinery or driving motor vehicles, should be warned about possible faintness, dizziness, or weakness. Hydralazine should be used with caution in patients with cerebrovascular accidents or with severe renal damage.

Parenteral hydralazine may be used for the management of severe hypertension when the drug cannot be given orally or when blood pressure must be lowered immediately. Other agents (e.g., sodium nitroprusside) are preferred for the management of severe hypertension or hypersensitive emergencies when a parenteral hypotensive agent is employed.

Drug interactions

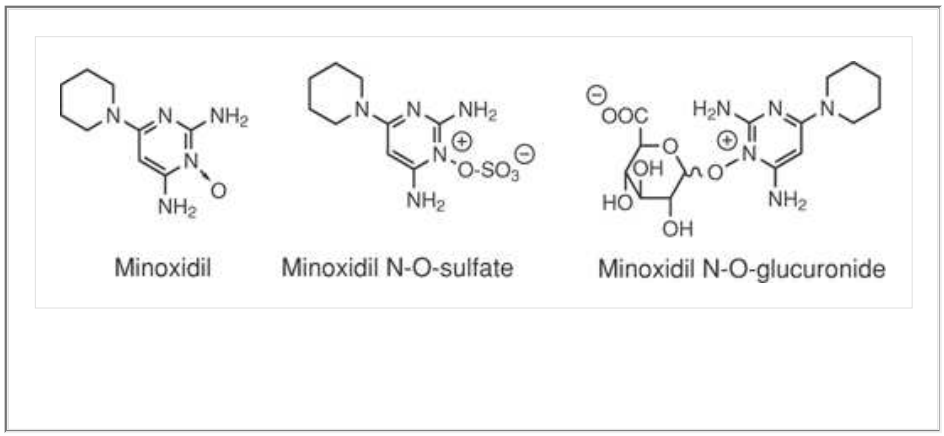
The coadministration of diuretics and other hypotensive drugs may have a synergistic effect, resulting in a marked decrease in blood pressure.

Potassium channel openers

Specific drugs

Minoxidil

Although several potassium channel openers have been used in research for many years, only one, minoxidil, is approved for use in humans for treating hypertension. Minoxidil is the N-oxide of a piperidinopyrimidine hypotensive agent, with a pK_a of 4.6, and is not an active hypotensive drug until it is metabolized by hepatic sulfotransferase to minoxidil N-O-sulfate (9).



Mechanism of Action

Potassium channel openers are drugs that activate (i.e., open) ATP-sensitive K^+ channels in the VSM (Fig. 29.1). By opening these potassium channels, there is increased efflux of potassium ions from the cells, causing hyperpolarization of VSM, which closes the voltage-gated calcium channels and, thereby, decreases intracellular calcium. With less calcium available to combine with calmodulin, there is less activation of MLCK and phosphorylation of myosin light chains. This leads to relaxation and vasodilation. Because small arteries and arterioles normally have a high degree of smooth muscle tone, these drugs are particularly effective in dilating these resistance vessels, decreasing systemic vascular resistance, and lowering arterial pressure. The fall in arterial pressure leads to reflex cardiac stimulation (baroreceptor-mediated tachycardia).

Minoxidil, as its active metabolite minoxidil O-sulfate, prolongs the opening of the potassium channel, sustaining greater vasodilation on arterioles than on veins. The drug decreases blood pressure in both the supine and standing positions, and there is no orthostatic hypotension. Associated with the decrease in peripheral resistance and blood pressure is a reflex response that is accompanied by increased heart rate, cardiac output, and stroke volume, which can be attenuated by the coadministration of a β-blocker (6). Along with this decrease in peripheral resistance is increased plasma renin activity and sodium and water retention, which can result in expansion of fluid volume, edema, and congestive heart failure. The sodium- and water-retaining effects of minoxidil can be reversed by coadministration of a diuretic. When minoxidil is used in conjunction with a β-adrenergic blocker, pulmonary artery pressure remains essentially unchanged.

Pharmacokinetics (35)

Minoxidil is absorbed from the GI tract and is metabolized to its active sulfate metabolite. Plasma concentrations for minoxidil sulfate peak within 1 hour and then decline rapidly. Following an oral dose of minoxidil, its hypotensive effect begins in 30 minutes, is maximal in 2 to 8 hours, and persists for approximately 2 to 5 days. The delayed onset of the hypotensive effect for minoxidil is attributed to its metabolism to its active metabolite. The drug is not bound to plasma proteins. The major metabolite for minoxidil is its N-O-glucuronide, which unlike the sulfate metabolite is inactive as a hypotensive agent. Approximately 10 to 20% of an oral dose of minoxidil is metabolized to its active metabolite, minoxidil O-sulfate, and approximately 20% of minoxidil is excreted unchanged.

Therapeutic Applications

Hypertension (6,35)

Being effective arterial dilators, potassium-channel openers are used in the treatment of hypertension. These drugs are not first-line therapy for hypertension because of their side effects; therefore, they are relegated to treating refractory, severe hypertension. They generally are used in conjunction with a β-blocker and a diuretic to attenuate the reflex tachycardia and retention of sodium and fluid, respectively.

Minoxidil is used in the management of severe hypertension and is considered to be a step 3 drug. It generally is reserved for resistant cases of hypertension that have not been managed with maximal therapeutic dosages of a diuretic and two other hypotensive drugs or for patients who have failed to respond adequately to step 3 therapy that includes hydralazine. To minimize sodium retention and increased plasma volume, minoxidil must be used in conjunction with a diuretic. A β-adrenergic blocker (e.g., propranolol) must be given before minoxidil therapy is begun and should be continued during minoxidil therapy

to minimize minoxidil-induced tachycardia and increased myocardial workload.

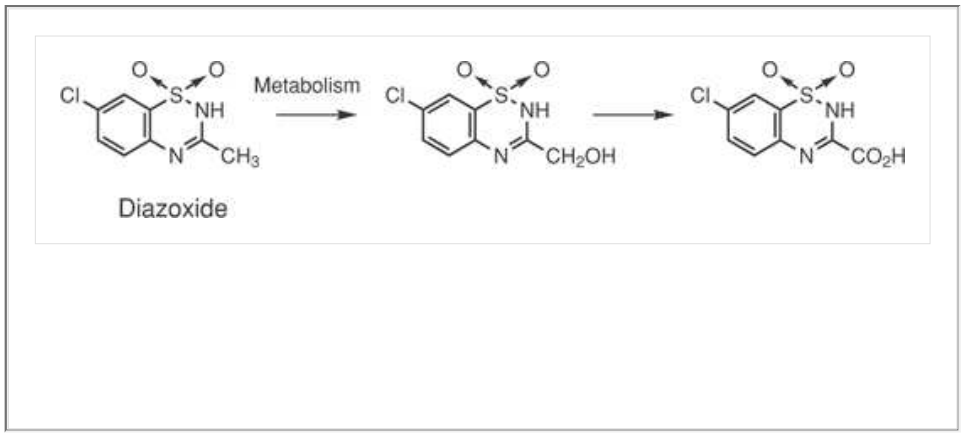
Androgenetic alopecia (6,36)

Minoxidil is used topically to stimulate regrowth of hair in patients with androgenic alopecia (male pattern alopecia, hereditary alopecia, or common male baldness) or alopecia areata. Commercially available topical minoxidil preparations should be used rather than the extemporaneous topical formulations from tablets to reduce the potential of minoxidil being absorbed systemically.

Drug Interactions

When minoxidil is administered with diuretics or other hypotensive drugs, the hypotensive effect of minoxidil increases, and concurrent use may cause profound orthostatic hypotensive effects.

Diazoxide



Diazoxide is a nondiuretic hypotensive and hyperglycemic agent that is structurally related to the thiazide diuretics. Being a sulfonamide with a pK_a of 8.5, it can be solubilized in alkaline solutions (pH of injection is 11.6). Solutions or oral suspension of diazoxide are unstable to light and will darken when exposed to light. Such dosage forms should be protected from light, heat, and freezing. Darkened solutions may be subpotent and should not be used.

Mechanism of Action

Diazoxide reduces peripheral vascular resistance and blood pressure by a direct vasodilating effect on the VSM with a mechanism similar to that described for minoxidil by activating (opening) the ATP-modulated potassium channel (36). Thus, diazoxide prolongs the opening of the potassium channel, sustaining greater vasodilation on arterioles than on veins (9). The greatest hypotensive effect is observed in patients with malignant hypertension. Although oral or slow IV administration of diazoxide can produce a sustained fall in blood pressure, rapid IV administration is required for maximum hypotensive effects, especially in patients with malignant hypertension (6). Diazoxide-induced decreases in blood pressure and peripheral vascular resistance are accompanied by a reflex response, resulting in an increased heart rate, cardiac output, and left ventricular ejection rate. In contrast to the thiazide diuretics, diazoxide causes sodium and water retention and decreased urinary output, which can result in expansion of plasma and extracellular fluid volume, edema, and congestive heart failure, especially during prolonged administration.

Diazoxide increases blood glucose concentration (diazoxide-induced hyperglycemia) by several different mechanisms: by inhibiting pancreatic insulin secretion, by stimulating release of catecholamines, or by increasing hepatic release of glucose (6,9). The precise mechanism of inhibition of insulin release has not been elucidated but, possibly, may result from an effect of diazoxide on cell-membrane potassium channels and calcium flux.

Pharmacokinetics (6)

Following rapid IV administration, diazoxide produces a prompt reduction in blood pressure, with maximum hypotensive effects occurring within 5 minutes. The duration of its hypotensive effect varies from 3 to 12 hours, but ranges from 30 minutes to 72 hours have been observed. The elimination half-life of diazoxide following a single oral or IV dose has been reported to range from 21 to 45 hours in adults with normal renal function. In patients with renal impairment, the half-life is prolonged. Approximately 90% of the diazoxide in the blood is bound to plasma proteins. Approximately 20 to 50% of diazoxide is eliminated unchanged in the urine, along with its major metabolites, resulting from the oxidation of the 3-methyl group to its 3-hydroxymethyl- and 3-carboxyl-metabolites.

Therapeutic Applications

Severe hypertension (6)

Intravenous diazoxide has been used in hypertensive crises for emergency lowering of blood pressure when a prompt and urgent decrease in diastolic pressure is required in adults with severe nonmalignant and malignant hypertension and in children with acute severe hypertension. Generally, however, other IV hypotensive agents are preferred for the management of hypertensive crises. Diazoxide is intended for short-term use in hospitalized patients only. Although diazoxide also has been administered orally for the management of hypertension, its hyperglycemic and sodium-retaining effects make it unsuitable for chronic therapy.

Hypoglycemia (6)

Diazoxide is administered orally in the management of hypoglycemia caused by hyperinsulinism associated with inoperable islet cell adenoma or carcinoma or extrapancreatic malignancy in adults.

Phosphodiesterase inhibitors

Mechanism of Action of cAMP-Dependent Phosphodiesterase Inhibitors (PDE3)

The PDE3 is one of the isoforms of phosphodiesterase found in the heart and VSM. The mechanism by which cAMP and cGMP relaxes VSM has been described previously in the section on VSM contraction and relaxation (Fig. 29.1) (see also Chapter 17). The cAMP released is broken down by a cAMP-dependent phosphodiesterase (PDE3). Therefore, inhibition of PDE3 increases intracellular cAMP, which further inhibits MLCK, thereby producing less contractile force (i.e., promoting relaxation). The overall cardiac and vascular effects of cAMP-dependent phosphodiesterase inhibitors cause cardiac stimulation, increasing cardiac output and reducing systemic vascular resistance, thereby lowering arterial pressure. Because cardiac output increases and systemic vascular resistance decreases, the change in arterial pressure depends on the relative effects of the phosphodiesterase inhibitor on the heart versus the VSM. At normal therapeutic doses, PDE3 inhibitors, such as milrinone, have a greater effect on VSM

than cardiac muscle so that arterial pressure is lowered in the presence of augmented cardiac output. Because of the dual cardiac and vascular effects of these compounds, they sometimes are referred to as inodilators.

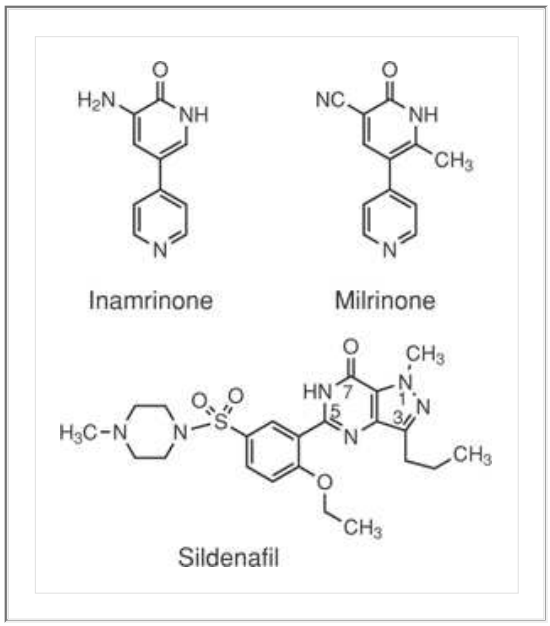
Mechanism of Action of cGMP-Dependent Phosphodiesterase Inhibitors (PDE5)

A second isoenzyme form of phosphodiesterase found in VSM is PDE5, a cGMP-dependent phosphodiesterase, which also is found in the corpus cavernosum of the penis (erectile dysfunction). This enzyme is responsible for breaking down cGMP that forms in response to increased NO (Fig. 29.1). Increased cGMP leads to smooth muscle relaxation primarily by reducing calcium entry into the cell. Inhibitors of cGMP-dependent phosphodiesterase increases intracellular cGMP, thereby enhancing VSM relaxation and vasodilation.

Therapeutic Indications

The cardiostimulatory and vasodilatory actions of PDE3 inhibitors make them suitable for the treatment of heart failure, because VSM relaxation reduces ventricular wall stress and the oxygen demands placed on the failing heart. The cardiostimulatory effects of the PDE3 increase inotropy, which further enhances stroke volume and ejection fraction. A baroreceptor reflex, which occurs in response to hypotension, may contribute to the tachycardia. Clinical trials have shown that long-term therapy with PDE3 inhibitors increases mortality in patients with heart failure; therefore, these drugs are not used for long-term, chronic therapy. They are very useful, however, in treating acute, decompensated heart failure or temporary bouts of decompensated chronic failure. They are not used as a monotherapy. Instead, they are used in conjunction with other treatment modalities, such as diuretics, ACE inhibitors, β-blockers, or digitalis. The somewhat selective vasodilatory actions of PDE5 inhibitors have made these compounds very useful in the treatment of male erectile dysfunction and as a combination therapy for pulmonary hypertension. The PDE3 inhibitors are used for treating heart failure, whereas the PDE5 inhibitors are used for treating male erectile dysfunction. Note that the generic names for PDE3 inhibitors end in “one” and those for the PDE5 inhibitors end in “fil”.

Specific Drugs



Milrinone (Primacor as Lactate Salt) and Inamrinone (Inocor as Lactate Salt)

Inamrinone and milrinone are positive inotropes and vasodilators indicated for the short-term IV management of congestive heart failure in patients who have not responded adequately to digitalis, diuretics, and/or vasodilators.

For IV infusion, inamrinone lactate and milrinone lactate injection solutions may be diluted in sodium chloride solution for injection. Inamrinone lactate for injection is preserved with sodium metabisulfite and needs protection from light. It should not be diluted with solutions containing dextrose, because a chemical interaction occurs over 24 hours. For milrinone, an immediate chemical interaction with furosemide with the formation of a precipitate is observed when furosemide is injected into an infusion of milrinone. Patients who are sensitive to bisulfites also may be sensitive to inamrinone lactate injection, which contains sodium metabisulfite.

The pharmacokinetics for inamrinone shows protein binding from 10 to 49%. Its half-life in healthy volunteers is approximately 3.6 hours, whereas in patients with congestive heart failure, the plasma half-life increases to approximately 5.0 to 8.3 hours. For infants younger than 4 weeks, the half-life is 12.7 to 22.2 hours, and for infants older than 4 weeks, the half-life is 3.8 to 6.8 hours. Time to peak effect is less than 10 minute. Its duration of action is dose related, ranging from 30 minutes at low dose to 2 hours at the higher dosages. Approximately 63% of the administered dose is eliminated via the urine as unchanged drug, and 18% is eliminated in the feces. Elderly patients are more likely to have age-related renal function impairment, which may require adjustment of dosage in patients receiving inamrinone.

The pharmacokinetics for milrinone following IV injections to patients with congestive heart failure showed a volume of distribution of 0.38 to 0.45 L/kg, a mean terminal elimination half-life of 2.3 hours, and a clearance of 0.13 L/kg/hour. These pharmacokinetic parameters were not dose-dependent, and the area under the plasma concentration versus time curve following injections was significantly dose-dependent. Milrinone is approximately 70% bound to human plasma protein. The primary route of excretion for orally administered milrinone is via the urine, with unchanged milrinone (83%) and its O-glucuronide metabolite (12%) being present. Elimination in normal subjects via the urine is rapid, with approximately 60% recovered within the first 2 hours following dosing and approximately 90% within the first 8 hours following dosing. In patients with renal function impairment, elimination of unchanged milrinone is reduced, suggesting that a dosage adjustment may be necessary.

The selective PDE5 inhibitor most commonly used is sildenafil (Viagra). Studies in vitro have shown that sildenafil is selective for PDE5. Its effect is more potent on PDE5 than on other known phosphodiesterases (10 times

for PDE6, >80 times for PDE1, and >700 times for PDE2, PDE3, PDE4, PDE7, PDE8, PDE9, PDE10, and PDE11). The approximately 4,000 times selectivity for PDE5 versus PDE3 is important, because PDE3 is involved in control of cardiac contractility. Sildenafil is only approximately 10 times as potent for PDE5 compared to PDE6, an enzyme found in the retina that is involved in the phototransduction pathway of the retina. This lower selectivity is thought to be the basis for abnormalities related to color vision observed with higher doses or plasma levels. (For a complete discussion of the pharmacokinetics including drug metabolism, see Chapter 45.)

Side Effects and Contraindications

The most common and severe side effect for PDE3 inhibitors is ventricular arrhythmias, some of which may be life-threatening. Other side effects include headaches and hypotension, which are not uncommon for drugs that increase cAMP in cardiac and vascular tissues (e.g., β-agonists).

In addition to human corpus cavernosum smooth muscle, PDE5 also is found in lower concentrations in other tissues, including platelets, vascular and visceral smooth muscle, and skeletal muscle. The inhibition of PDE5 in these tissues by sildenafil may be the basis for the enhanced platelet antiaggregatory activity of NO observed in vitro, an inhibition of platelet thrombus formation in vivo, and peripheral arterial-venous dilatation in vivo. The most common side effects for PDE5 inhibitors include headache and cutaneous flushing, both of which are related to vascular dilation caused by increased vascular cGMP. Clinical evidence suggests that nitrodilators may interact adversely with PDE5 inhibitors. The reason for this adverse reaction is that nitrodilators stimulate cGMP production, whereas PDE5 inhibitors inhibit cGMP degradation. When combined, these two drug classes greatly potentiate cGMP levels, which can lead to hypotension and impaired coronary perfusion.

Nitrodilators

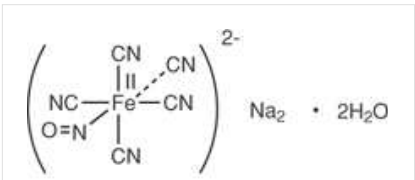
Mechanism of Action

Nitric oxide, a molecule produced by many cells in the body, has several important actions. NO is a highly reactive gas that participates in many chemical reactions. It is one of the nitrogen oxides ("NOx") in automobile exhaust and plays a major role in the formation of photochemical smog, but NO also has many physiological functions. It is synthesized within cells by an enzyme NO synthase (NOS). There are three isoenzymes, neuronal NOS (nNOS or NOS-1), inducible NOS (iNOS or NOS-2) found in macrophages, and endothelial NOS (eNOS or NOS-3) found in the endothelial cells that line the lumen of blood vessels. Whereas the levels of nNOS and eNOS are relatively steady, expression of iNOS genes awaits an appropriate stimulus. All types of NOS produce NO from arginine with the aid of molecular oxygen and NADPH. Because NO diffuses freely across cell membranes, there are many other molecules with which it can interact, and NO is quickly consumed close to where it is synthesized. Thus, NO affects only cells adjacent to its point of synthesis. NO relaxes the smooth muscle in the walls of the arterioles. At each systole, the endothelial cells that line the blood vessels release a puff of NO, which diffuses into the underlying smooth muscle cells, causing them to relax and, thus, to permit the surge of blood to pass through easily. The signaling functions of NO begin with its binding to protein receptors on or in the cell, triggering the formation of cGMP from soluble guanylyl cyclase (Fig. 29.1). Mice in which the genes for the NOS found in endothelial cells (eNOS) has been "knocked out" suffer from hypertension. Nitroglycerin, which often is prescribed to reduce the pain of angina, does so by generating NO, which relaxes venous walls and arterioles improving the oxygen supply/decreased ratio (see Chapter 24). Nitric oxide also inhibits the aggregation of platelets and, thus, keeps inappropriate clotting from interfering with blood flow. Other actions on smooth muscle include penile erection and peristalsis aided by the relaxing effect of NO on the smooth muscle in intestinal walls; NO also inhibits the contractility of the smooth muscle wall of the uterus, but at birth, the production of NO decreases, allowing contractions to occur. Nitroglycerin has helped some women who were at risk of giving birth prematurely to carry their baby to full term. The NO from iNOS inhibits inflammation in blood vessels by blocking the release of mediators of inflammation from the endothelial cells, macrophages, and T lymphocytes. The NO from iNOS has been shown to S-nitrosylate COX-2, increasing its activity, and drugs that prevent this interaction could work synergistically with the nonsteroidal anti-inflammatory drugs inhibiting COX-2. Nitric oxide affects hormonal secretion from several endocrine glands. Hemoglobin transports NO at the same time that it carries oxygen, and when it unloads oxygen in the tissues, it also unloads NO. Fireflies use NO to turn on their flashers.

Since the dawn of recorded human history, nitrates have been used to preserve meat from bacterial spoilage. Harmless bacteria in our throat convert nitrates in our food into nitrites. When the nitrites reach the stomach, the acidic gastric juice (pH ~1.4) generates NO from these nitrites, killing almost all the bacteria that have been swallowed in our food.

In the cardiovascular system, NO is produced primarily by vascular endothelial cells. This endothelial-derived NO has several important functions, including relaxing VSM (vasodilation), inhibiting platelet aggregation (antithrombotic), and inhibiting leukocyte–endothelial interactions (anti-inflammatory). These actions involve NO-stimulated formation of cGMP (Fig. 29.1). Nitrodilators are drugs that mimic the actions of endogenous NO by releasing NO or forming NO within tissues. These drugs act directly on the VSM to cause relaxation and, therefore, serve as endothelial-independent vasodilators.

Sodium Nitroprusside (Sodium Nitroferricyanide; Nitropress; Nipride)



Sodium nitroprusside

There are two basic types of nitrodilators: those that release NO spontaneously (e.g., sodium nitroprusside), and those that require an enzyme activation to form NO (organic nitrates). Sodium nitroprusside is a direct-acting vasodilator on VSM, producing its vasodilation by the release of NO. Since 1929, it has been known as a rapidly acting hypotensive agent when administered as an infusion. It is chemically and structurally unrelated to other available hypotensive agents. As a reminder in preparing extemporaneous infusions, the potency of sodium nitroprusside is expressed in terms of the dihydrated drug. When reconstituted with 5% dextrose injection, sodium nitroprusside solutions are reddish-brown in color, with a pH of 3.5 to 6.0. Its crystals and solutions are sensitive and unstable to light and should be protected from extremes of light and heat. The exposure of sodium nitroprusside solutions to light causes deterioration, which may be evidenced by a change from a reddish-brown to a green to a blue color, indicating a rearrangement of the nitroso to the inactive isonitro form. Sodium nitroprusside solutions in glass bottles undergo approximately 20% degradation within 4 hours when exposed to fluorescent light and even more rapid degradation in plastic bags. Sodium nitroprusside solutions should be protected from light by wrapping the container with aluminum foil or other opaque material. When adequately protected from light, reconstituted solutions are stable for 24 hours. Trace metals, such as iron and copper, can catalyze the degradation of nitroprusside solutions, releasing cyanide. Any change in color for the nitroprusside solutions is an indication of degradation, and the solution should be discarded. No other drug or preservative should be added to stabilize sodium nitroprusside infusions.

Mechanism of Action

Sodium nitroprusside is not an active hypotensive drug until metabolized to its active metabolite, NO, the mechanism of action of which has been previously described (Fig. 29.1). Studies with sodium nitroprusside suggest that it releases NO by its interaction with glutathione or with sulfhydryl groups in the erythrocytes and tissues to form a S-nitrosothiol intermediate, which spontaneously produces NO, which in turn freely diffuses into the VSM, thereby increasing intracellular cGMP concentration (6,9). NO also activates K^+ channels, which leads to hyperpolarization and relaxation.

The hypotensive effect of sodium nitroprusside is augmented by concomitant use of other hypotensive agents and is not blocked by adrenergic blocking agents. It has no direct effect on the myocardium, but it may exert a direct coronary vasodilator effect on VSM. When sodium nitroprusside is administered to hypertensive patients, a slight increase in heart rate commonly occurs, and cardiac output usually is decreased slightly. Moderate doses of sodium nitroprusside in patients with hypertension produce renal vasodilation without an appreciable increase in renal blood flow or decrease in glomerular filtration (6).

Intravenous infusion of sodium nitroprusside produces an almost immediate reduction in blood pressure. Blood pressure begins to rise immediately when the infusion is slowed or stopped and returns to pretreatment levels within 1 to 10 minutes.

Pharmacokinetics

Sodium nitroprusside undergoes a redox reaction that releases cyanide (6,9). The cyanide that is produced is rapidly converted into thiocyanate in the liver by the enzyme thiosulfate sulfotransferase (rhodanase) and is excreted in the urine (6,9). The rate-limiting step in the conversion of cyanide to thiocyanate is the availability of sulfur donors, especially thiosulfate. Toxic symptoms of thiocyanate begin to appear at plasma thiocyanate concentrations of 50 to 100 mg/mL. The elimination half-life of thiocyanate is 2.7 to 7.0 days when renal function is normal but longer in patients with impaired renal function.

Therapeutic Applications (6)

Intravenous sodium nitroprusside is used as an infusion for hypertensive crises and emergencies. The drug is consistently effective in the management of hypertensive emergencies, irrespective of etiology, and may be useful

even when other drugs have failed. It may be used in the management of acute congestive heart failure.

Adverse Effects (6)

The most clinically important adverse effects of sodium nitroprusside are profound hypotension and the accumulation of cyanide and thiocyanate. Thiocyanate may accumulate in the blood of patients receiving sodium nitroprusside therapy, especially in those with impaired renal function. Thiocyanate is mildly neurotoxic at serum concentrations of 60 µg/mL and may be life-threatening at concentrations of 200 µg/mL. Other adverse effects of thiocyanate includes inhibition of both the uptake and binding of iodine producing symptoms of hypothyroidism.

Sodium nitroprusside can bind to vitamin B_{12} interfering with its distribution and metabolism, and it should be used with caution in patients having low plasma vitamin B_{12} concentrations. Excess cyanide also can bind to hemoglobin, producing methemoglobinemia.

Ganglionic blockers

Mechanism of Action

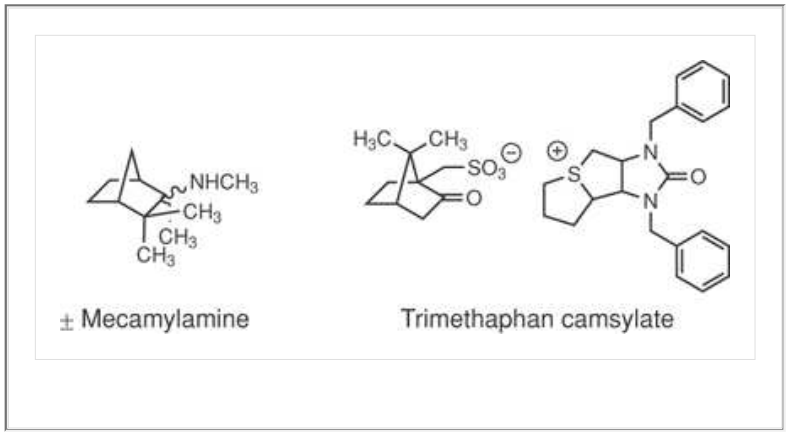
Ganglionic blockers block impulse transmission at the sympathetic ganglia. Neurotransmission within the sympathetic and parasympathetic ganglia

involves the release of acetylcholine from preganglionic efferent nerves, which binds to nicotinic receptors on the postganglionic efferent nerves. Ganglionic blockers inhibit autonomic activity by interfering with neurotransmission within autonomic ganglia. This reduces sympathetic outflow to the heart, thereby decreasing cardiac output by decreasing heart rate and contractility. Reduced sympathetic output to the vasculature decreases sympathetic vascular tone, which causes vasodilation and reduced systemic vascular resistance, which decreases arterial pressure. Parasympathetic outflow also is reduced by ganglionic blockers.

Therapeutic Indications

Ganglionic blockers are not commonly used in the treatment of chronic hypertension largely because of their side effects and because numerous more effective and safer antihypertensive drugs can be used. They are, however, occasionally used for hypertensive emergencies.

The ganglionic blockers available for clinical use include trimethaphan camsylate and mecamylamine.



They are competitive antagonists at nicotinic acetylcholine receptors. Trimethaphan is a quaternary sulfonium ion and cannot cross lipid cell membranes, whereas mecamylamine is a secondary amine. Therefore, trimethaphan is a short-acting peripheral direct vasodilator that must be given as an IV infusion, whereas mecamylamine can be given orally. Mecamylamine rapidly disappears from the blood with a plasma half-life of 1 hour, and crosses the blood-brain barrier into the CNS. Trimethaphan is rapidly excreted in unchanged form by the kidney. Mecamylamine is excreted by the kidney much more slowly. Trimethaphan is the drug of choice for managing acute aortic dissection and for hypertensive emergencies. Both drugs are of limited use, because of the availability of more specific acting vasodilators. Mecamylamine has been used for labeling CNS nicotinic receptors and crosses into the CNS, where it can block neuronal nicotinic acetylcholine receptors. Mecamylamine has been studied for use with nicotine for smoking cessation.

Side Effects and Contraindications

Side effects of trimethaphan include prolonged neuromuscular blockade and potentiation of neuromuscular blocking

agents. It can produce excessive hypotension and impotence (because of its sympatholytic effect) as well as constipation, urinary retention, and dry mouth (because of its parasympatholytic effect).

Pulmonary Arterial Hypertension

Pulmonary hypertension, which was once a rare life-threatening disease, reportedly affects about 160,000 people today. Pulmonary arterial hypertension (PAH) is defined as a group of diseases characterized by a progressive increase of pulmonary vascular resistance, leading to right ventricular failure. It includes a variety of pulmonary hypertensive diseases with different etiologies but similar clinical presentation (36). Primary pulmonary hypertension can occur, without any apparent cause (idiopathic), or can be inherited. Pulmonary arterial hypertension is a disease of the small pulmonary arteries, characterized by progressive narrowing of the pulmonary vascular bed. Vasoconstriction and scarring (or fibrosis) cause the pulmonary wall to become stiffer and thicker, contributing to an increased pulmonary vascular resistance. This extra stress causes the heart to enlarge and become less flexible. Less blood flows from the heart, through the lungs, and into the body, resulting in additional symptoms. One direct effect of these abnormally elevated pressures is blood leakage from the pulmonary vessels. A blood-producing cough often is an indicator of leakage from the pulmonary vessels. The pulmonary arterial walls produce a substance called endothelin, which causes these blood vessels to constrict. The reasons for this overproduction are unknown. In some cases, the cause is genetically programmed or the person is predisposed genetically to primary pulmonary hypertension after being exposed to a certain drug (e.g. the diet drugs Fen-Phen [fenfluramine/phentermine], Redux [dexfenfluramine], or Pondimin [fenfluramine]).

Often, primary pulmonary hypertension is not diagnosed in a timely manner, because its early symptoms can be confused with those of many other conditions (Table 29.4). To establish a diagnosis of pulmonary hypertension, a series of tests are performed that show how well a person's heart and lungs are working. These tests may include assessment of daily living tasks, such as a 6-minute walk test, a computed tomography scan to rule out a pulmonary embolism or lung disease, a pulmonary function test to rule out obstructive lung disease, a formal sleep study to rule out sleep apnea, and laboratory tests to rule out hepatitis, collagen disease, HIV, or other conditions.

Rationale for Pharmacologic Treatment

If PAH has an identifiable cause, then measures can be taken to correct the underlying problem. If the diagnosis

is primary PAH, then pharmacologic intervention is required to reduce the pressure. This is done using vasodilator drugs to decrease pulmonary vascular resistance and, thereby, to lower the pressure. Adjunct therapy may include diuretics to reduce blood volume, which will reduce central venous pressure and right ventricular stroke volume, as well as to reduce some of the signs and symptoms of edema and shortness of breath associated with PAH. Anticoagulants are administered to prevent the formation of pulmonary thrombi. Patients with cardiovascular hypertension generally are treated with antihypertensive drugs that reduce blood volume (which reduces central venous pressure and cardiac output), reduce systemic vascular resistance, or reduce cardiac output by depressing heart rate and stroke volume.

Table 29.4. Symptoms of Primary Pulmonary Hypertension

Breathlessness or shortness of breath
Feeling tired all the time
Dizziness, especially when climbing stairs or standing up
Fainting (often the symptom that brings people to their doctors)
Swollen ankles and legs
Chest pain, especially during physical activity

Drugs Used to Treat Pulmonary Hypertension

Classes of drugs used in the treatment of PAH include thiazide diuretics, loop diuretics, vasodilators, calcium channel blockers, prostaglandins, endothelin receptor antagonists, NO, and PDE5 inhibitors (38). During the last decade, substantial improvements in the therapeutic options for PAH have emerged that target the mechanisms involved in the pathogenesis of this devastating disease. Intravenous epoprostenol was the first drug to improve symptoms and

survival of patients with PAH (40). Novel prostanoids, including subcutaneous treprostinil and inhaled iloprost, have beneficial effects in many patients, although their long-term efficacy is less well known. Among the newer treatments for PAH, endothelin receptor antagonists and PDE5 inhibitors have reshaped clinical practice. The endothelin receptor antagonist bosentan has been approved, and most guidelines recommend this drug as first-line treatment for patients with PAH and New York Heart Association (NYHA) functional class III heart failure (i.e., patients with marked limitation of activity; they are comfortable only at rest). Novel endothelin receptor antagonists, such as sitaxsentan sodium and ambrisentan, are currently being investigated. The combination of the PDE5 inhibitor sildenafil and iloprost, prostacyclin analogue, are being intensively studied in patients with pulmonary hypertension. Targeting a single pathway cannot be expected to be uniformly successful, because PAH is a complex disorder. Thus, combining substances with different modes of action is expected to improve symptoms, hemodynamics, and survival in PAH patients, although combination therapy has yet to undergo the scrutiny of large randomized clinical trials.

Specific Drugs

Phosphodiesterase Inhibitors

Sildenafil (Revatio)

Sildenafil has recently been approved for treatment of PAH through its inhibition of cGMP and smooth muscle relaxation of the pulmonary vasculature. The reader is referred to the previous discussion of phosphodiesterase inhibitors under the topic of vasodilators.

Endothelin Receptor Antagonists

Mechanism of action

Endothelin-1 (ET-1) is a 21-amino-acid peptide that is produced by the vascular endothelium. It is a very potent vasoconstrictor that binds to VSM endothelin receptors ET_A and ET_B(Fig. 29.1). The ET-1 receptors are linked to the G_q protein and IP_3 signal transduction pathway (Fig. 29.11). Therefore, ET-1 causes sarcoplasmic reticulum release of calcium, increasing the VSM contractility. Vascular endothelial cells secrete the majority of ET-1. The endothelins bind to two receptor subtypes: ET_A, and ET_B. In vascular tissue, ET_A is located predominantly on smooth muscle cells, whereas ET_B is found on both endothelial and smooth muscle cells. Activation of ET_A by ET-1 leads to potent vasoconstriction from an increase in cytosolic calcium levels via influx of extracellular calcium and release from intracellular stores (Fig. 29.1). The actions of ET_B are more complicated. Like ET_A, ET-1 activation of ET_B on VSM cells leads to vasoconstriction. Furthermore, some studies suggest that in the pulmonary hypertensive state, blockade of both ET_A and ET_B is necessary to achieve maximal vasodilation. Activation of ET-B by

ET-1 stimulates cyclooxygenase (COX) which catalyzes the formation of prostacyclin from arachidonic acid. Prostacyclin then binds to and activates the isoprostanoid receptor (IP) on VSM. ET-1 also activates ET-B which stimulates endothelial nitric oxide synthease (eNOS) to produce NO from L-arginine. Both prostacyclin and NO are potent vasodilators of VSM (relaxation). Additionally, ET-1 binds to the ET_B receptors on the endothelium of pulmonary smooth muscle and stimulate the formation of NO, which produces vasodilation in the absence of smooth muscle ET_A and ET_B receptor activation. This receptor distribution helps to explain the phenomenon that ET-1 administration causes transient vasodilation (initial endothelial ET_B activation) and hypotension, followed by prolonged vasoconstriction (smooth muscle ET_A and ET_B activation) and hypertension.

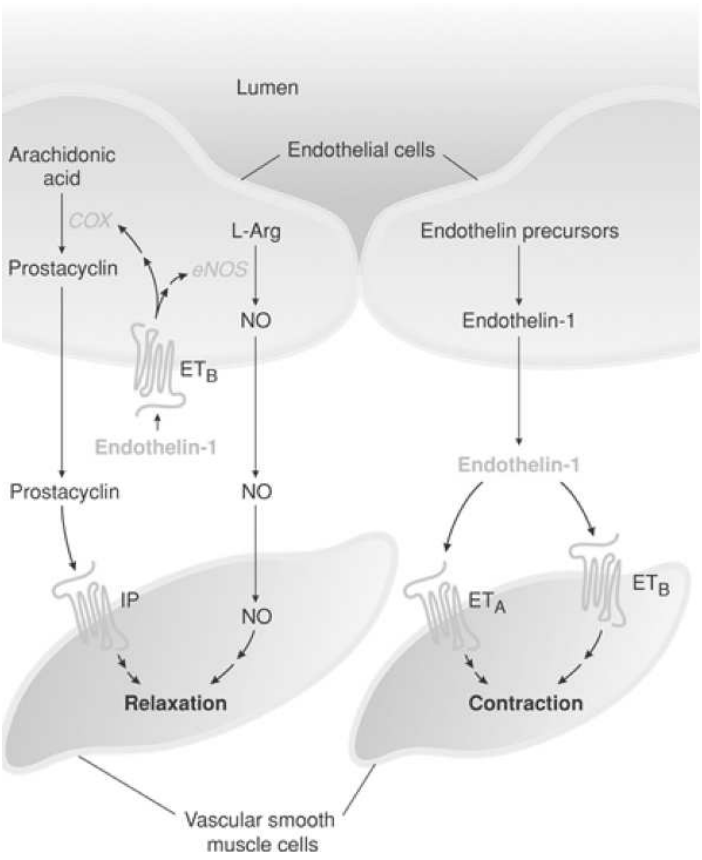


Fig. 29.11. The effects of endothelin-1, prostacyclin and nitric oxide on the contraction and relaxation (vasodilation) of vascular smooth muscle cells. (From Yeh DC, Michel T. Pharmacology of Vascular Tone. In: Golan DE, Tashjian AH, Armstrong E, et al., Principles of Pharmacology: The Pathophysiologic Basis of Drug Therapy. Baltimore: Lippincott Williams & Wilkins, 2004; with permission)

Therapeutic indications

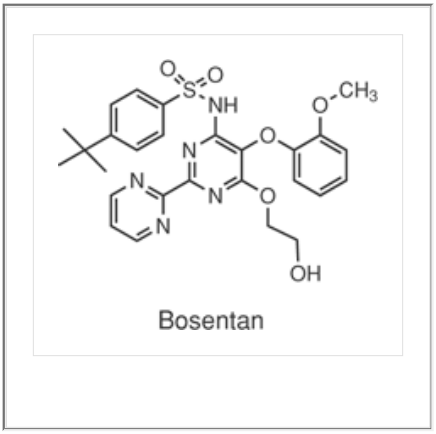
Because of its powerful vasoconstrictor properties and its effects on intracellular calcium, ET-1 has been implicated in the pathogenesis of hypertension, coronary vasospasm, and heart failure. A number of studies suggest a role for ET-1 in pulmonary hypertension as well as in systemic hypertension. Additionally, ET-1 has been shown to be released by the failing myocardium, where it can contribute to cardiac calcium overload and hypertrophy.

Endothelin receptor antagonists, by blocking the vasoconstrictor and cardiotonic effects of ET-1, produce vasodilation and cardiac inhibition. Endothelin receptor antagonists have been shown to decrease mortality and to improve hemodynamics in experimental models of heart failure.

At present, the only approved indication for endothelin antagonists is pulmonary hypertension.

Specific drugs

Bosentan (Tracleer)



Bosentan

Bosentan is an orally administered, nonselective ET-1 receptor antagonist blocking ET_A and ET_B receptors and is approved for the treatment of patients with PAH. Following oral administration, bosentan attains peak plasma concentrations in approximately 3 hours, with an absolute bioavailability of approximately 50%. Food has no clinically relevant effect on its absorption recommended doses. Bosentan is approximately 98% bound to albumin, with a volume of distribution of 30 L. Its terminal half-life after oral administration is 5.4 hours and is unchanged at steady state. Steady-state concentrations are achieved within 3 to 5 days after multiple-dose administration. Bosentan is mainly eliminated from the body by hepatic metabolism and subsequent biliary excretion of the metabolites. Three metabolites have been identified, formed by CYP2C9 and CYP3A4 (Fig. 29.12). The pharmacokinetics of bosentan are dose-proportional up to 500 mg/day (multiple doses). The pharmacokinetics of bosentan in pediatric patients with PAH are comparable to those in healthy subjects, whereas adult patients with PAH show a twofold increase in clearance. Severe renal impairment and mild hepatic impairment do not have a clinically relevant influence on its pharmacokinetics. Bosentan generally should be avoided in patients with moderate or severe hepatic impairment and/or elevated liver aminotransferases. Inhibitors of CYP3A4 increase the plasma concentration of bosentan as well as cause an increase in the clearance of drugs metabolized by CYP3A4 and CYP2C9 because of induction of these metabolizing enzymes. The possibility of reduced efficacy of CYP2C9 and CYP3A4 substrates coadministered with bosentan is increased. No clinically relevant interaction was detected for P-glycoprotein. Bosentan can increase plasma levels of ET-1. Adverse effects include hypotension, headache, flushing, increased liver aminotransferases, leg edema, and anemia. Bosentan may cause birth defects and, therefore, is contraindicated in pregnancy. It also can cause liver injury.

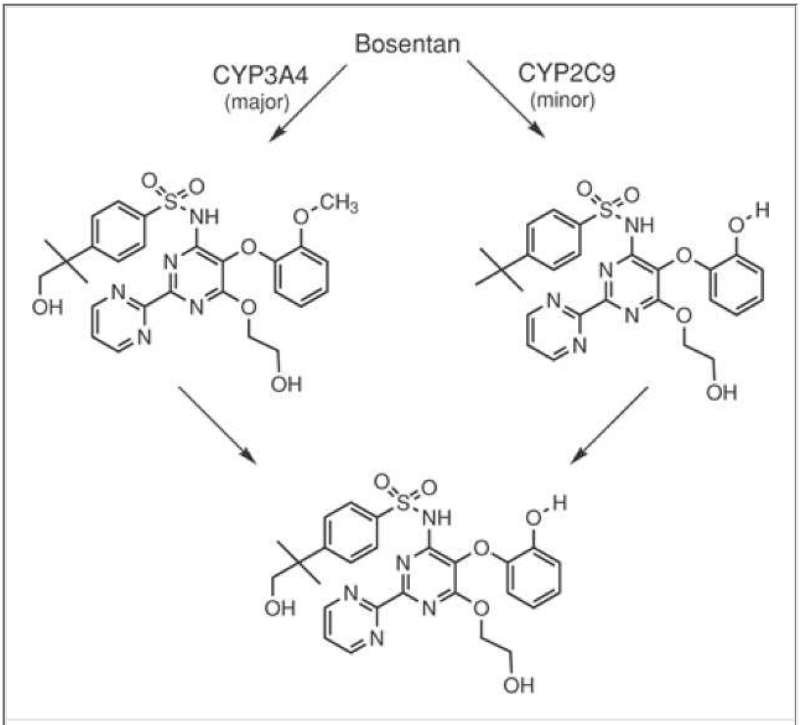


Fig. 29.12. Metabolism of bosentan.

Prostanoids (39)

Epoprostenol (Flolan)

Prostacyclin and its analogs (prostanoids) (Fig. 29.13) are potent vasodilators and possess antithrombotic and antiproliferative properties. Prostacyclin is derived from the endothelium of VSM, and its synthesis is reduced in patients with PAH. Its physiological antagonist, thromboxane A_2, is increased, however, causing vasoconstriction. Prostacyclin produces its

vasodilation via activation of the PIP_2 signal transduction pathway, increasing concentrations of cAMP (Fig. 29.11). Epoprostenol is the sodium salt of prostacyclin and is administered as an implanted, continuous IV infusion because of its very short duration of action (2–3 minutes). It must be reconstituted with a special glycine buffer diluent, giving a reconstituted solution with pH 10 to 11 that is stable for 15 minutes at 4°C and for less than 10 minutes at 37°C. Its injection solution is unstable at a lower pH because of acid-catalyzed hydrolysis of the vinylether structure to 6-oxo-$PGF_{1\alpha}$ (Fig. 29.13). It is short acting because of rapid metabolism at the 15-hydroxy group to the inactive 15-oxo metabolite.

Treprostinil (Remodulin)

Treprostinil (Fig. 29.13) is a synthetic, stable form of prostacyclin for the treatment for advanced pulmonary hypertension with NYHA class III or IV symptoms as well as for late-stage peripheral vascular disease (PVD). Its sodium salt injectable form is administered either as a continuous subcutaneous infusion directly into the skin or, if the subcutaneous infusion is not tolerated, as a continuous IV infusion without an implanted catheter. Treprostinil is rapidly absorbed from the subcutaneous site of infusion, with an almost 100% bioavailability and a mean half-life of 85 minutes (34 minutes for the IV infusion). The IV solution must be diluted with normal saline or sterile water before starting the infusion. Unlike epoprostenol, treprostinil is stable at room temperature for up to 5 years, with vasodilation action lasting from 4 to 6 hours, compared with the short, 2- to 3-minute action for epoprostenol. Because of its long life in the body, it can be administered under the skin with a microinfusion subcutaneous infusion pump rather than into the bloodstream and, thus, without hospitalization, as contrasted with the central IV infusion of epoprostenol.

Side effects include jaw pain, headaches, nausea, diarrhea, flushing, and localized pain at the delivery site under the skin. This pain has been reported as slight to severe irritation. Patients using the drug seem to ex-perience improvement in their condition, including decreased fatigue, decreased shortness of breath, and decreased pulmonary artery pressures, as well as overall improvement in quality of life.

Beraprost

Beraprost is an oral formulation of a prostacyclin analog for the treatment of early stage pulmonary hypertension as well as early stage PVD. Beraprost is a chemically stable, oral form of prostacyclin that is readily absorbed from GI tract. Like natural prostacyclin, beraprost dilates blood vessels, prevents platelet aggregation, and prevents proliferation of smooth muscle cells surrounding blood vessels. It may be an important treatment for early stage PVD and for early stage pulmonary hypertension. Intermittent oral doses of beraprost, however, do not seem to provide the consistent blood levels

necessary to treat the advanced stages of pulmonary hypertension. Beraprost has proven to be safe and effective for the treatment of PVD in the clinical studies conducted, and it has been approved for the treatment of PVD in Japan since 1994. It may soon be available for use in patients with pulmonary hypertension in the United States. Adverse effects include headache, flushing, jaw pain, and diarrhea.

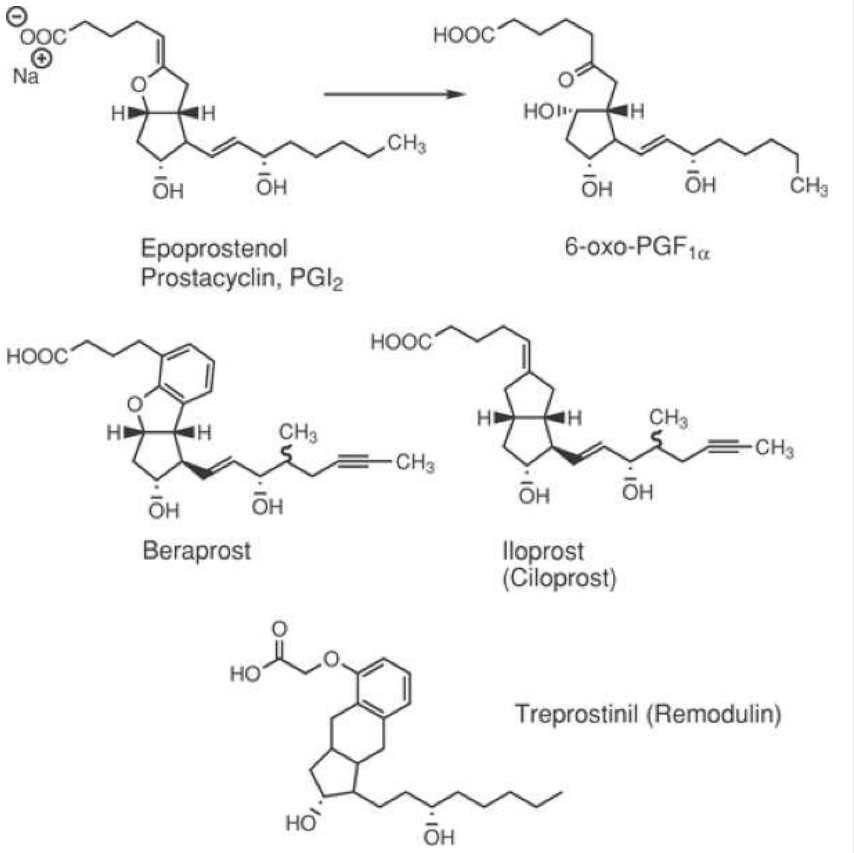

Fig. 29.13. Prostacyclin analogs.

Iloprost (Ventavis)

Iloprost is administered as an inhalation solution of a prostacyclin analog for the treatment of NYHA class III and class IV PAH. The drug also can be administered as an IV infusion. It is stable at room temperature and to light, with a body half-life of 30 minutes. Iloprost has approximately 10 times greater potency than prostacyclin as a vasodilator of the pulmonary blood vessels; this greater potency of inhaled iloprost results from coating of the drug on the alveoli of the lungs. It relieves pulmonary vascular resistance. Patients inhale six to eight puffs every 2 to 3 hours. Each puff lasts approximately 15 minutes. This therapy is used mainly in Europe and is not available in United States. Studies have reported minor side effects, such as coughing, headaches, and jaw pain.

Case Study

Victoria F. Roche

S. William Zito

KG is a 73-year-old, single, retired bank executive living in Paris who is in the early stages of Alzheimer's disease. Four months ago, she began therapy with tacrine HCl (Cognex currently 20 mg q.i.d.), which seems to be halting the advance of dementia. She experienced some dyspepsia from the tacrine which is being treated with omeprazole (Prilosec), as well as mild bradycardia which is not currently interfering with her function. Although she no longer smokes cigarettes, KG does have mild emphysema from her years as a pack-a-day smoker. Most recently, she has experienced urinary incontinence. “Accidents” have been few, but she now wears protective undergarments. Her only other medication is calcium atorvastatin (Lipitor, 10 mg q.d.) for elevated plasma low-density lipoprotein and total cholesterol. KG invested wisely as a young woman, owns a chalet on the outskirts of the city, and is able to afford quality in-home assistance. An attentive niece who studies art at the Sorbonne lives with her.

KG has been borderline hypertensive for several years and elected to keep things under control with diet and a walking regimen. She did well restricting her fat and overall calorie consumption, but she found it very difficult to effectively monitor her sodium intake. Her blood pressure is now elevated to the point that antihypertensive therapy is no longer optional. Consider the sympatholytic choices shown below, and prepare to make a therapeutic recommendation (en Francais).

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient

Chapter 30

Antihyperlipoproteinemics and Inhibitors of Cholesterol Biosynthesis

Marc Harrold

The Chemistry and Biochemistry of Plasma Lipids

The major lipids found in the bloodstream are cholesterol, cholesterol esters, triglycerides, and phospholipids. An excess plasma concentration of one or more of these compounds is known as hyperlipidemia. Because all lipids require the presence of soluble lipoproteins to be transported in the blood, hyperlipidemia ultimately results in an increased concentration of these transport molecules, a condition known as hyperlipoproteinemia. Hyperlipoproteinemia has been strongly associated with atherosclerotic lesions and coronary heart disease (CHD) (1,2). Before discussing lipoproteins, their role in cardiovascular disease, and agents to decrease their concentrations, it is essential to examine the biochemistry of cholesterol, triglycerides, and phospholipids.

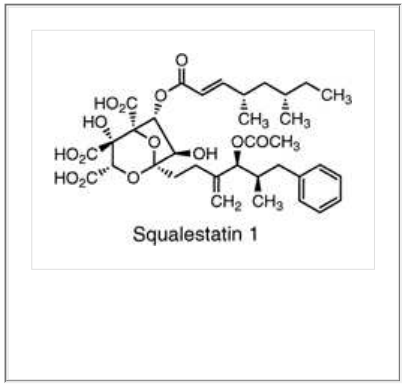
Synthesis and Degradation of Cholesterol

Cholesterol is a C_{27} steroid that serves as an important component of all cell membranes and as the precursor for androgens, estrogens, progesterone, and adrenocorticoids (Fig. 30.1). It is synthesized from acetyl coenzyme A (CoA), as shown in Figure 30.2 (4). The first stage of the biosynthesis is the formation of isopentenyl pyrophosphate from three acetyl CoA molecules. The conversion of 3-hydroxy-3-methylglutaryl (HMG)–CoA to mevalonic acid is especially important, because it is a primary control site for cholesterol biosynthesis. This reaction is catalyzed by HMG-CoA reductase and reduces the thioester of HMG-CoA to a primary hydroxyl group. The second stage involves the coupling of six isopentenyl pyrophosphate molecules to form squalene. Initially, three isopentenyl pyrophosphate molecules are condensed to form farnesyl pyrophosphate, a C_{15} intermediate. Two farnesyl pyrophosphate molecules are then combined using a similar type of reaction. The next stage involves the cyclization of squalene to lanosterol. This process involves an initial epoxidation of squalene, followed by a subsequent cyclization requiring a concerted flow of four pairs of electrons and the migration of two methyl groups. The final stage

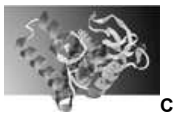
involves the conversion of lanosterol to cholesterol. This process removes three methyl groups from lanosterol, reduces the side-chain double bond, moves the other double bond within the ring structure, and requires approximately 20 steps.

Squalene Synthase: A Potential Drug Target

Inhibitors of squalene synthase, the enzyme responsible for catalyzing the two-step conversion of two molecules of farnesyl pyrophosphate to squalene, are currently being investigated as antihyperlipidemic agents. Squalene synthase catalyzes the first committed step in sterol biosynthesis and offers some potential advantages over 3-hydroxy-3-methylglutaryl–coenzyme A (HMG-CoA) reductase as a drug target. The latter group of compounds inhibits cholesterol synthesis at an early stage of the pathway and, thus, lacks specificity. Mevalonic acid, the immediate product of HMG-CoA reductase, is a common intermediate in the biosynthesis of other isoprenoids, such as ubiquinone (an electron carrier in oxidative phosphorylation), dolichol (a compound involved in oligosaccharide synthesis), and farnesylated proteins (the farnesyl portion targets the protein to cell membrane as opposed to the cytosol). Inhibitors of squalene synthase target an enzyme involved in a later stage of cholesterol biosynthesis and could potentially accomplish the same desired outcomes as currently available agents without interfering with the biosynthesis of other essential, nonsteroidal compounds. One class of compounds currently under investigation are the squalestatins. These compounds were originally isolated as fermentation products produced by a species of *Phoma.* Squalestatin 1 is a potent inhibitor of squalene synthetase and has been shown to produce a marked decrease in serum cholesterol. Additional analogues as well as other structural classes continue to be investigated and, ultimately, may produce alternatives to currently available therapy (5,6).



Squalestatin 1



Clinical Significance

The development and availability of cholesterol and triglyceride-lowering agents has evolved significantly over the past 10 to 15

years. The structure–activity relationships and structural modifications of bile acid sequestrants, fibrates, and 3-hydroxy-3-methylglutaryl–coenzyme A reductase inhibitors form the basis for this evolution and the therapeutic advances that have resulted.

The most widely used cholesterol-lowering agents in cardiovascular medicine today are the "statins" (vastatins). Lovastatin was the first statin to be used clinically on a large scale. Structural modifications of the early statin molecules have produced superior agents in terms of their pharmacokinetic profile, potency, drug interactions, and perhaps, selective adverse effects. This has resulted in the widespread clinical use of superior agents, such as atorvastatin. Such agents have been demonstrated in randomized clinical trials to exert a potent effect in lowering low-density lipoprotein (LDL) cholesterol as well as an important anti-inflammatory action.

The net effect of applying basic science in modifying the chemical structure of cholesterol-lowering drugs is that patient outcomes such as death, myocardial infarction, and other cardiovascular events have been vastly improved. This is clearly a situation in which the application of basic science has produced a profound effect on tens of millions of patients.

Thomas L. Rihn Pharm.D.
Senior Vice President and Chief Clinical Officer, University Pharmacotherapy Associates, Associate Professor of Clinical Pharmacy, Duquesne University, School of Pharmacy

Cholesterol is enzymatically transformed by two different pathways. As illustrated in Figure 30.1, cholesterol can be oxidatively cleaved by the enzyme desmolase (side chain–cleaving enzyme). The resulting compound, pregnenolone, serves as the common intermediate in the biosynthesis of all other endogenous steroids. As illustrated in Figure 30.3, cholesterol also can be converted to bile acids and bile salts. This pathway represents the most important mechanism for cholesterol catabolism. The enzyme 7α-hydroxylase catalyzes the initial, rate-limiting step in this metabolic pathway and, thus, is the key control enzyme for this pathway. Cholic acid and its derivatives are primarily (99%) conjugated with either glycine (75%) or taurine (24%). Bile salts, such as glycocholate, are surface-active agents that act as anionic detergents.

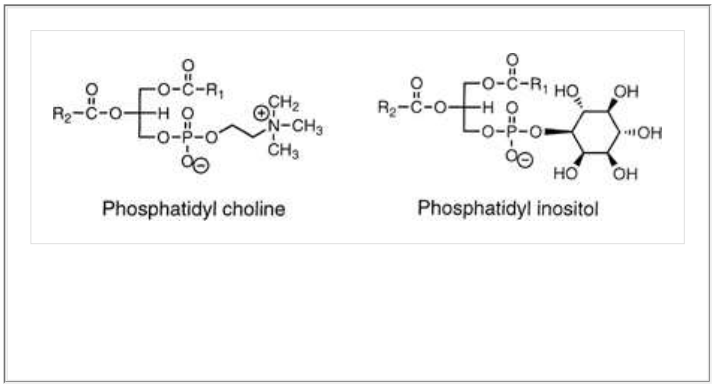
The bile salts are synthesized in the liver, stored in the gallbladder, and released into the small intestine, where they emulsify dietary lipids and fat-soluble vitamins. This solubilization promotes the absorption of these dietary compounds through the intestinal mucosa. Bile salts are predominantly reabsorbed through the enterohepatic circulation and returned to the liver, where they exert a negative feedback control on 7α-hydroxylase and, thus, regulate any subsequent conversion of cholesterol (4,7).

The terms "bile acid" and "bile salt" refer to the un-ionized and ionized forms, respectively, of these compounds. For illustrative purposes only, Figure 30.3 shows cholic acid as a un-ionized bile acid and glycocholate as an ionized bile salt (as the sodium salt). At physiologic and intestinal pH values, both compounds would exist almost exclusively in their ionized forms.

Overview of Triglycerides and Phospholipids

Triglycerides (or, more appropriately, triacylglycerols) are highly concentrated stores of metabolic energy. They are formed from glycerol 3-phosphate and acylated CoA (Fig. 30.4) and accumulate primarily in the cytosol of adipose cells. When required for energy production, triglycerides are hydrolyzed by lipase enzymes to liberate free fatty acids that are then subjected to β-oxidation, the citric acid cycle, and oxidative phosphorylation.

Phospholipids, or phosphoglycerides, are amphipathic compounds that are used to make cell membranes, generate second messengers, and store fatty acids for use in the generation of prostaglandins. They can be synthesized from phosphatidate, an intermediate in triglyceride synthesis. Two common phospholipids, phosphatidyl choline and phosphatidyl inositol, are shown below (4).



Lipoproteins and Transport of Cholesterol and Triglycerides

Cholesterol, triglycerides, and phospholipids are freely soluble in organic solvents, such as isopropanol, chloroform, and diethyl ether, but are relatively insoluble in

aqueous, physiologic fluids. To be transported within the blood, these lipids are solubilized through association with macromolecular aggregates known as lipoproteins. Each lipoprotein is associated with additional proteins, known as apolipoproteins, on their outer surface. These apolipoproteins provide structural support and stability, bind to cellular receptors, and act as cofactors for enzymes involved in lipoprotein metabolism. The compositions and primary functions of the six major lipoproteins are listed in Table 30.1 (7,8).

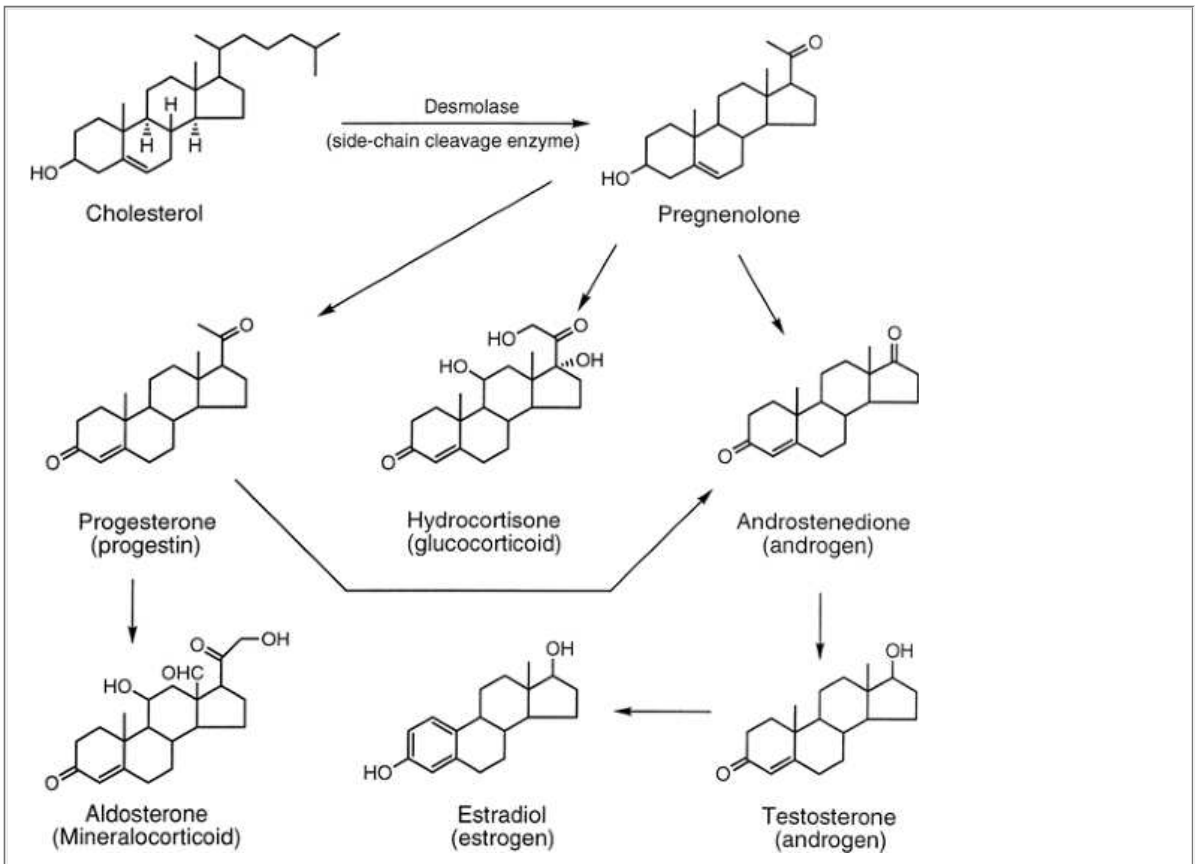


Fig. 30.1. Cholesterol's role as a key intermediate in the biosynthesis of endogenous steroids.

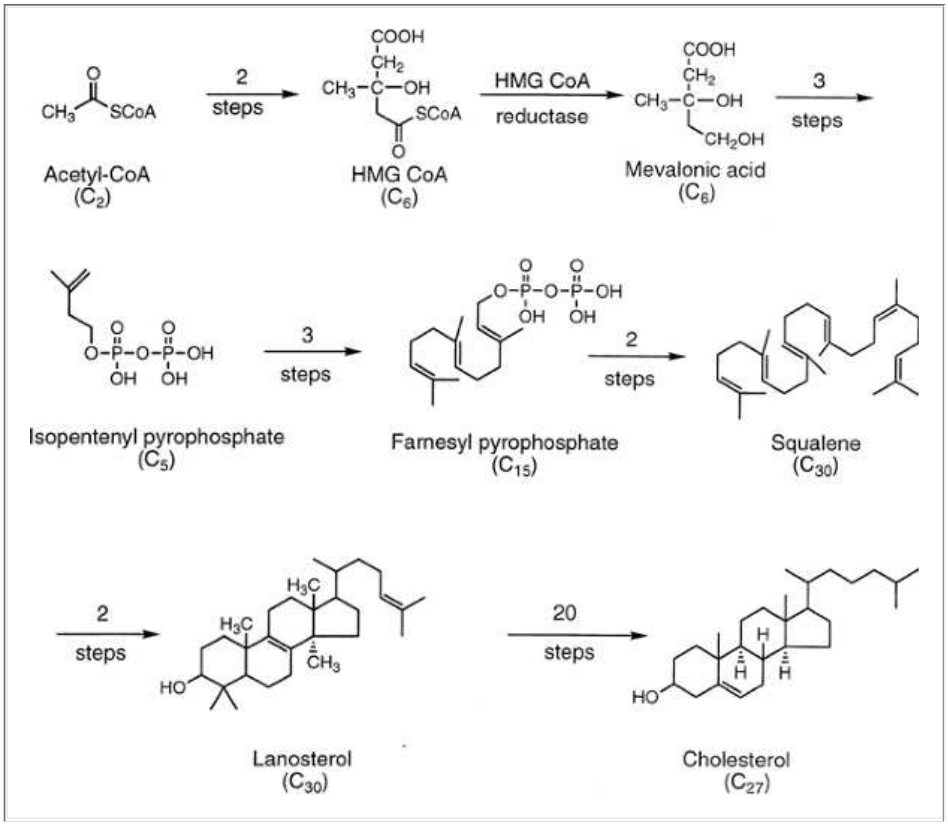

Fig. 30.2. The biosynthesis of cholesterol.

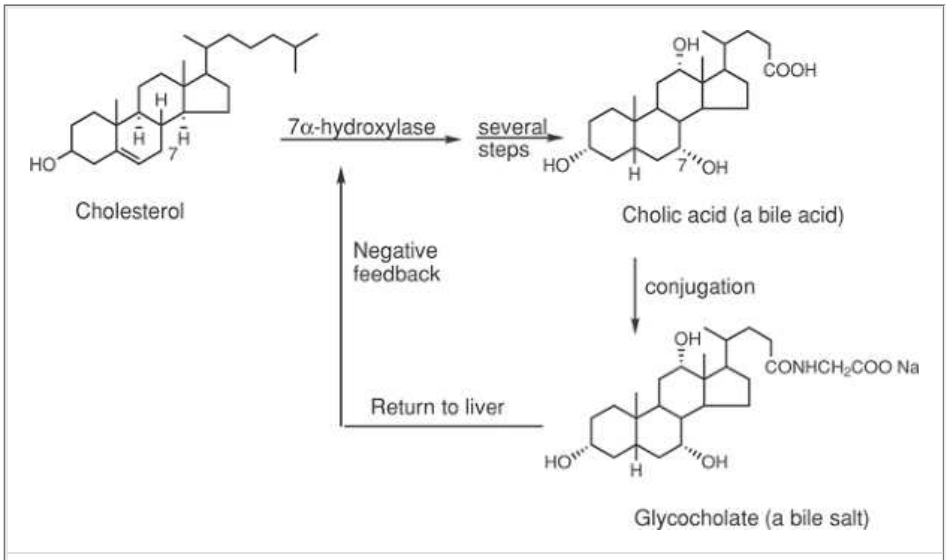

Fig. 30.3. The conversion of cholesterol to bile acids and bile salts.

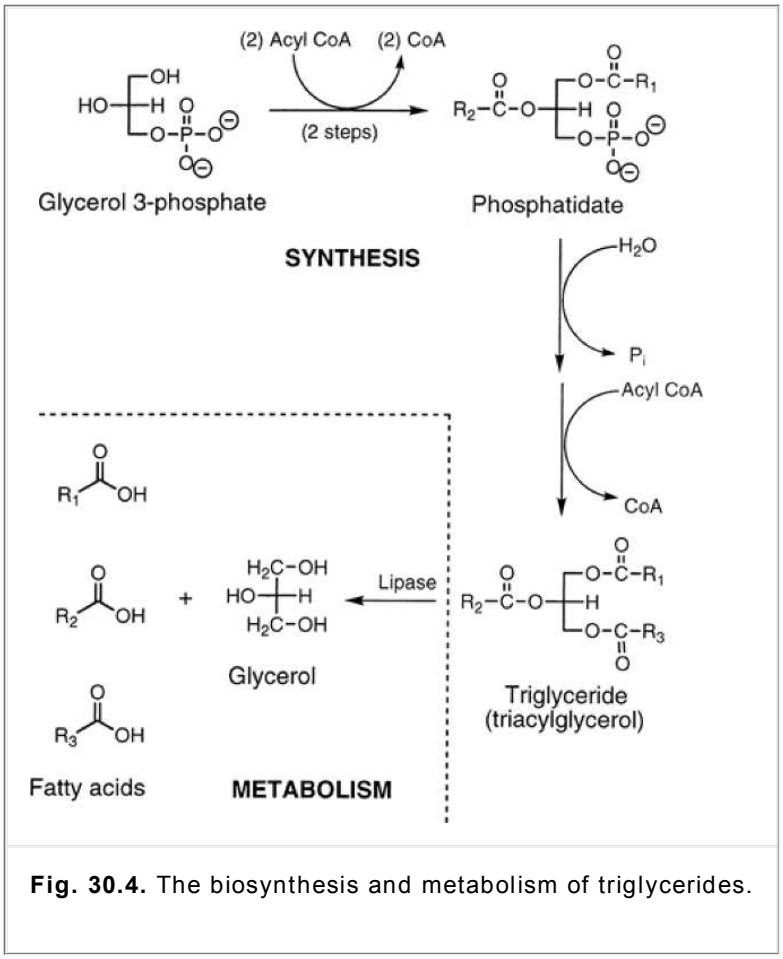

Fig. 30.4. The biosynthesis and metabolism of triglycerides.

Lipoprotein nomenclature is based on mode of separation. When preparative ultracentrifugation is used, lipoproteins are separated according to their density and identified as very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). When electrophoresis is employed in the separation, lipoproteins are designated as pre-β, β, and α. The IDLs are mainly found in the pre-β fraction as a second electrophoretic band and are currently

believed to be an intermediate lipoprotein in the catabolism of VLDL to LDL. Chylomicron remnants and IDLs may show similar electrophoretic and ultracentrifugation separation characteristics. In general, VLDL, LDL, and HDL correspond to pre-β, β, and α lipoprotein, respectively.

The interrelationship among the lipoproteins is shown in Figure 30.5 (7,8). As illustrated, the pathway can be divided into both exogenous (dietary intake) and endogenous (synthetic) components. The exogenous pathway begins following the ingestion of a fat-containing meal or snack. Dietary lipids are absorbed in the form of cholesterol and fatty acids. The fatty acids are then reesterified within the intestinal mucosal cells and, along with the cholesterol, are incorporated into chylomicrons, the largest lipoprotein. During circulation, chylomicrons are degraded into remnants by the action of lipoprotein lipase, a plasma membrane enzyme located on capillary endothelial cells in adipose and muscle tissue. The interaction of chylomicrons with lipoprotein lipase requires apolipoprotein (apo) C-II, and the absence of either the enzyme or the apolipoprotein can lead to hypertriglyceridemia and pancreatitis. The liberated free acids are then available for either storage or energy generation by these tissues. The remnants are predominantly cleared from the plasma by liver parenchymal cells via recognition of the apoE portion of the carrier.

Table 30.1. Classification and Characteristics of Major Plasma Lipoproteins

Classification	Composition	Major Apolipoproteins	Primary Function(s)
Chylomicrons	Triglycerides 80–95%, free cholesterol 1–3%, cholesterol esters 2–4%, phospholipids 3–9%, apoproteins 1–2%	apoA-I, apoA-IV, apoB-48, apoC-I, apoC-II, apoC-III	Transport dietary triglycerides to adipose tissue and muscle for hydrolysis by lipoprotein lipase.
Chylomicron remnants	Primarily composed of dietary cholesterol esters.	apoB-48, apoE	Transport dietary cholesterol to liver for receptor-mediated endocytosis.
VLDL	Triglycerides 50–65%, free cholesterol 4–8%, cholesterol esters 16–22%, phospholipids 15–20%, apoproteins 6–10%	apoB-100, apoE, apoC-I, apoC-II, apoC-III	Transport endogenous triglycerides to adipose tissue and muscle for hydrolysis by lipoprotein lipase.
IDL	Intermediate between VLDL and LDL	apoB-100, apoE, apoC-II, apoC-III	Transport endogenous cholesterol for either conversion to LDL or receptor-mediated endocytosis by the liver.
LDL	Triglycerides 4–8%, free cholesterol 6–8%, cholesterol esters 45–50%, phospholipids 18–24%, apoproteins 18–22%	apoB-100	Transport endogenous cholesterol for receptor-mediated endocytosis by either the liver or extrahepatic tissues.
HDL	Triglycerides 2–7%, free cholesterol 3–5%, cholesterol esters 15–20%, phospholipids 26–32%, apoproteins 45–55%	apoA-I, apoA-II, apoE, apoC-I, apoC-II, apoC-III	Removal of cholesterol from extrahepatic tissues via transfer of cholesterol esters to IDL and LDL

apo, apolipoprotein; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; HDL, high-density lipoprotein.

The endogenous pathway begins in the liver with the formation of VLDL. Similar to chylomicrons, triglycerides are present in a higher concentration than either cholesterol or cholesterol esters; however, the concentration difference between these lipids is much less than that seen in chylomicrons. The metabolism of VLDL also is similar to chylomicrons in that lipoprotein lipase reduces the triglyceride content of VLDL and increases the availability of free fatty acids to the muscle and adipose tissue. The resulting lipoprotein, IDL, either can be further metabolized to LDL or can be transported to the liver for receptor-mediated endocytosis. This latter effect involves an

interaction of the LDL receptor with the apolipoproteins, apoB-100 and apoE, on IDL. The amount of IDL delivered to the liver is approximately the same as that converted to LDL. The half-life of IDL is relatively short as compared to that of LDL and, thus, accounts for only a small portion of total plasma cholesterol. In contrast, LDL accounts for approximately two-thirds of total plasma cholesterol and serves as the primary source of cholesterol for both hepatic and extrahepatic cells. As with IDL, the uptake of LDL by these cells is mediated by a receptor interaction with the apoB-100 on LDL. The number of LDL receptors on the cell surface mediates regulation of cellular LDL uptake. Cells requiring increased amounts of cholesterol will increase the biosynthesis of LDL receptors. Conversely, it has been demonstrated that increased hepatic concentrations of cholesterol will inhibit both HMG-CoA reductase as well as the production of LDL receptors. As previously discussed, hepatic cholesterol can be converted to bile acids and bile salts and reenter the endogenous pathway through the bile and enterohepatic circulation.

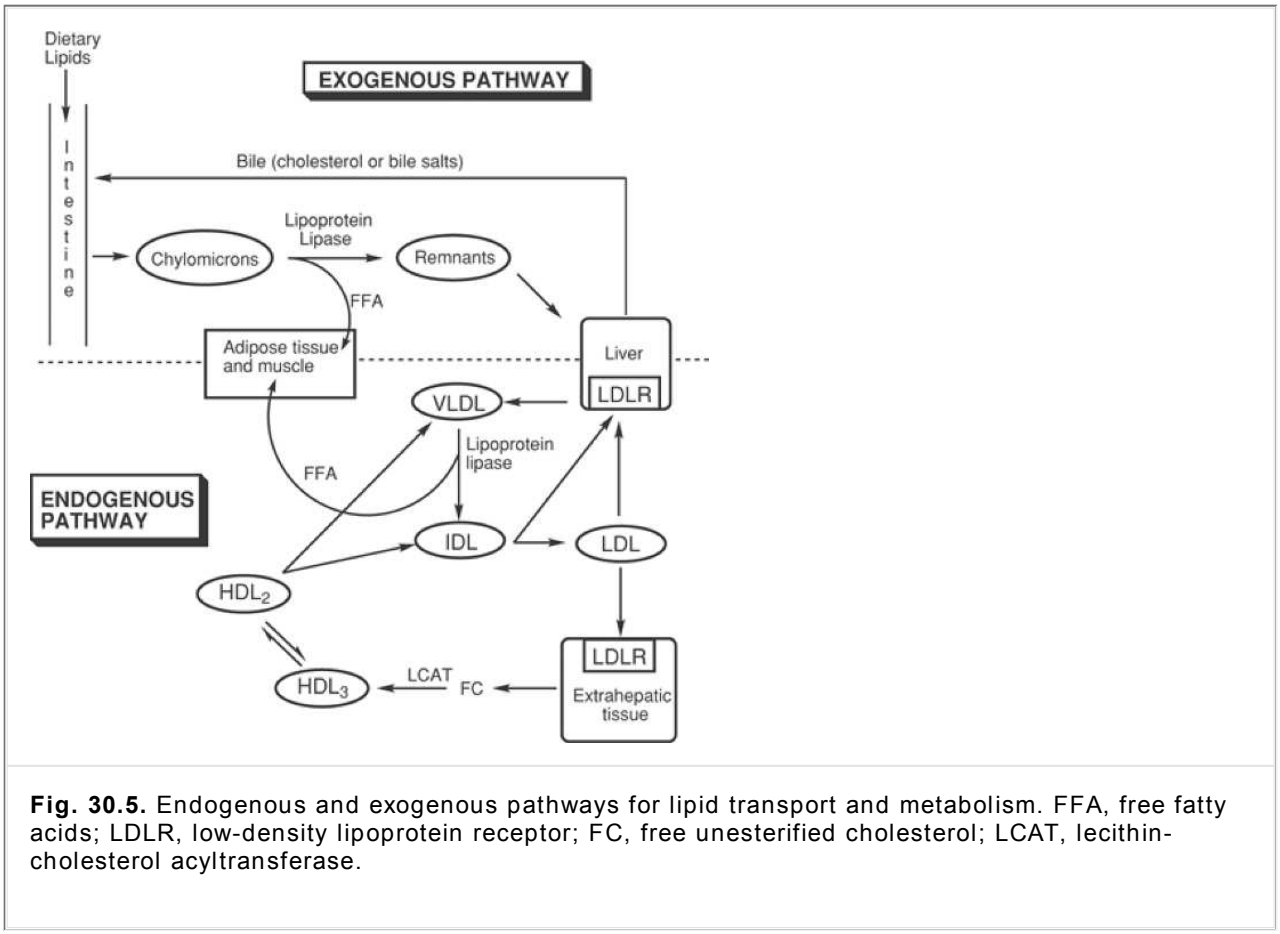

Fig. 30.5. Endogenous and exogenous pathways for lipid transport and metabolism. FFA, free fatty acids; LDLR, low-density lipoprotein receptor; FC, free unesterified cholesterol; LCAT, lecithin-cholesterol acyltransferase.

Synthesized in the liver and intestine, HDL initially exists as a dense, phospholipid disk composed primarily of apoA-I. The primary function of HDL is to act as a scavenger to remove cholesterol from extrahepatic cells and to facilitate its transport back to the liver. Nascent HDL accepts free, unesterified cholesterol. A plasma enzyme, lecithin-cholesterol acyltransferase, then esterifies the cholesterol. This process allows the resulting cholesterol esters to move from the surface to the core and results in the production of spherical HDL_3 particles. As cholesterol content is added, HDL_3 is converted

to HDL_2, which is larger and less dense than HDL_3. The ultimate return of cholesterol from HDL_2 to the liver is known as reverse cholesterol transport and is accomplished via an intermediate transfer of cholesterol esters from HDL_2 to either VLDL or IDL. This process regenerates spherical HDL_3 molecules that can recirculate and acquire excess cholesterol from other tissues. In this manner, HDL serves to prevent the accumulation of cholesterol in arterial cell walls and other tissue and may serve as the basis for its cardioprotective properties (7,8).

Classification of Hyperlipoproteinemias

Hyperlipoproteinemia can be divided into primary and secondary disorders. Primary disorders are the result of genetic deficiencies or mutations, whereas secondary disorders are the result of other conditions or diseases. Secondary hyperlipoproteinemia has been associated with diabetes mellitus, hypothyroidism, renal disease, liver disease, alcoholism, and certain drugs (1,7,8).

In 1967, Fredrickson et al. (9) classified primary hyperlipoproteinemias into six phenotypes (I, IIa, IIb, III, IV, and V) based on which lipoproteins and lipids were elevated. Current literature and practice, however, appear to favor the more descriptive classifications and subclassifications listed in Table 30.2 Primary disorders are currently classified as those that primarily cause hypercholesterolemia, those that primarily cause hypertriglyceridemia, and those that cause a mixed elevation of both cholesterol and triglycerides. Subclassifications are based on the specific biochemical defect responsible for the disorder. Classifications developed by Fredrickson have been included in Table 30.2 under the heading *Previous Classification* for comparative and reference purposes.

As shown in Table 30.2, some disorders are well characterized, whereas others are not (1,7,8). Familial hypercholesterolemia is caused

by a deficiency of LDL receptors. This results in a decreased uptake of IDL and LDL by hepatic and extrahepatic tissues and an elevation in plasma LDL levels. The homozygous form of this disorder is rare but results in extremely high LDL levels and early morbidity and mortality because of the total lack of LDL receptors. A related disorder, familial defective apoB-100, also results in elevated LDL levels but is caused by a genetic mutation rather than a deficiency. Alteration of apoB-100 decreases the affinity of LDL for the LDL receptor and thus hinders normal uptake and metabolism. Elevations in chylomicron levels can result from a deficiency of either lipoprotein lipase or apoC-II. These deficiencies cause decreased or impaired triglyceride hydrolysis and result in a massive accumulation of chylomicrons in the plasma. Dysbetalipoproteinemia results from the presence of an altered form of apoE and is the only mixed hyperlipoproteinemia with a known cause. Proper catabolism of chylomicron and VLDL remnants requires apoE. The presence of a binding-defective form of apoE, known as $apoE_2$, results in elevated levels of VLDL and IDL triglyceride and cholesterol levels.

Diseases and Disorders Caused by Hyperlipidemias

Coronary heart disease, which includes acute myocardial infarction, ischemic heart disease, and angina pectoris, is the leading cause of mortality in the United States. In 2002, more than 494,382 deaths were caused by CHD. Additionally, mortality from CHD often occurs rapidly, either in an emergency room or before hospitalization. The highest mortality is seen in patients older than 65 years; however, the vast majority of deaths in patients younger than 65 years occur during an initial attack. Risk factors associated with CHD include hypertension, cigarette smoking, elevated plasma cholesterol levels, physical inactivity, diabetes, and obesity (10).

Atherosclerosis, which is named from the Greek terms for “gruel” (*athere*) and “hardening” (*sclerosis*), is the underlying cause of CHD. It is a gradual process in which

an initial accumulation of lipids in the arterial intima leads to thickening of the arterial wall, plaque formation, thrombosis, and occlusion (11,12,13). The involvement of LDL cholesterol in this process is shown in Figure 30.6. Within the extracellular space of the intima, LDL is more susceptible to oxidative metabolism, because it is no longer protected by plasma antioxidants. This metabolism alters the properties of LDL such that it is readily scavenged by macrophages. Unlike normal LDL, the uptake of oxidized LDL is not regulated; thus, macrophage cells can readily become engorged with oxidized LDL. Subsequent metabolism produces free cholesterol, which either can be released into the plasma or reesterified by the enzyme acyl CoA–cholesterol acyltransferase (ACAT). Cholesterol released into plasma can be scavenged by HDL_3 and returned to the liver, thus preventing any accumulation or damage. In this manner, HDL acts as a cardioprotective agent, because high concentrations of reesterified cholesterol can morphologically change macrophages into foam cells. Accumulation of lipid-engorged foam cells in the arterial intima results in the formation of fatty streaks, the initial lesion of atherosclerosis. Later, the deposition of lipoproteins, cholesterol, and phospholipids causes the formation of softer, larger plaques. Associated with this lipid deposition is the proliferation of arterial smooth muscle cells into the intima and the laying down of collagen, elastin, and glycosaminoglycans, leading to fibrous plaques. Ultimately, the surface of the plaque deteriorates, and an atheromatous ulcer is formed with a fibrous matrix, accumulation of necrotic tissue, and appearance of cholesterol and cholesterol ester crystals. A complicated lesion also shows calcification and hemorrhage with the formation of organized mural thrombi. Thrombosis results from changes in the arterial walls and in the blood-clotting mechanism.

Table 30.2. Characteristics of the Major Primary Hyperlipoproteinemias

Current Classification	Biochemical Defect	Elevated Lipoproteins	Previous Classification
Hypercholesterolemias			
Familial hypercholesterolemia	Deficiency of LDL receptors	LDL	IIa
Familial defective apoB-100	Mutant apoB-100	LDL	IIa
Polygenic hypercholesterolemia	Unknown	LDL	IIa
Hypertriglyceridemias			
Familial hypertriglyceridemia	Unknown	VLDL	IV
Familial lipoprotein lipase deficiency	Deficiency of lipoprotein lipase	Chylomicrons, VLDL	I (chylomicron elevation only), V
Familial apoC-II deficiency	Deficiency of apoC-II	Chylomicrons, VLDL	I (chylomicron elevation only), V

Mixed hypercholesterolemia and hypertriglyceridemia			
Familial combined hyperlipidemia	Unknown	VLDL, LDL	IIb

LDL, low-density lipoprotein; apo, apolipoprotein; VLDL, very-low-density lipoprotein; IDL, intermediate-density lipoprotein.

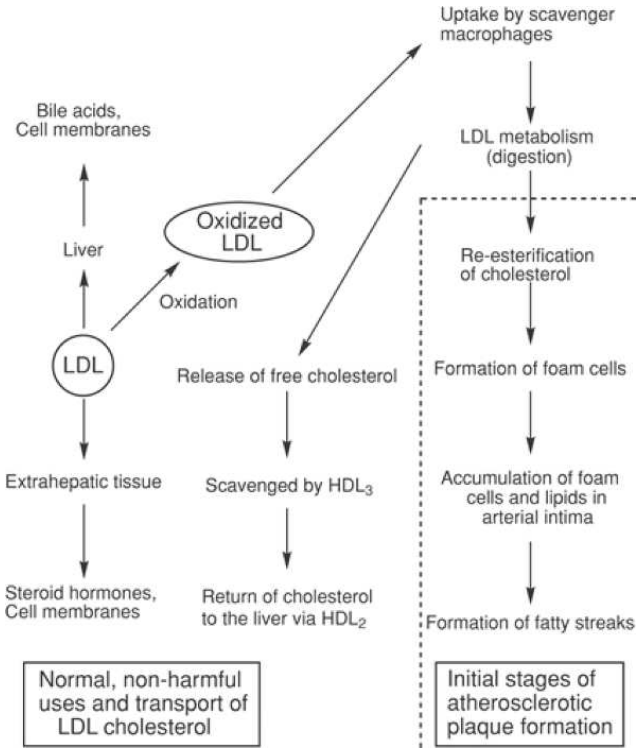

Fig. 30.6. The role of LDL cholesterol in the development of atherosclerotic plaques. The mechanism by which HDL provides a cardioprotective action also is shown.

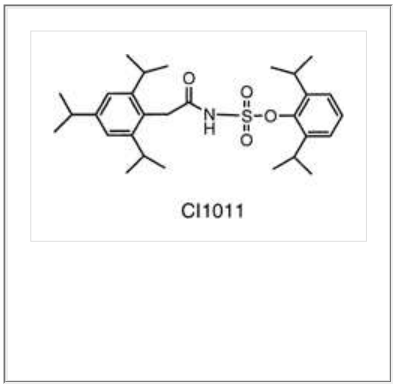
Obviously, individuals with higher cholesterol and LDL levels are more susceptible to these detrimental effects than those with normal cholesterol and LDL levels. Total plasma cholesterol levels less than 200 mg/dL are considered desirable. Levels above 240 mg/dL are considered high, and levels between 200 and 239 mg/dL are considered borderline. For LDL, plasma levels of less than 100 mg/dL are considered optimal, plasma levels equal to or greater than 160 are considered high, plasma levels between 130 and 159 mg/dL are considered borderline, and plasma levels between 100 and 129 are considered above optimal. Current guidelines (8,13) also recommend an LDL level below 70 mg/dL as a goal for very high-risk patients (i.e., those with multiple risk factors and known cardiovascular disease).

Elevated plasma triglyceride levels can contribute to atherosclerosis and CHD in mixed hyperlipoproteinemias, whereas pure hypertriglyceridemias are primarily associated with pancreatitis and show little to no relationship to CHD (7,8).

ACAT: A Potential Drug Target

Inhibitors of acyl CoA–cholesterol acyltransferase (ACAT) are currently being investigated as cholesterol-lowering or antiatherosclerotic agents. In addition to its role in foam cell formation, ACAT also is required for esterification of cholesterol in intestinal mucosal cells and for synthesis of cholesterol esters in hepatic VLDL formation. Thus, ACAT inhibitors have the potential of providing three beneficial effects in patients with hypercholesterolemia: decreased cholesterol absorption, decreased hepatic VLDL synthesis, and decreased foam cell formation. Initial successes at inhibiting ACAT were dampened by the discovery of accompanying adrenal toxicity. Subsequent structural modifications have lead to the development of

potent, orally active ACAT inhibitors (e.g., CI1011), which lack this toxicity and have given new hope that inhibitors of this enzyme may provide an alternative treatment of atherosclerotic disorders (12,14).



Overview of Drug Therapy Affecting Lipoprotein Metabolism

Bile acid sequestrants, HMG-CoA reductase inhibitors (HMGRIs), ezetimibe, fibrates, and niacin are all used in the treatment of hyperlipoproteinemia. In general, successful use of these compounds depends on proper identification and classification of the hyperlipoproteinemia affecting the patient. With the possible exceptions of niacin, atorvastatin, and rosuvastatin, currently available compounds do not have equal efficacy in reducing both hypercholesterolemia and hypertriglyceridemia and, thus, are used primarily for their ability to decrease either cholesterol or triglyceride levels. Bile acid sequestrants, inhibitors of HMG-CoA reductase, and ezetimibe are effective in decreasing plasma cholesterol and LDL levels. The fibrates also have some actions on plasma cholesterol; however, their main effect is to stimulate lipoprotein lipase and to increase the clearance of triglycerides. Niacin, through its ability to decrease VLDL formation, has been shown to decrease the plasma levels of both triglycerides and cholesterol. All of these compounds are discussed below. References for these sections have been limited to current reviews and texts, selected papers, and product literature, both traditional and electronic. Readers requiring additional references for any of these compounds should consult either the previous edition of this text or the references contained within the cited reviews and texts.

Bile Acid Sequestrants

Historical Overview

Cholestyramine was originally developed in the 1960s to treat pruritus secondary to elevated plasma concentrations of bile acids in patients with cholestasis. Its ability to bind (i.e., to hold or to sequester) bile acids and to increase their fecal elimination was subsequently shown to produce beneficial effects in lowering serum cholesterol levels. In 1973, cholestyramine was approved for the treatment of hypercholesterolemia in patients who do not respond to dietary modifications. Colestipol and colesevelam, which retain the key structural features required to bind bile acids, were approved in 1977 and 2000, respectively (7,15).

Cholestyramine, colestipol, and colesevelam are chemically classified as anion-exchange resins. This term arises from their ability to selectively bind and exchange negatively charged atoms or molecules with one another. The selectivity comes from the fact that these positively charged resins do not bind equally to all anions. For example, the chloride ion of cholestyramine can be displaced by, or exchanged with, other anions (e.g., bile acids) that have a greater affinity for the positively charged functional groups on the resin.

Mechanism of Action

Cholestyramine, colestipol, and colesevelam lower plasma LDL levels by indirectly increasing the rate at which LDL is cleared from the bloodstream. Under normal circumstances, approximately 97% of bile acids are reabsorbed into the enterohepatic circulation. As previously discussed, these compounds are returned to the liver where they regulate their own production. Bile acid sequestrants are not orally absorbed but, rather, act locally within the gastrointestinal tract to interrupt this process. They bind the two major bile acids, glycocholic acid and taurocholic acid, and greatly increase their fecal excretion. As a result, decreased concentrations of these compounds are returned to the liver. This removes the feedback inhibition of 7α-hydroxylase and increases the hepatic conversion of cholesterol to bile acids (Fig. 30.3). The decrease in hepatic cholesterol concentrations leads to several compensatory effects: increased expression of LDL receptors, increased hepatic uptake of plasma LDL, induction of HMG-CoA reductase, and increased biosynthesis of cholesterol. The latter two effects are insufficient to counteract the increases in cholesterol clearance and catabolism; however, concurrent use of an HMGRI can provide an additive effect in lowering LDL cholesterol. Bile acid sequestrants do not alter the removal of plasma LDL by nonreceptor-mediated mechanisms and, thus, are ineffective in treating homozygous familial hypercholesterolemia (7,15,16,17).

The decreased return of bile acids to the liver also will produce an increase in triglyceride synthesis and a transient rise in VLDL levels. Subsequent compensatory mechanisms will increase VLDL removal, most likely through the increased LDL receptors, and return VLDL levels to predrug levels. For those patients with preexisting hypertriglyceridemia, the compensatory mechanisms are inadequate, and a persistent rise in VLDL levels occurs (7).

Structure–Activity Relationships

Cholestyramine (Fig. 30.7) is a copolymer consisting primarily of polystyrene, with a small amount of divinylbenzene as the cross-linking

agent. In addition, it contains approximately 4 mEq of fixed quaternary ammonium groups per gram of dry resin. These positively charged groups function as binding sites for anions. Virtually all of these sites are accessible to bile acids. Increasing the amount of divinylbenzene from 2 to 4 to 8% increases the cross-linkage and reduces the porosity of the resin. This prevents binding of bile acids to interior sites and decreases the efficacy of the compound.

Colestipol (Fig. 30.7) is a copolymer of tetraethylenepentamine and epichlorhydrin and is commercially marked as its hydrochloride salt. The key functional groups on colestipol are the basic secondary and tertiary amines. Although the total nitrogen content of colestipol is greater than that of cholestyramine, the functional anion-exchange capacity of the resin depends on intestinal pH and may be less than cholestyramine. Recent in vitro studies indicate that cholestyramine has a higher adsorption capacity than colestipol for bile salts (18). Quaternization of colestipol with methyl iodide increases the capacity in vitro for glycocholate (19).

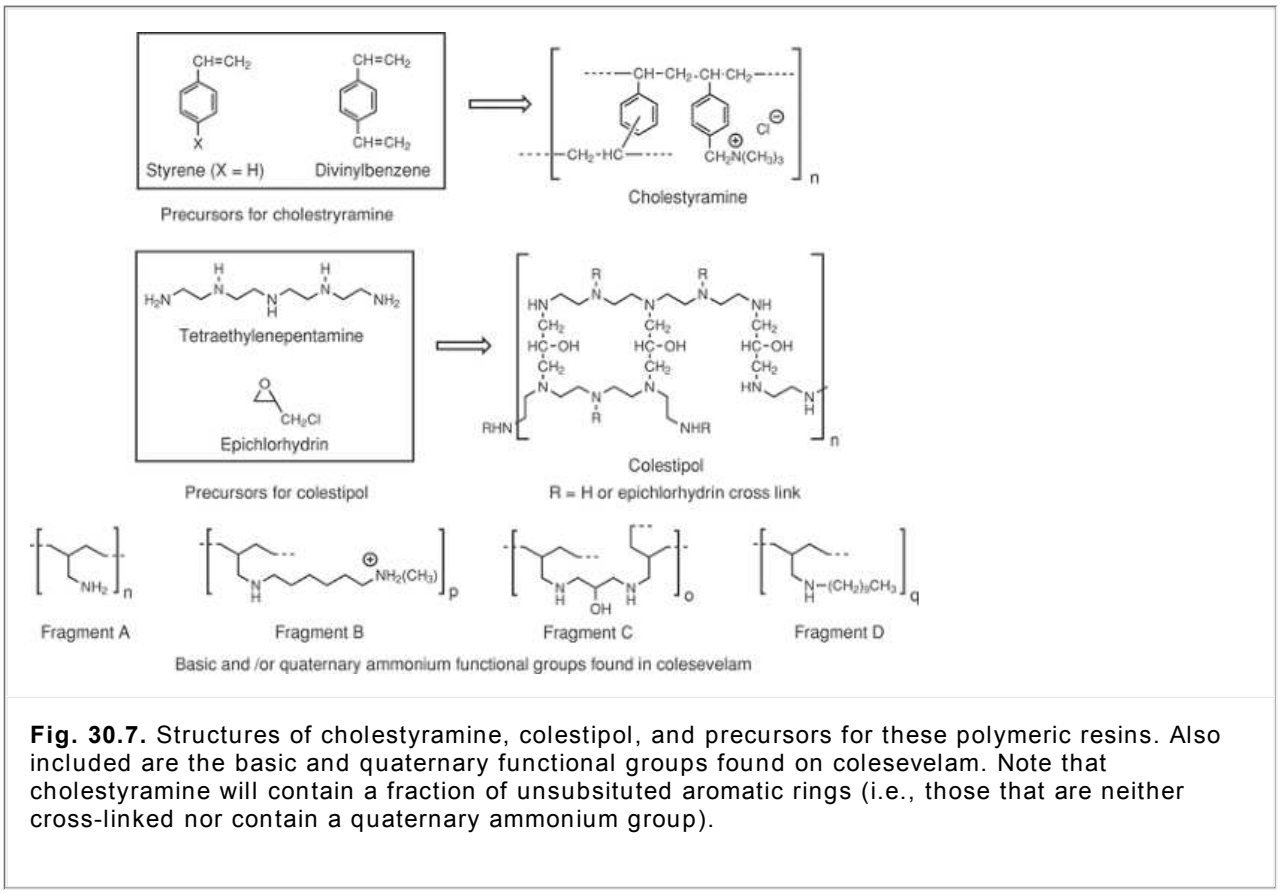


Fig. 30.7. Structures of cholestyramine, colestipol, and precursors for these polymeric resins. Also included are the basic and quaternary functional groups found on colesevelam. Note that cholestyramine will contain a fraction of unsubsituted aromatic rings (i.e., those that are neither cross-linked nor contain a quaternary ammonium group).

Colesevelam is a more diverse polymer; however, its initial formation is similar to colestipol. In the case of colesevelam, poly(allyamine) is initially cross-linked with epichlorhydrin and then alkylated with 1-bromodecane and (6-bromohexyl)-trimethylammonium bromide. The resulting polymer contains four basic and/or quaternary functional groups, as shown in Figure 30.7. Fragment A is a primary amine, fragment B is a pair of secondary amines, fragment C is an alkylated amine attached to a quaternary ammonium group, and fragment D is a decylated amine. The overall polymer is a hydrophilic gel and is insoluble in water (7).

Physicochemical Properties

All bile acid sequestrants are large, hygroscopic, water-insoluble resins. The molecular weight of cholestyramine is reported to be greater than 1,000,000 daltons; however, no specific molecular weight has been assigned to either colestipol or colesevelam. Cholestyramine contains a large number of quaternary ammonium groups and, thus, has multiple permanent positive charges. Colestipol contains a large number of secondary and tertiary amines, whereas colesevelam contains quaternary ammonium groups as well as primary and secondary amines. Normal pK_a values for the amines range from 9.0 to 10.5; thus, all of these groups should be primarily ionized at intestinal pH.

Pharmacokinetic Parameters, Metabolism, and Dosing

Cholestyramine, colestipol, and colesevelam are not orally absorbed and are not metabolized by gastrointestinal enzymes. They are excreted in the feces as an insoluble complex with bile acids. Their onset of action occurs within 24 to 48 hours; however, it may take up to 1 month to achieve peak response (7,15,20).

Cholestyramine is available as a powder that is mixed with water, juice, or other noncarbonated beverages to create a slurry to drink. Patients should experiment with various liquids to find the most palatable combination; however, patient acceptance and compliance with this dosage formulation can limit its use. Each packet or scoop of cholestyramine is equivalent to 4 g of cholestyramine. The recommended daily dose for the treatment of hypercholesterolemia is 8 to 16 grams (two to four packets or scoops) per day divided into two doses and taken with meals. The maximum daily dose for hypercholesterolemia is 24 g. Colestipol is available as either granules or

1-g tablets. The granules should be taken in a manner similar to that described for the cholestyramine powder. The starting dose for the granules is 5g once or twice daily. This dose can be increased in 5g increments every 1 to 2 months until therapeutic goals or a maximum of 30 g/day have been reached. The starting dose for the tablets is 2g once or twice daily. This dose can then be increased in 2g segments up to a maximum daily dose of 16 g. Patients must be advised that colestipol tablets should not to be chewed, crushed, or cut and should be taken with plenty of water (15,21). Colesevelam is available as 625-mg tablets and should be taken with a meal. The starting dose is three tablets (1.875 g) twice a day or six tablets (3.75 g) once a day. The dose may be increased to a maximum of seven tablets per (4.375 g) per day.

Unlabeled Uses

Diarrhea, digitalis toxicity, and pseudomembranous colitis

Therapeutic Applications

Bile acid sequestrants are indicated for the treatment of hypercholesterolemia in patients who do not adequately respond to dietary modifications. They may be used either alone or in combination with HMGRIs or niacin. These combinations often can achieve a 50% reduction in plasma LDL levels. Cholestyramine, but neither colestipol nor colesevelam, also is approved for the relief of pruritus associated with partial biliary obstruction. Bile acid sequestrants should not be used to treat hypertriglyceridemias or mixed hyperlipoproteinemias in which hypertriglyceridemia is the primary concern. These compounds also are contraindicated in patients with cholelithiasis or complete biliary obstruction because of the impaired secretion of bile acids caused by these conditions. Finally, cholestyramine and colestipol are contraindicated in patients with primary biliary cirrhosis, because this can further raise serum cholesterol (7,15,21).

Adverse Effects

Because bile acid sequestrants are not orally absorbed, they produce minimal systemic side effects and, thus, are one of the safest drugs to use for hypercholesterolemia. Constipation is by far the most frequent patient complaint. Increasing dietary fiber or using bulk-producing laxatives, such as psyllium, often can minimize this adverse effect. Other gastrointestinal symptoms, such as bloating and abdominal discomfort, usually disappear with continued use; however, the possibility of fecal impaction requires that extreme caution be used in patients with preexisting constipation. All three of these compounds release chloride ions as part of their exchange mechanism and can cause hyperchloremic acidosis. This is not a common occurrence, but it may limit the use of bile acid sequestrants in patients with renal disease. Hypoprothrombinemia and bleeding are caused by the ability of bile acid sequestrants to bind with and impair the absorption of dietary vitamin K. These effects also are rare, but they may limit the use of these agents in patients with preexisting clotting disorder and in those being concurrently treated with anticoagulants (2,7,15,21).

Drug Interactions

Because of their mechanism of action, bile acid sequestrants can potentially bind with and decrease the oral absorption of almost any other drug. Because these anion-exchange resins contain numerous positive charges, they are much more likely to bind to acidic compounds than to basic compounds or nonelectrolytes. This is not an absolute, however, because cholestyramine and colestipol have been reported to decrease the oral absorption of propranolol (a base) and the lipid-soluble vitamins, A, D, E, and K (nonelectrolytes). As a result, the current recommendation is that all other oral medication should be administered at least 1 hour before or 4 hours after cholestyramine and colestipol. Interestingly, this drug interaction has been used in a beneficial manner to treat digitalis overdose and toxicity.

Adverse Effects of Bile Acid Sequestrants

Bloating, abdominal discomfort, constipation, bowel obstruction, steatorrhea, anorexia, cholelithiasis, pancreatitis, hyperchloremic acidosis, hypoprothrombinemia, and bleeding.

Colesevelam appears to be less likely to interfere with the absorption of concurrently administered drugs. No significant decreases in absorption were seen when colesevelam was coadministered with either digoxin, lovastatin, warfarin, metoprolol, quinidine, or valproic acid. Because of potential interactions, especially for drugs with a low therapeutic index, the administration of drugs that have not been directly studied in combination with colesevelam should be spaced accordingly, as described above for cholestryamine and colestipol (7,15).

HMG-CoA Reductase Inhibitors

Currently, six HMGRIs are approved for therapeutic use in the United States. Chemically, they can be divided into two groups, natural products and synthetic agents. All of these compounds effectively block the conversion of HMG-CoA to mevalonic acid and have similar effects on plasma cholesterol levels. The compounds differ somewhat in their indications, potencies, and pharmacokinetic profiles. They often are referred to as statins or, more recently, vastatins. Because of the potential confusion of the terms “statin” and “statine” (i.e., a stable dipeptide mimic [see Chapter 28]), it is suggested here that classifying an HMGRI as a vastatin is preferable to classifying it as a statin.

Historical Overview and Development

The development and use of HMGRIs began in 1976 with the discovery of mevastatin. Originally named compactin, this fungal metabolite was isolated from two different species of *Penicillium* and demonstrated potent, competitive inhibition of HMG-CoA reductase. Its affinity for the enzyme was shown to be 10,000-fold greater than that of the substrate HMG-CoA (22). Several years later, a structurally similar compound was isolated from *Monascus ruber* and *Aspergillus terreus*. This compound was originally known as

mevinolin, was later renamed lovastatin, and was more than twofold more potent than mevastatin (Fig. 30.8). Structurally, it differed from mevastatin only by the presence of a methyl group at

the 6′ position of the bicyclic ring. As illustrated in Figure 30.8, mevastatin and lovastatin can bind very tightly with HMG-CoA reductase, because their hydrolyzed lactones mimic the tetrahedral intermediate produced by the reductase enzyme (7). Studies published in 1985 confirmed this theory and also established that the bicyclic portions of these compounds bind to the CoA site of the enzyme (23). Clinical trials of mevastatin were halted after reports of altered intestinal morphology in dogs (24); however, lovastatin received approval by the U.S. Food and Drug Administration (FDA) in 1987, representing the first HMGRI to be available in the U.S. for therapeutic use.

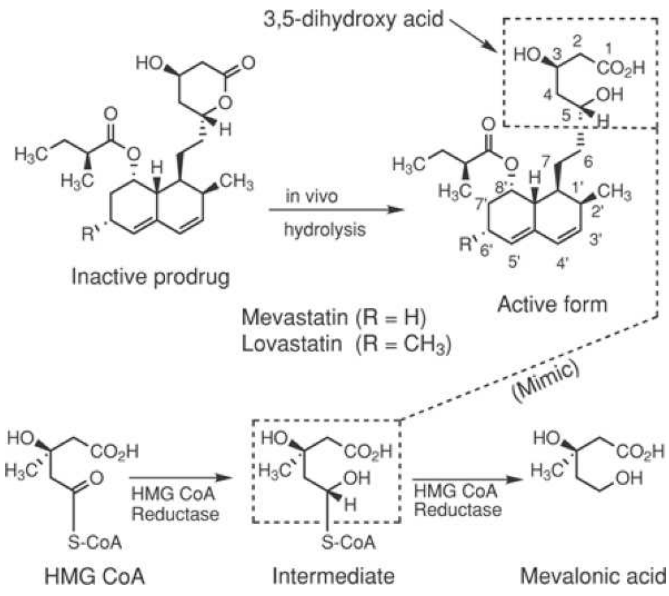

Fig. 30.8. Mechanism of action of mevastatin and lovastatin. Hydrolysis of these pro-drugs produces a 3,5-dihydroxy acid that mimics the tetrahedral intermediate produced by HMG-CoA reductase.

Structure–Activity Relationship

Mevastatin and lovastatin served as lead compounds in the development of additional HMGRIs. Initial research published by Merck Pharmaceuticals examined alterations of the lactone and bicyclic rings as well as the ethylene bridge between them. The results demonstrated that the activity of HMGRIs is sensitive to the stereochemistry of the lactone ring, the ability of the lactone ring to be hydrolyzed, and the length of bridge connecting the two ring systems. Additionally, it was found that the bicyclic ring could be replaced with other lipophilic rings and that the size and shape of these other ring systems were important to the overall activity of the compounds (25).

Minor modifications of the bicyclic ring and side-chain ester of lovastatin produced simvastatin and pravastatin (Fig. 30.9). Pravastatin, a ring-opened dihydroxy acid with a 6α-hydroxyl group, is much more hydrophilic than either lovastatin or simvastatin. Proposed advantages of this enhanced hydrophilicity are minimal penetration into the lipophilic membranes of peripheral cells, better selectivity for hepatic tissues, and a reduction in the incidence of side effects seen with lovastatin and simvastatin. (26,27).

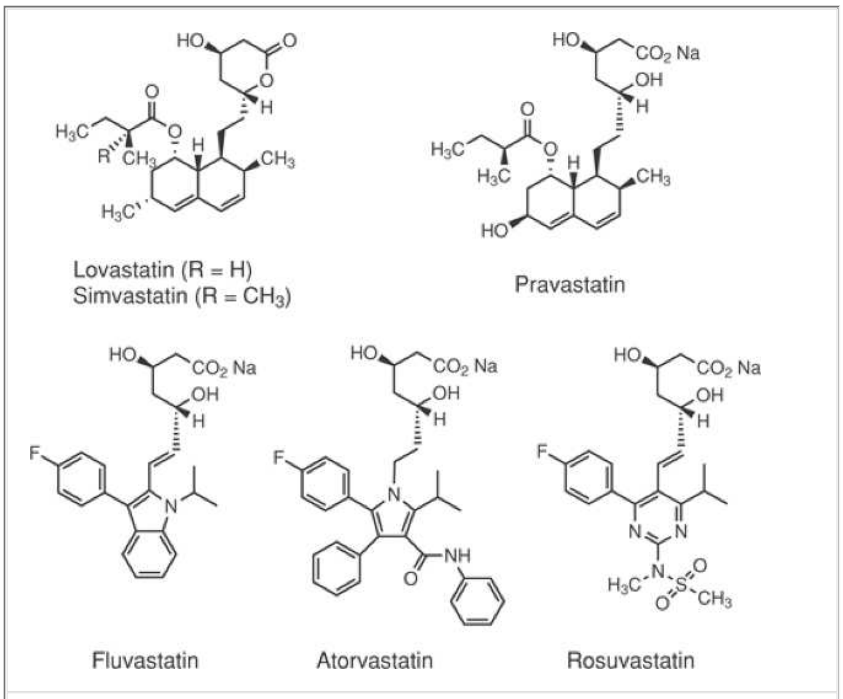

Fig. 30.9. Commercially available HMG-CoA reductase inhibitors.

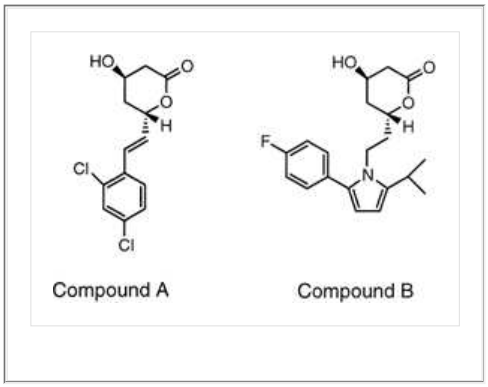
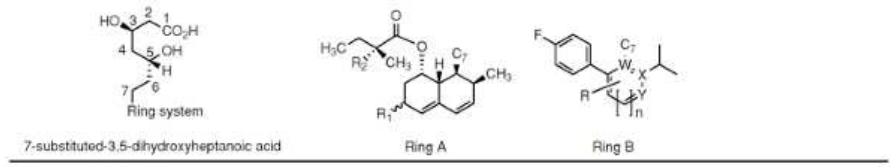
The replacement of the bicyclic ring with various substituted, aromatic ring systems led to the development of fluvastatin, atorvastatin, and rosuvastatin (Fig. 30.9). The initial rationale centered on a desire to simplify the structures of mevastatin and lovastatin. The 2,4-dichlorophenyl analogue (compound A) was one of the first compounds to demonstrate that this type of substitution was possible; however, compound A was considerably less potent than mevastatin. Subsequent research investigated a variety of aromatic substitutions and heterocyclic ring systems to optimize HMGRI activity. The substituted pyrrole (compound B) retained 30% of the activity of mevastatin (28) and was a key intermediate in the development of atorvastatin. The 4-fluorophenyl and isopropyl substitutions found in compound B also are seen in the indole and pyrimidine ring systems of fluvastatin and rosuvastatin, respectively, and most likely represent the optimum substitutions at their respective positions. The design of all three of these compounds included the ring-opened dihydroxyacid functionality first seen in pravastatin.





Common for all HMGRIs:
1. The 3,5-dihydroxycarboxylate is essential for inhibitory activity. Compounds containing a lactone are prodrugs requiring in vivo hydrolysis.
2. The absolute stereochemistry of the 3- and 5-hydroxyl groups must be the same as that found in mevastatin and lovastatin.
3. Altering the two carbon distance between C5 and the ring system diminishes or fails to improve activity.
4. A double bond between C6 and C7 can either increase or decrease activity. The ethyl group provides optimal activity for compounds containing ring A and some heterocyclic rings (e.g., pyrrole ring of atorvastatin). The ethenyl group is optimal for compounds with other ring systems, including the indole and pyrimidine rings seen in fluvastatin and rosuvastatin, respectively.

Ring A subclass:
- The decalin ring is essential for anchoring the compound to the enzyme active site. Replacement with a cyclohexane ring resulted in a 10,000 fold decrease in activity
- Stereochemistry of the ester side chain is not important for activity; however, conversion of this ester to an ether results in a decrease in activity.
- Methyl substitution at the R2 position increases activity (*i.e.*, simvastatin is more potent than lovastatin).
- β-Hydroxyl group substitution at the R1 position enhances hydrophilicity and may provide some cellular specificity.

Ring B subclass:
- Substituents W, X, and Y can be either carbon or nitrogen, n is equal to either zero or one (i.e., five or six member heterocyclic).
- The para-fluorophenyl cannot be coplanar with the central aromatic ring. (Structural restraints to cause coplanarity have resulted in a loss of activity).
- R substitution with aryl groups, hydrocarbon chains, amides, or sulfonamides enhances lipophilicity and inhibitory activity.

Table 30.3. Structure-activity Relationship of HIMG CoA Reductase Inhibitors

All HMGRIs can be chemically classified as 7-substituted-3,5-dihydroxyheptanoic acids, the general structure of which is shown in Table 30.3. Additionally, these compounds can be subclassified based on their lower ring. Compounds structurally related to the natural products mevastatin and lovastatin have structural features common to ring A, whereas those that are completely synthetic have structural features common to ring B (25,27,28,29,30,31,32,33,34,35).

Mechanism of Action

Inhibitors of HMG-CoA reductase lower plasma cholesterol levels by three related mechanisms: inhibition of cholesterol biosynthesis, enhancement of receptor-mediated LDL uptake, and reduction of VLDL precursors (15,21). As previously discussed, HMG-CoA reductase is the rate-limiting step in cholesterol biosynthesis. Inhibition of this enzyme causes an initial decrease in hepatic cholesterol. Compensatory mechanisms result in an enhanced expression of both HMG-CoA reductase and LDL receptors. The net result of all these effects is a slight to modest decrease in cholesterol synthesis, a significant increase in receptor-mediated LDL uptake, and an overall lowering of plasma LDL levels. Evidence to support the theory that enhanced LDL receptor expression is the primary mechanism for lowering LDL levels comes from the fact that most statins do not lower LDL levels in patients who are unable to produce LDL receptors (i.e., homozygous familial hypercholesterolemia). The increased number of LDL receptors also may increase the direct removal of VLDL and IDL. Because these lipoproteins are precursors to LDL, this action may contribute to the overall lowering of plasma LDL cholesterol. Finally, all HMGRIs can produce a modest (8–12%) increase in HDL (15).

Atorvastatin, rosuvastatin, and simvastatin appear to have some effects beyond those seen with the other HMGRIs. These compounds have been shown to decrease plasma LDL levels in patients with homozygous familial hypercholesterolemia, an effect that is proposed to result from their ability to produce a more significant decrease in the hepatic production of LDL cholesterol. Additionally, atorvastatin and rosuvastatin can produce a significant lowering in plasma triglycerides. In the case of atorvastatin, this effect has been attributed to its ability to produce an enhanced removal of triglyceride-rich VLDL (15,36,37).

Physicochemical Properties

In their active forms, all HMGRIs contain a carboxylic acid. This functional group is required for inhibitory activity, has a pK_a in the range of 2.5 to 3.5, and will be primarily ionized at physiologic pH. Lovastatin and simvastatin are neutral, lactone pro-drugs and should be classified as nonelectrolytes. Pravastatin, fluvastatin, and atorvastatin can be classified as acidic drugs. The nitrogen atoms in the indole and pyrrole rings of fluvastatin and atorvastatin, respectively, are aromatic nitrogens that are not ionizable. This is because the lone pair electrons of these atoms are involved in maintaining the aromaticity of their respective rings and are not available to bind protons. Rosuvastatin is technically an amphoteric compound; however, its pyrimidine ring is weakly basic and most likely will not be ionized at physiologic pH.

The calculated log P values for the HMGRIs are shown in Table 30.4. Although some variation exists among the values for lovastatin, pravastatin, and simvastatin, the general trends are the same regardless of what program was used to calculate the values. Atorvastatin, fluvastatin, and the pro-drugs lovastatin and simvastatin have a much higher lipid solubility than either pravastatin and rosuvastatin. Hydrolysis of the lactone ring for the two pro-drugs

produces a 3,5-dihydroxycarboxylate with significantly improves water solubility.

Table 30.4. Pharmacokinetic Parameters of HMG-CoA Reductase Inhibitors

Drug	Calculated Log Pa	Oral Bioavailability (%)	Active Metabolite(s)	Protein Binding (%)	Time to Peak Conc.	Elimination Half-Life (hours)	Major Route(s) of Elimination

					(hours)		
Atorvastatin	4.13	12–14	ortho- and para-hydroxylated	98	1–2	14–19	Biliary/feca (>90%) Renal (<2%)
Fluvastatin	3.62	20–30	None	98	0.5–1.0	1	Biliary/feca (95%) Renal (5%)
Lovastatin	4.07 (4.04)b	5	3,5-Dihydroxy acid	>95	2	3–4	Fecal (83%) Renal (10%)
Pravastatin	1.44 (0.5)b	17	None	43–55	1.0–1.5	2–3	Fecal (70%) Renal (20%)
Rosuvastatin	0.42	20	N-desmethyl	88	3–5	19–20	Fecal (90%) Renal (10%)
Simvastatin	4.42 (4.2)b	5	3,5-Dihydroxy acid	95	4	3	Fecal (60%) Renal (13%)

[a]A commercial program was used for calculated values (45).
[b]Calculated using the CLOG program (38).

The HMG-CoA reductase enzyme is stereoselective. The 3R,5R stereochemistry seen in the active forms of mevastatin and lovastatin (Fig. 30.8) is required for inhibitory activity and is present in all other HMGRIs. Stereochemistry of the substituents on the bicyclic rings of lovastatin, simvastatin, and pravastatin is less crucial to activity, as indicated in the summary of the structure–activity relationships (SARs).

Metabolism

As previously mentioned, lovastatin and simvastatin are inactive pro-drugs that must undergo in vivo hydrolysis to produce their effects (Fig. 30.8). The active forms of these two compounds as well as most HMGRIs undergo extensive first-pass metabolism (15,20,36,37). The CYP3A4 isozyme is responsible for the oxidative metabolism of atorvastatin, lovastatin, and simvastatin. In the case of atorvastatin, the ortho- and para-hydroxylated metabolites are equiactive with the parent compound and contribute significantly to the overall activity of the drug (Table 30.4). Rosuvastatin is metabolized to a limited extent by CYP2C9 to form an N-desmethyl metabolite that can contribute to activity, but is sevenfold less potent. In contrast, the activity of lovastatin and simvastatin resides primarily in the initial hydrolysis product (i.e., further oxidation decreases activity). Fluvastatin is metabolized by the CYP2C9 and CYP3A4 isozymes to active hydroxylated metabolites; however, these metabolites do not circulate systemically and do not contribute to the overall activity. Pravastatin also undergoes oxidative metabolism, but the resulting compounds retain only minimal activity and are not significant. Neither pravastatin nor rosuvastatin is metabolized by CYP3A4; therefore, these drugs are potentially advantageous for patients who must take concurrent medication that alters the activity of this isozyme.

Pharmacokinetic Parameters

The pharmacokinetic parameters and dosing information for HMGRIs are summarized in Tables 30.4 and 30.5 respectively (2,7,15,20,21,36,38,39). With a few exceptions, all of these compounds have similar onsets of action, durations of action, dosing intervals, and plasma protein binding. Despite the ability to attain a peak

plasma concentration in 1 to 4 hours, HMGRIs require approximately 2 weeks to demonstrate an initial lowering of plasma cholesterol. Peak reductions of plasma cholesterol occur after 4 to 6 weeks of therapy for most compounds. Studies with atorvastatin, however, indicate that it may only need 2 weeks to produce its peak reduction. Atorvastatin and rosuvastatin also are unique in that they have much longer durations of action than the other compounds. With the exception of pravastatin, which is one of the more hydrophilic

compounds in this class, most HMGRIs bind extensively to plasma proteins.

Table 30.5. Dosing Information for HMG-CoA Reductase Inhibitors

Generic Name	Brand Name(s)	Dosing Range	Maximum Daily Dose	Dose Reduction with Renal Dysfunction	Tablet Strengths (mg)
Atorvastatin	Lipitor	10–80 mg q.d.	80 mg	No	10, 20, 40,80
Fluvastatin	Lescol Lescol XR	20–80 mg q.d. or b.i.d.	80 mg	Caution in severe impairment	20, 40, 80 (XR)
Lovastatin	Mevacor Altoprev (XR)	20–80 mg q.d. or b.i.d.	80 mg (60 mg if XR) (20 mg with fibrate)	Yes	10, 20, 40, 60 (XR)
Pravastatin	Pravachol	10–40 mg q.d.	80 mg	Yes	10, 20, 40, 80
Resuvastatin	Crestor	5–40 mg q.d.	40 mg (10 mg with fibrate)	Only with severe impairment	5, 10, 20, 40
Simvastatin	Zocor	5–40 mg q.d.	80 mg (10 mg with fibrate)	Only with severe impairment	5, 10, 20, 40, 80

Because of first-pass metabolism, the oral bioavailability of this class of drugs generally is low and does not reflect the actual absorption of the individual drugs. For example, 60 to 80% of a dose of simvastatin is orally absorbed, but only 5% is actually available to produce an effect. The same is true with fluvastatin, pravastatin, and lovastatin, which have oral absorptions of 90%, 34%, and 35%, respectively, but much lower bioavailabilities (Table 30.4). With the exception of lovastatin, the concurrent administration of food does not affect the overall therapeutic effects of HMGRIs. Lovastatin should always be administered with food to maximize oral bioavailability. Failure to do this results in a 33% decrease in plasma concentrations. In general, HMGRIs should be administered in the evening or at bedtime to counteract the peak cholesterol synthesis, which occurs in the early morning hours. Exceptions to this are atorvastatin and rosuvastatin, which because of their long half-lives are equally effective regardless of when they are administered.

The primary route of elimination of these compounds is through the feces. Because of extensive hepatic transformation and the ability to elevate hepatic enzymes, HMGRIs are contraindicated in patients with active hepatic disease or unexplained persistent elevations in serum aminotransferase concentrations. Dosage reductions in patients with renal dysfunction depend on the individual agent. Atorvastatin, which has minimal renal excretion, requires no dosage reduction and may be the best agent for patients with renal disorders. Fluvastatin, rosuvastatin, and simvastatin require dosage reductions only in cases of severe renal impairment and are better choices than lovastatin and pravastatin, which require dosage reductions in mild or moderate impairment.

Therapeutic Applications

All HMGRIs are approved for the treatment of primary hypercholesterolemia and familial combined hyperlipidemia (Fredrickson's type IIa and IIb) (Table 30.2) in patients who have not responded to diet, exercise, and other nonpharmacological methods (Table 30.6) (15,21). They may be used either alone or in combination with bile acid sequestrants, ezetimibe, or niacin. As previously mentioned, they should be administered at least 1 hour before or 4 to 6 hours after bile acid sequestrants when this combination is desired. Fluvastatin, lovastatin, pravastatin, and simvastatin have been specifically indicated to reduce the mortality of CHD and stroke. By reducing plasma LDL levels, these compounds slow the progression of atherosclerosis and reduce the risk of myocardial infarction and other ramifications of vascular occlusion. Atorvastatin, rosuvastatin, and simvastatin have been shown to be effective in homozygous familial hyperlipidemia and are indicated for this use. Additionally, atorvastatin, pravastatin, and simvastatin are indicated for primary dysbetalipoproteinemia (Fredrickson's type III) (Table 30.2). Finally, atorvastatin, pravastatin, rosuvastatin, and simvastatin are indicated for the treatment of hypertriglyceridemia.

Therapeutics Condition	Atorvastatin	Fluvastatin	Lovastatin	Pravastatin	Rosuvastatin	Simvastatin
Primary hypercholesterolemia	√	√	√	√	√	√
Primary dysbetalipoproteinemia	√			√		√
Mixed dyslipidemia	√	√	√	√	√	√
Hypertriglyceridemia	√			√	√	√

Table 30.6. Approved Therapeutics Conditions for HMG CoA Reductase Inhibitors

Inhibitors of HMG-CoA reductase are contraindicated in pregnancy. Fetal development requires cholesterol as a precursor for the synthesis of steroids and cell membranes; thus, inhibition of its synthesis may cause fetal harm. Additionally, HMGRIs are excreted in breast milk and should not be used by nursing mothers.

Adverse Effects

The most prevalent or significant side effects of HMGRIs are listed below (7,15,21). In general, this class of drugs is well tolerated. Gastrointestinal disturbances are the most common complaint; however, these and other adverse reactions tend to be mild and transient. Elevations in hepatic transaminase levels can occur with all HMGRIs. These increases usually occur shortly after the initiation of therapy and resolve after the discontinuation of medication.

In a small percentage of patients, these levels can increase to more than threefold the upper limit of normal. Therefore, liver function tests should be done at the initiation of therapy, at 6 and 12 weeks after the initiation of therapy, and at periodic intervals (e.g., every 6 months) thereafter. Similar testing should be done with dosage increases. Approximately 5 to 10% of patients will experience mild increases in creatine phosphokinase levels; however, less than 1% will develop symptoms of myalgia and myopathy (e.g., fever, muscle aches or cramps, and unusual tiredness or weakness). Tests for creatine phosphokinase levels should be performed in patients reporting muscle complaints. Rhabdomyolysis (i.e., massive muscle necrosis with secondary acute renal failure) has occurred, but this is rare. The risk of this very serious adverse effect increases when an HMGRI is taken with certain other medications, such as cyclosporine, erythromycin, niacin, or fibrates (Table 30.7). Specific dosage reductions have been suggested for the combination use of fibrates with lovastatin, rosuvastatin, or simvastatin. Despite reports that some HMGRIs present more of a risk of rhabdomyolysis than others, a U.S. FDA advisory statement in 2005 suggests that the risk is similar for all members of this drug class (15).

Combination Products That Include an HMGRI

HMGRI and antithrombotic

Pravastatin/aspirin (Pravigard PAC)

HMGRI and calcium channel blocker

Atrovastatin/amlodipine (Caduet)

HMGRI and additional antihypercholesterolemic agent

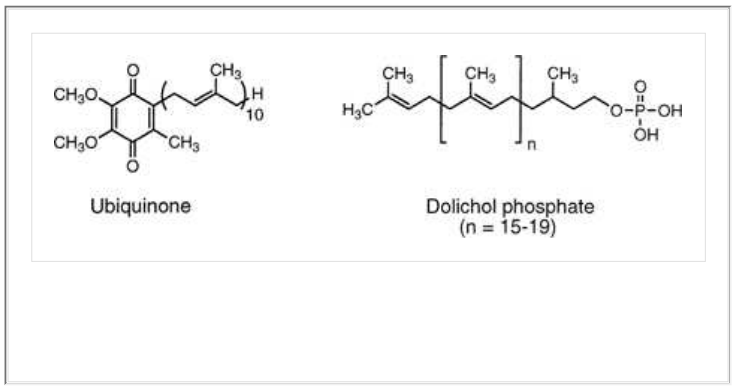
Lovastatin/niacin (Advicor)

Simvastatin/ezetimibe (Vytorin)

Potential Nonlipid-Lowering Uses of HMGRIs

Cellular metabolites derived from mevalonic acid are required for cell proliferation. Cholesterol is an essential component of cell membranes, farnesyl pyrophosphate is required to covalently bind to intracellular proteins and modify their function, ubiquinone is required for mitochondrial electron transport, and dolichol phosphates are required for glycoprotein synthesis.

Farnesyl pyrophosphate (Fig. 30.2) is an intermediate in the biosynthesis of cholesterol, ubiquinone, and dolichol phosphates. Based on their site of action, HMGRIs will decrease the availability of all four of these compounds and, thus, decrease cell proliferation. Potential applications of this antiproliferative effect include the prevention of restenosis following angioplasty, prevention of glomerular injury in renal disease, treatment of malignant disease, and prevention of organ transplantation rejection (40).



Adverse Effects of HMGRIs

Constipation, flatulence, dyspepsia, abdominal pain, diarrhea, nausea, vomiting, headache, rhinitis, sinusitis, elevated hepatic enzymes, arthralgia, myalgia, myopathy, muscle cramps, rhabdomyolysis, and chest pain

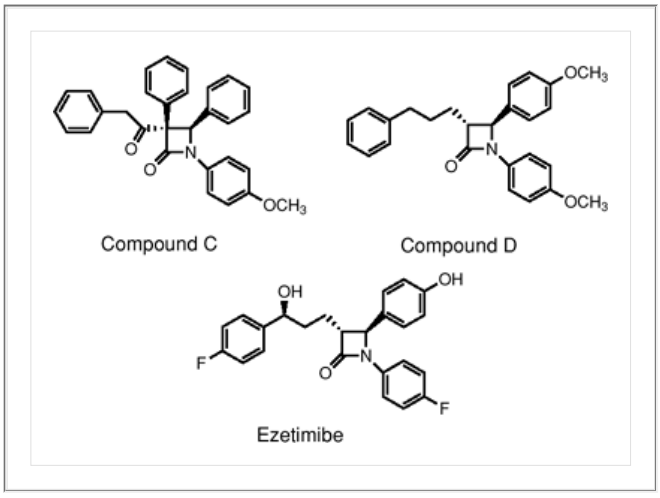
Drug Interactions

Drug interactions for HMGRIs are listed in Table 30.7

Ezetimibe, a Cholesterol Absorption Inhibitor

Historical Overview

The discovery of ezetimibe and its mechanism of action began with a desire to develop novel ACAT inhibitors, a potential target for hypercholesterolemia described earlier in this chapter (41). Compound C was one of the initial azetidinones tested for the ability to inhibit ACAT and to lower plasma cholesterol. Interestingly, this compound's ability to decrease plasma cholesterol exceeded its ability to inhibit ACAT. Further SAR studies resulted in the development of compound D and confirmed that the cholesterol-lowering activity of this class of compounds was independent of its ability to inhibit ACAT. Using compound D as a lead, as well as in vivo data suggesting that metabolic transformations produced the active compound ultimately responsible for the cholesterol lowering effect, structural modifications were made that, eventually, led to the development of ezetimibe. The most important changes involved the introduction of hydroxyl groups to help localize the compound in the intestine and the introduction of *p*-fluoro groups to block undesirable metabolism.



Mechanism of Action

Ezetimibe lowers plasma cholesterol levels by inhibiting the absorption of cholesterol at the brush border of the small intestine (15). Specifically, it has been proposed to bind to a specific transport protein located in the wall of the small intestine, resulting in a reduction of cholesterol transport and absorption (42). Ezetimibe appears to be selective in its actions in that it does not interfere with the absorption of triglycerides, lipid-soluble vitamins or other nutrients. The decreased absorption of cholesterol

eventually leads to enhanced receptor-mediated LDL uptake similar to that seen with bile acid sequestrants and HMGRIs. When used as monotherapy, the decreased absorption of cholesterol causes a compensatory increase in cholesterol biosynthesis. This is similar to that described for bile acid sequestrants and is insufficient to override the overall LDL lowering effects of ezetimibe.

Table 30.7. Drug Interactions for HMG-CoA Reductase Inhibitors (HMGRIs)

Drug	HMGRIs	Result of Interaction
Amiodarone	Lovastatin, Simvastatin	Increased risk of myopathy
Antacids	Atorvastatin, Rosuvastatin	Decreased levels of atorvastatin rosuvastatin; no change in plasma LDL reduction; administer rosuvastatin at least 2 hours after antacid
Azole antifungal agents	All	Increased risk of severe myopathy or rhabdomyolysis; increased plasma levels of atorvastatin, lovastatin, and simvastatin because of inhibition of CYP3A4; additive decreases in concentrations or activity of endogenous steroid hormones
Bile acid sequestrants	All	Decreased bioavailability of HMGRI if administration is not adequately spaced
Cimetidine	Fluvastatin	Increase in plasma fluvastatin levels
Cyclosporine	All	Increased risk of severe myopathy or rhabdomyolysis
Danazol	Lavastatin	Increased risk of severe myopathy or rhabdomyolysis
Digoxin	Atorvastatin, Fluvastatin, Simvastatin	Slight elevation in plasma concentrations of digoxin
Diltiazem	Atorvastatin, Lovastatin, Simvastatin	Increased risk of severe myopathy
Erythromcyin Clarithromycin	All	Increased risk of severe myopathy or rhabdomyolysis; increased plasma levels of atorvastatin, lovastatin, and simvastatin because of inhibition of CYP3A4
Ethanol	Fluvastatin, Lovastatin	Increased risk of hepatotoxicity
Fibrates	All	Increased risk of severe myopathy or rhabdomyolysis
Grapefruit juice (>1 quart/day)	Atorvastatin, Lovastatin, Simvastatin	Elevated plasma levels of the HMGRIs and increased risk of myopathy
HIV protease inhibitors	Atorvastatin, Lovastatin, Simvastatin	Elevated plasma levels of the HMGRIs and increased risk of myopathy
Isradipine	Lovastatin	Increased clearance of lovastatin and its metabolites

Niacin	All	Increased risk of severe myopathy or rhabdomyolysis
Omeprazole	Fluvastatin	Increase in plasma fluvastatin levels
Oral contraceptives	Atorvastatin, Rosuvastatin	Increased plasma concentrations of norethindrone and ethinyl estradiol
Phenytoin	Fluvastatin	Increased plasma concentrations of both compounds because of CYP2C9 interaction
Ranitidine	Fluvastatin	Increase in plasma fluvastatin levels
Rifampin	Fluvastatin	Increased plasma clearance of fluvastatin
Ritonavir, Squinavir	Pravastatin	Decreased plasma levels of pravastatin
Spironolactone	All	Additive decreases in concentrations or activity of endogenous steroid hormones
St. John's wort	Lovastatin, Simvastatin	Decreased HMGRI plasma levels
Warfarin	Fluvastatin, Lovastatin, Rosuvastatin, Simvastatin	Anticoagulant effect of warfarin may be increased

Physicochemical Properties

Ezetimbie is a crystalline powder that is practically insoluble in water but is freely soluble in ethanol and other organic solvents. Its calculated log P value is 3.50 (38). The phenol present in ezetimibe allows this compound to be classified as an acidic compound; however, the phenol has a pK_a of 9.72 and is predominantly un-ionized at physiologic pH.

Metabolism

Following oral administration, ezetimibe is rapidly and extensively metabolized in the intestinal wall and the liver to its active metabolite, a corresponding phenol glucuronide. This glucuronide is reexcreted in the bile back to its active site. A small amount (<5%) of ezetimibe undergoes oxidation to covert the benzylic hydroxyl group to a ketone; however, ezetimibe does not appear to exert any significant effect on the activity of CYP450 enzymes (15,20,42).

Pharmacokinetic Parameters

Ezetimibe is administered orally; however, its absolute bioavailability cannot be determined because of its aqueous insolubility and the lack of an injectable formulation. Based on area under the curve values, the oral absorption ranges from 35 to 60%. Mean peak concentrations of the active glucuronidated metabolite are reached within 1 to 2 hours. Both ezetimibe and its glucuronide conjugate are extensively bound (>90%) to plasma proteins. The relative plasma concentrations of ezetimibe and its glucuronide conjugate range from 10 to 20% and from 80 to 90%, respectively. Both compounds have a long half-life of approximately 22 hours. The coadministration of food with ezetimibe has no effect on the extent of absorption.

Table 30.8. Drug Interactions for Ezetimibe

Drug	Result of Interaction
Antacid	Aluminum and magnesium-containing antacids decrease the C_{max} of ezetimibe

Bile Acid Sequestrants	Decreased bioavailability of ezetimibe if administration is not adequately spaced
Cyclosporine	Increased ezetimibe concentration.
Fibrates	Increased ezetimibe concentration and possible increased risk of cholelithiasis. Concomitant use is not recommended.

The normal dose of ezetimibe is 10 mg once daily. Dosage reduction for patients with renal impairment, intermittent hemodialysis, or mild hepatic impairment is not necessary. Because of insufficient data, the use of ezetimibe is not recommended in patients with moderate to severe hepatic impairment (15,20,21).

Therapeutic Applications

Ezetimibe is indicated as monotherapy or in combination with an HMGRI for the reduction of elevated total cholesterol, LDL cholesterol, and apoB in patients with primary (heterozygous familial and nonfamilial) hypercholesterolemia. When used as monotherapy, ezetimibe reduces LDL cholesterol by approximately 18%. When used in combination therapy with an HMGRI, LDL levels are reduced by 25 to 65% depending on the dose of the HMGRI inhibitor. Ezetimibe also is indicated for homozygous familial hypercholesterolemia in combination with either atorvastatin or simvastatin and for homozygous familial sitosterolemia. All indications are for patients who have not responded to diet, exercise, and other nonpharmacological methods.

Adverse Effects of Ezetimibe

Abdominal pain, diarrhea, arthralgia, back pain, cough, pharyngitis, sinusitis, fatigue, and viral infection

Adverse Effects

Ezetimibe generally is well tolerated. The most common adverse effects are listed above. Whenever ezetimibe is used in combination with an HMGRI, the incidence of myopathy or rhabdomyolysis does not increase above that seen with HMGRI monotherapy (15,21).

Drug interactions for ezetimibe are listed in Table 30.8.

Fibrates

Historical Overview and Development

The use of this class of drugs to treat hyperlipoproteinemias can be traced back to 1962 and, thus, predates the use of bile acid sequestrants and HMGRIs. A random screening test on a series of aryloxyisobutyric acids demonstrated that these compounds could lower both plasma cholesterol and total lipid levels (43). The compound that produced the best balance between activity and toxicity was ethyl *p*-chlorophenoxyisobutyrate (Fig. 30.10). Later renamed clofibrate, this compound was subsequently shown to be a pro-drug for *p*-chlorophenoxyisobutyric acid (clofibric acid). It was approved for therapeutic use in 1967, and for a time, it was a very popular and widely prescribed drug. Results from a 1978 World Health Organization trial changed the acceptance of clofibrate and dramatically decreased its use. These trials indicated that despite a 9% lowering of cholesterol, patients taking clofibrate showed no reduction of

cardiovascular events and actually had an increase in overall mortality (7). Although clofibrate is no longer available in the United States, it has served as the prototype for the design of safer and more effective fibrates. Structural modifications, focused primarily on ring substitutions and the addition of spacer groups, have produced a number of active compounds (Fig. 30.10). Gemfibrozil and fenofibrate became available for therapy in 1981 and 1998, respectively. Fenofibrate was actually approved in 1993; however, its marketing was voluntarily delayed until a more bioavailable, micronized formulation of the drug was available (44). Both of these compounds are safer and more effective than clofibrate in lowering plasma triglyceride levels and increasing plasma HDL levels. Additional compounds, such as ciprofibrate and bezafibrate, are not currently available in the United States but have been used in other countries.

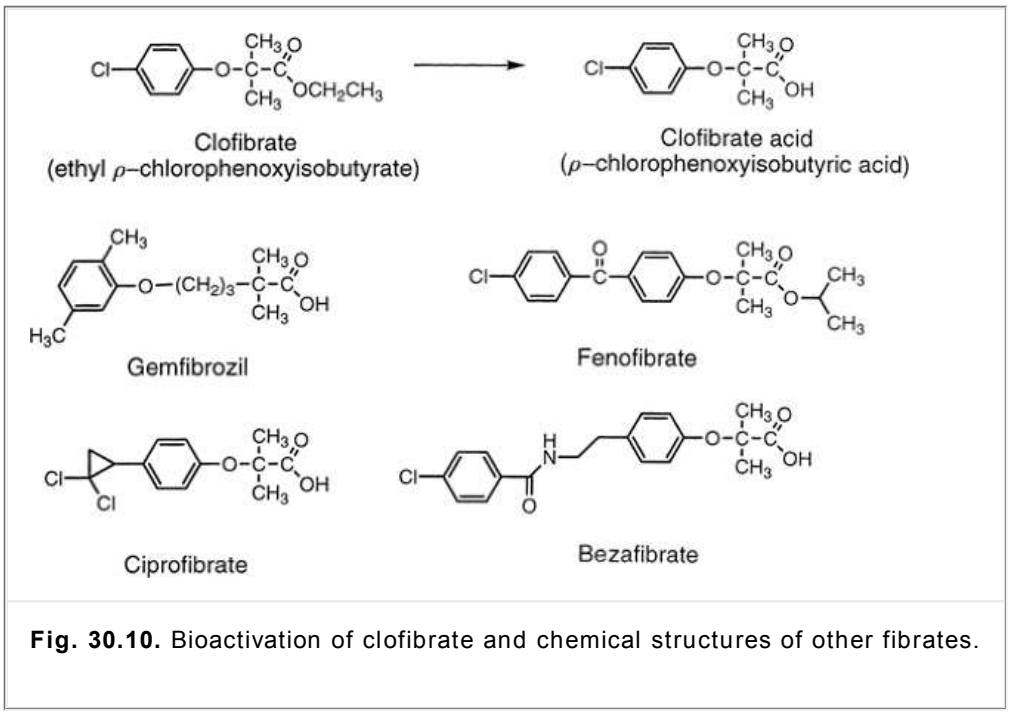


Fig. 30.10. Bioactivation of clofibrate and chemical structures of other fibrates.

Mechanism of Action

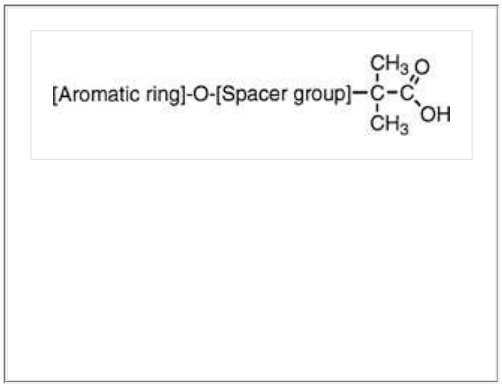
Overall, fibrates decrease plasma triglyceride levels much more dramatically than they decrease plasma cholesterol levels. They significantly decrease VLDL levels, cause a moderate increase in HDL levels, and have variable effects on LDL concentrations. As an example of this latter point, gemfibrozil will raise LDL levels in patients with hypertriglyceridemia but lower LDL levels in patients with normal triglyceride levels. The exact mechanisms for these actions have not been fully elucidated; however, studies have shown that this class of compounds can produce a variety of beneficial effects on lipoprotein metabolism. Many of these effects have been proposed to be mediated through the activation of peroxisome proliferator-activated receptors (PPARs) and an alteration of gene expression. Specifically, fibrates bind to PPARα (7,15,27,44).

Decreases in plasma VLDL primarily result from the ability of these compounds to stimulate the activity of lipoprotein lipase, the enzyme responsible for removing triglycerides from plasma VLDL (Fig. 30.5). Additionally, fibrates can lower VLDL levels through PPARα-mediated stimulation of fatty acid oxidation, inhibition of triglyceride synthesis, and reduced expression of apoC-III. This latter effect enhances the action of lipoprotein lipase, because apoC-III normally serves as an inhibitor of this enzyme. Favorable effects on HDL levels appear to be related to increased transcription of apoA-I and apoA-II as well as a decreased activity of cholesteryl ester transfer protein.

All fibrates accelerate the turnover and removal of cholesterol from the liver. This increases the biliary secretion of cholesterol, enhances its fecal excretion, and may cause cholelithiasis (i.e., gallstone formation).

Structure–Activity Relationships

Fibrates can be chemically classified as analogues of phenoxyisobutyric acid. Literature references to the SARs for this class of drugs are sparse; however, all compounds are analogues of the following general structure.



The isobutyric acid group is essential for activity. Fenofibrate, which contains an ester, is a pro-drug and requires in vivo hydrolysis. Substitution at the para position of the aromatic ring with a chloro group or a chlorine containing isopropyl ring produces compounds with significantly longer half-lives. Although most compounds contain a phenoxyisobutyric acid, the addition of an n-propyl spacer, as seen in gemfibrozil, results in an active drug.

Physicochemical Properties

Similar to HMGRIs, the active forms of all fibrates contain a carboxylic acid. The pK_a of this functional group on clofibric acid is reported to be 3.5 (45) and, thus, will be primarily ionized at physiologic pH. Although not reported, the pK_a and ionization values of gemfibrozil and fenofibric acid can reasonably be assumed to be similar. Both clofibrate and fenofibrate are neutral, ester pro-drugs and should be classified as nonelectrolytes. Gemfibrozil can be classified as an acidic drug. The calculated log P values for fenofibrate and gemfibrozil are shown in Table 30.9 (45). Both compounds are highly lipid soluble despite the fact that gemfibrozil contains a water-soluble carboxylic acid. This can be partially explained by examining the π values for the substituents on fenofibrate and gemfibrozil (46). The 2,5-dimethyl ring in gemfibrozil is predicted to be much more hydrophobic than the 4-chloro ring of fenofibrate. Additionally, the propyl bridge seen in gemfibrozil, but not in fenofibrate, significantly adds to its hydrophobicity. The isopropyl ester as well as the additional aromatic ring account for the enhanced lipid solubility of fenofibrate. All currently available fibrates are achiral molecules and not subject to stereochemical concerns.

Table 30.9. Pharmacokinetic Parameters of Fibrates

Drug	Calculated Log P	Oral Bioavailability (%)	Active Metabolite	Protein Binding (%)	Time to Peak Conc (hrs)	Elimination Half-Life (hrs)	Major Route(s) of Elimination
Fenofibrate	5.24	60-90	Fenofibric acid	99	4-8	20-22	Renal (60-90%) Fecal (5-25%)
Gemfibrozil	3.9	> 90	none	99	1-2	1.5	Renal (70%) Fecal (6%)

Table 30.10. Dosage Information for Fibrates

Generic Name	Brand Name	Dosing Range	Maximum Daily Dose	Dose Reduction with Renal Dysfunction	Tablet/Capsule Strengths (mg)
Fenofibrate	TriCor	48-145 mg q.d. 54-160 mg q.d. 67-200 mg q.d.	145mg 160 mg 200 mg	Only with severe impairment	48, 145 54, 160 (generic) 67, 134, 200 (generic)
Gemfibrozil	Lopid	600 mg b.i.d.	1200 mg	Yes	600

Metabolism

The pro-drug fenofibrate undergoes rapid hydrolysis to produce fenofibric acid. This active metabolite can then be further metabolized by oxidative or conjugative pathways. Gemfibrozil is slightly different in that it does not require initial bioactivation; however, similar to fenofibric acid, it can be oxidized or conjugated. Oxidation of the aromatic methyl groups produces inactive hydroxymethyl and carboxylic acid analogues. As a drug class, fibrates and their oxidized analogues are primarily excreted as glucuronide conjugates in the urine. Oxidization requires the CYP3A4 isozyme; however, because of the ability of these compounds to be conjugated and eliminated either with or without oxidation, drug interactions with other compounds affecting the CYP3A4 system are less important here than with other drug classes.

Pharmacokinetic Parameters

The pharmacokinetic parameters and dosing information for the fibrates are summarized in Tables 30.9 and 30.10, respectively (7,15,20,21,45). The pro-drug, fenofibrate, requires a longer time to reach peak concentrations compared with gemfibrozil. Because of differences in aromatic substitution, fenofibrate also has a much longer half-life than gemfibrozil. As previously mentioned, the 2,5-dimethyl substitution in gemfibrozil is much more susceptible to oxidative metabolism than the para-chloro group present in fenofibrate. Similar to HMGRIs, changes in lipid levels are not seen immediately, and up to 2 months may be required to reach maximal clinical effects and to determine the overall clinical efficacy.

Fibrates have excellent bioavailability and are extensively bound to plasma proteins. Because food can significantly enhance their oral absorption, these compounds should be taken either with or just before meals. Fenofibrate was available in Europe and elsewhere as standard tablet and capsule formulations for many years before its approval and marketing in the United States, where it was introduced only after the development of a micronized formulation that allowed better oral absorption, a lower daily dose, and once-daily administration. A 67-mg dose of micronized fenofibrate is bioequivalent to a 100-mg dose of nonmicronized drug. Since that time, two additional tablet formulations have been developed. Abbott Laboratories currently markets TriCor as 48- and 145-mg tablets. The 48-mg formulation is equivalent to previous 54- and 67-mg formulations, and the 145-mg tablet is equivalent to previous 160- and 200-mg formulations. As noted in Table 30.10, fenofibrate is currently available in all of these strengths.

Renal elimination is the primary route through which these compounds are excreted from the body. Patients with mild renal dysfunction often can be managed with minor dosage adjustments, whereas those with severe impairment or renal failure may have to discontinue its use.

Therapeutic Applications

Fibrates are approved to treat hypertriglyceridemia and familial combined hyperlipidemia (Fredrickson's type IIa, IIb, IV, and V) (Table 30.2) in patients who are at risk of pancreatitis and have not responded to dietary adjustments or in patients who are at risk of CHD and have not responded to weight loss, dietary adjustments, and other pharmacological treatment. They can be used either alone or in combination with niacin, bile acid sequestrants, or HMGRIs. If used with bile acid sequestrants, fibrates must be taken either 1 hour before or 4 to 6 hours after the sequestrant. As discussed previously and reemphasized below, caution should be used if fibrates are combined with HMGRIs. Fibrates are not effective in the treatment of hypertriglyceridemia associated solely to elevated chylomicron levels (Fredrickson's type I).

Adverse Effects

The most prevalent or significant side effects caused by the fibrates are listed below (7,15,21). Despite the potential to cause serious side effects, fibrates usually are well tolerated. Gastrointestinal complaints are the most common but do not usually cause discontinuation of therapy. In general, gemfibrozil and fenofibrate appear to be less problematic than the original compound, clofibrate. In fact, many of the concerns regarding fibrate therapy are based on the effects of clofibrate and the results of a 1978 clinical trial in which patients taking clofibrate had a significantly higher morbidity and mortality from causes other than CHD. These causes included malignancy, gallbladder disease, pancreatitis, and postcholecystectomy

complications. Studies with gemfibrozil and fenofibrate have not shown similar increases; however, because all fibrates have similar pharmacological actions, cautions and contraindications generally are applied to the entire drug class. As an example, even though gemfibrozil and fenofibrate have not demonstrated a significant increase in gallbladder disease, as seen with clofibrate, all three of these compounds are contraindicated in patients with preexisting gallbladder disease or cholelithiasis. Similar to HMGRIs, fibrates can cause myopathy, myositis, and rhabdomyolysis. Although rare, the risk of these serious effects increases when these two classes of agents are used together. Fibrates also cause increases in plasma aspartate transaminase (AST), alanine transaminase (ALT), and creatine phosphokinase levels.

Unlabeled Uses

Polymetabolic syndrome X (fenofibrate)

Adverse Effects

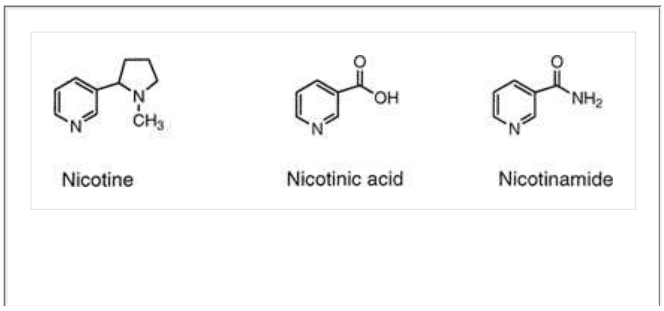
Abdominal pain, dyspepsia, nausea, vomiting, diarrhea, constipation, cholestasis, jaundice, cholelithiasis, pancreatitis, headache, dizziness, drowsiness, blurred vision, mental depression, impotence, decreased libido, myopathy, myositis, rhabdomyolysis, anemia, leukopenia, eosinophilia, pruritus, and rash

Drug interactions for fibrates are listed in Table 30.11.

Nicotinic Acid

Historical Overview

The history of nicotinic acid (niacin) began in 1867, when it was first synthesized by oxidation of nicotine. The name niacin was derived later from the words *ni*cotinic *a*cid and vitam*in* in an effort to avoid confusing nicotinic acid and nicotinamide with nicotine. Although the terms “niacin” and “nicotinic acid” are today used interchangeably, only the more chemically descriptive term, “nicotinic acid,” will be used in the following discussions.



Discovery of the biochemical and pharmacological actions of nicotinic acid began in the early 1900s, when brewer's yeast was demonstrated to prevent pellagra in humans. The subsequent isolation of nicotinic acid from brewer's yeast established its role as an essential dietary requirement. In the 1930s, its amide metabolite, nicotinamide, was isolated from liver extracts and found to be a required structural feature of nicotinamide adenine dinucleotide phosphate ($NADP^+$), a cofactor involved in electron transport and intermediary metabolism (47). In 1955, Altschul et al. (48) observed that high doses of nicotinic acid lowered cholesterol levels in humans, an activity unrelated to its properties as a vitamin. Subsequent studies have shown that nicotinic acid also lowers serum triglyceride levels and is effective against a variety of hyperlipoproteinemias. None of these antihyperlipidemic effects are seen with nicotinamide.

Mechanism of Action

Nicotinic acid exerts a variety of effects on lipoprotein metabolism (7,16,49). One of its most important actions is the inhibition of lipolysis in adipose tissue. This initial inhibition, like those of previously discussed antihyperlipidemic agents, produces a sequence of events that ultimately result in the lowering of plasma triglycerides and cholesterol. Impaired lipolysis decreases the mobilization of free fatty acids, thus reducing their plasma levels and their delivery to the liver. In turn, this decreases hepatic triglyceride synthesis and results in a decreased production of VLDL. Enhanced clearance of VLDL through stimulation of lipoprotein lipase also has been proposed to contribute to the reduction of plasma VLDL levels. Because LDL is derived from VLDL (Fig. 30.5), the decreased production of VLDL ultimately leads to a decrease in LDL levels. The sequential nature of this process has been clinically demonstrated. The reduction in triglyceride levels occurs within several hours after

initiation of nicotinic acid therapy, whereas the reduction in cholesterol does not occur until after several days of therapy. Nicotinic acid also increases HDL levels because of a reduction in the clearance of apoA-I, an essential component of HDL. Unlike bile acid sequestrants and HMGRIs, nicotinic acid does not have any effects on cholesterol catabolism or biosynthesis.

Table 30.11. Drug Interactions for Fibrates

Drug	Fibrate	Result of Interaction
Antidiabetic agents	All	Increased hypoglycemic effect through increased sensitivity and decreased glucagon secretion
Bexarotene	Gemfibrozil	Increased bexarotene plasma concentrations
Bile acid sequestrants	All	Decreased bioavailability of fibrate if administration is not adequately spaced
Cyclosporine	Fenofibrate	Increased potential for nephrotoxicity
Ezetimibe	All	Increased ezetimibe concentration and possible increased risk of cholelithiasis; concomitant use is not recommended
HMG-CoA reductase inhibitors	All	Increased risk of severe myopathy or rhabdomyolysis
Oral anticoagulants	All	Increased hypoprothrombinemic effect
Repaglinide	Gemfibrozil	Increased repaglinide plasma concentrations
Ursodiol	All	Increased hepatic cholesterol secretion which may increase the possibility of gallstone formation and counteract the effectiveness of ursodiol

Physicochemical Properties

Nicotinic acid (niacin) is a stable, nonhygroscopic, white, crystalline powder. Its carboxylic acid has a pK_a of 4.76 and, thus, is predominantly ionized at physiologic pH. The pyridine nitrogen is a very weak base (pK_a = 2.0) and, therefore, primarily exists in the un-ionized form. Nicotinic acid is freely soluble in alkaline solutions and has a measured log P of -0.20 at pH 6.0 (45).

Metabolism

Nicotinic acid is a B-complex vitamin that is converted to nicotinamide, NAD^+, and $NADP^+$. The latter two compounds are coenzymes and are required for oxidation/reduction reactions in a variety of biochemical pathways. Additionally, nicotinic acid is metabolized to a number of inactive compounds, including nicotinuric acid and N-methylated derivatives. Normal biochemical regulation and feedback prevent large doses of nicotinic acid from producing excess quantities of NAD^+ and $NADP^+$. Thus, small doses of nicotinic acid, such as those used for dietary supplementation, will be primarily excreted as metabolites, whereas large doses, such as those used for the treatment of hyperlipoproteinemia, will be primarily excreted unchanged by the kidney (15).

Pharmacokinetic Parameters

Nicotinic acid is readily absorbed. Peripheral vasodilation is seen within 20 minutes, and peak plasma concentrations occur within 45 minutes. The half-life of the compound is approximately one hour, thus necessitating frequent dosing or an extended-release formulation. Extended release tablets produce peripheral vasodilation within 1 hour, reach peak plasma concentrations within 4 to 5 hours, and have a duration of 8 to 10 hours.

Dosing of nicotinic acid should be titrated to minimize adverse effects. An initial dose of 50 to 100 mg t.i.d. often is used with immediate-release tablets. The dose then is gradually increased by 50 to 100 mg every 3 to 14 days, up to a maximum of 6 g/day, as tolerated. Therapeutic monitoring to assess efficacy and prevent toxicity is essential until a stable and effective dose is reached. Similar dosing escalations are available for extended-release products, with doses normally starting at 500 mg once daily at bedtime. (7,15,21).

Therapeutic Applications

Nicotinic acid is approved for the treatment of hyper-cholesterolemia, hypertriglyceridemia, and familial combined hyperlipidemia (Fredrickson's type IIa, IIb, IV, and V) (Table 30.2) in patients who have not responded to diet, exercise, and other nonpharmacological methods. It also is approved for nutritional supplementation, the prevention of pellagra, and as adjunct therapy for peripheral vascular disease and circulatory disorders. It is contraindicated in patients with hepatic disease and peptic ulcer disease. Additionally, because of its ability to elevate glucose and uric acid levels, especially when taken in large doses, nicotinic acid should be used with caution in patients who have or are predisposed to diabetes mellitus and gout (15,20,21).

Table 30.12. Drug Interactions for Nicotinic Acid

Drug	Result of Interaction
Adrenergic blocking agents	Enhanced vasodilation and postural hypotension
Bile acid sequestrants	Decreased bioavailability of nicotinic acid if administration is not adequately spaced
Ethanol	Potential enhanced hepatotoxicity and excessive peripheral or cutaneous vasodilation
HMG-CoA reductase inhibitors	Increased risk of myopathy and rhabdomyolysis
Vasodilating agents (calcium channel blockers, epoprostenol, nitrates)	Enhanced cutaneous vasodilation

Adverse Effects

The most common (and, often, dose-limiting) side effects of nicotinic acid treatment are cutaneous vasodilation (flushing and pruritus) and gastrointestinal intolerance, which may occur in 20 to 50% of treated patients. Flushing and pruritus are prostaglandin-mediated effects and may be prevented by taking aspirin or indomethacin before nicotinic acid. Gastrointestinal side effects, such as flatulence, nausea, vomiting, and diarrhea, can be minimized if nicotinic acid is taken either with or immediately after meals. As previously mentioned, all of these effects can be minimized by slowly titrating the dose of nicotinic acid. Hepatic dysfunction is one of the more serious complications of high dose nicotinic acid. Plasma AST, ALT, lactate dehydrogenase, and alkaline phosphatase levels often are elevated but usually return to normal when therapy is either adjusted or discontinued (7,15,21).

Drug interactions for nicotinic acid are listed in Table 30.12.

Adverse Effects of Niacin

Flushing, pruritus, headache, nausea, vomiting, diarrhea, flatulence, hepatic dysfunction, jaundice, hyperglycemia, hyperuricemia, blurred vision, and tachycardia

Case Study

Victoria F. Roche

S. William Zito

MK is a 38-year-old female with a history of congenital cardiomyopathy that resulted in aortic value replacement surgery 3 years ago. MK opted for a mechanical valve and is now on chronic coumadin anticoagulant therapy and doing well. She is a fibromyalgia patient and manages her pain with oxycodone, 5 mg as needed (not to exceed every 4 hours). She manages the constipation that has accompanied her regular use of opioids with Senna (two tablets at bedtime and two in the morning). Feeling somewhat helpless about her health situation, she has begun tai-chi and yoga and to meditate regularly, and she has joined her husband in his vegetarian lifestyle (he's the sous-chef at the world-famous “Meatless in Seattle” restaurant). While difficult at first, she now religiously restricts her intake of fats and cholesterol-rich foods. She has been taking St. John's wort (purchased at the local Health & Nutrition outlet) for a mild, self-diagnosed depression that she hopes is temporary. After trying unsuccessfully for several years to conceive a child, MK and her husband are actively exploring adoption.

At her annual medical checkup, it was noted that MK's total serum cholesterol and LDL levels were mildly elevated, although her triglycerides and HDL levels were hovering around normal. Given her cardiovascular history, the physician wishes to implement therapy to bring her blood lipids down to National Cholesterol Education Program (NCEP)-recommended levels.

1. Identify the therapeutic problem(s) in which the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in this case.
4. Evaluate the SAR findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient

Chapter 31

Antithrombotics, Thrombolytics, Coagulants, and Plasma Extenders

Matthias C. Lu

Thomas L. Lemke

Introduction

Venous thromboembolism (VTE) is a complicating condition responsible for high morbidity and mortality in North America and Europe. This disease commonly is linked to advanced age but has both hereditary and acquired risk factors, such as surgery, any form of trauma, and childbirth, associated with it. It encompasses the conditions of deep vein thrombosis (DVT) and pulmonary embolism. In excess of 60,000 deaths annually are attributed to pulmonary embolism. Preventative therapy consists of the use of two different classes of antithrombotic agents, namely anticoagulants and antiplatelet drugs (1,2).

Heparin was discovered serendipitously in 1916 by a young coal miner turned medical student, Jay McLean, while working in the research laboratory of Professor W.H. Howell (3). Its beneficial effects were not realized until the early 1970s, when Kakkar et al. (4) established in a prospective, double-blind trial that low doses of heparin can prevent DVT after major surgery. In 1933, Dr. K.P. Link discovered that hydroxycoumarins are contained in sweet clover after finding cattle hemorrhaging to death (3). This discovery lead to the development of orally active anticoagulants for prophylaxis in VTE and other thrombotic disorders. Optimal therapy with warfarin and other coumarin derivatives are not easy, however, because of their narrow therapeutic indexes. The need to carefully assess the benefit and risks for anticoagulation with frequent drug monitoring and dose adjustment also is troublesome (5). Thus, further development of novel antithrombotic agents with greater specificity on the coagulation cascade, with more predictable pharmacodynamic and pharmacokinetic profiles, and with fewer or no laboratory monitoring requirements is still needed for optimal treatment of thrombotic disorders (6,7).

Thrombolytics, on the other hand, are drugs needed to dissolve the newly formed thrombi in conditions such as DVT, acute pulmonary embolism, or myocardial infarction. Because of their lack of specificity, however, these agents actually may cause internal bleeding and, thus, are contraindicated with the use of many other therapeutic agents.

A variety of pathological and toxicological conditions can result in excessive bleeding from inadequate coagulation. Depending on the etiology and severity of the hemorrhagic episode, select coagulants that induce blood coagulation are therapeutically used to prevent excessive bleeding in these conditions.

Plasma extenders and blood substitutes are used to maintain blood volume and blood circulation for resuscitation of severely anemic patients in emergency conditions. Although notable progress has been made in the development of oxygen-carrying blood substitutes that will someday bring effective replacements for whole blood into clinical practice, most still concentrate only on reproducing the function of hemoglobin, the molecule that carries oxygen through the body, and do not attempt to replicate the blood's other functions.

Disease States Requiring Antithrombotic Therapy

A number of serious medical conditions are thrombotic in nature. In fact, in Western society, thrombotic conditions are the major cause of morbidity and mortality, and

it is speculated that these disorders will be the leading cause of death worldwide within 20 years (1,8). As would be expected from the gravity of thrombotic disorders, many of the conditions involve the major vasculature, heart, brain and lungs.

Clinical Significance

Thrombotic disorders are among the most common causes of morbidity and mortality in the United States. More than 2 million people die each year from arterial or venous thrombosis or the consequences thereof. Antithrombotic and thrombolytic agents are the most commonly used pharmacological therapies to prevent and treat the whole spectrum of thrombotic disorders. The management of patients with thrombotic disorders involves multidisciplinary specialties, such as medicine, pharmacy, and nursing. Approaching clinical thrombosis in a multidisciplinary manner has the ultimate goal of rendering the best possible care to our patients. Regardless of the discipline involved, mastering the basic chemical and pharmacological principles of the major drug classes used in the prevention and treatment of thrombotic disorders is the first and most critical step to implementing a successful treatment approach.

Understanding the intricacies and the determinants of the coagulation cascade, along with the primary and secondary hemostatic and fibrinolytic pathways, allows us to clinically select and apply the best pharmacological agents targeted at these pathways. Furthermore, mastering the chemical and pharmacological properties of the various antithrombotic therapies is a necessary tool for clinicians involved in caring for patients with thrombosis. Often, selection of the safest and most effective therapeutic agent in certain specific patient circumstances will depend on our ability to differentiate among the characteristics of various options available. For example, in a patient with an allergic reaction to heparin (because of a suspected pork allergy), a good alternate anticoagulant for treatment of an acute thrombotic event is a synthetic agent, such as fondaparinux. In a patient with a deficiency of antithrombin (formerly known as antithrombin III), none of the heparin products or indirect factor Xa inhibitor products would work, because all of these have a mechanism of action dependent on Antithrombin. Alternate agents, such as direct inhibitors of thrombin, would need to be considered. In patients taking chronic warfarin therapy, dosing adjustments are made in increments of 5 to 20% of the patient's total weekly dose, because warfarin does not follow linear kinetics. Are there situations when using a combination of various antithrombotic agents would be appropriate? In certain indications, such as acute coronary syndromes, a combination of aspirin and clopidogrel is used, because these two agents have a complementary mechanism of action. The examples given above show just a few scenarios of how some of the basic concepts presented in this chapter are applied in clinical practice and how they eventually will aid clinicians to apply this knowledge toward providing specific and tailored treatment plans for their patients.

Edith A. Nutescu, Pharm.D.

Clinical Associate Professor

Director, Antithrombosis Center

College of Pharmacy

University of Illinois at Chicago

In the heart, a thrombotic condition may be involved in the disease state of acute myocardial infarction, valvular heart disease, unstable angina, and atrial fibrillation as well as surgical procedures, such as percutaneous transluminal coronary angioplasty and prosthetic heart valve replacement. Thrombotic conditions involving the vasculature include VTE, primary and secondary prevention of arterial thromboembolism, and peripheral vascular disease. The most significant such condition involving the lungs is pulmonary embolism and, in the brain, cerebrovascular accidents. Anticoagulation therapy is indicated for all of these conditions.

Venous Thromboembolism and Pulmonary Embolism

Venous thromboembolism occurs when red bloods cells, fibrin, and to a lesser extent, platelets and leukocytes coagulate to form a thrombus within an intact cardiovascular system (9). A patient undergoing orthopaedic surgery incurs the greatest risk for VTE (10). Pulmonary embolism occurs when a segment of a thrombus within the deep venous system detaches itself from the blood vessel, travels to the lungs, and lodges within the pulmonary arteries. Both of these conditions, if not

properly detected and treated, can have serious consequences, such as sudden death or recurrent VTE and postthrombotic syndrome characterized by persistent pain, swelling, and skin discoloration or necrosis and ulceration of the affected limb (6,7).

Atrial Fibrillation

Atrial fibrillation is the most common cardiac arrhythmia, being found in more than 2 million Americans. It is characterized as a storm of electrical energy that travels in spinning wavelets throughout the atria, causing the upper chambers to quiver or fibrillate. It also is one of the leading risk factors for ischemic stroke for those individuals older than 50 years (11,12,13). Atrial fibrillation is more prevalent in men than in women, and the median age of patients with atrial fibrillation is approximately 72 years. Anticoagulation with warfarin and lifestyle modification are the most effective treatment modalities for patients with atrial fibrillation.

Pathophysiology of Thrombogenesis

Arterial thrombosis usually is initiated by the exposure of the thrombogenic material as a result of spontaneous or mechanical rupture of an atherosclerotic plaque (6,14). Arterial thrombi usually form in medium-sized vessels as a result of surface lesions on endothelial cells roughened by atherosclerosis. In most cases, circulating platelets adhere to the areas of abnormal vascular endothelium. More platelets then aggregate with those stuck to the vascular wall, forming a clot known as an occlusive thrombus (14). The formation of the occlusive thrombus at the site of the lesion is the major cause of complications of stroke and myocardial infarction. Venous thrombosis results from either an excessive activation of the coagulation cascade (hypercoagulability) or from some disease process or venous pooling (stasis) of the blood. Venous thrombus is initiated in the same fashion as the arterial thrombus formation, except that the bulk of the clot is formed of long fibrin tails that enmesh red blood cells. Venous thrombosis also can occur from vascular trauma caused by damage to the vessel wall, especially after major orthopedic surgery (9). Hypercoagulability, venous stasis, and vascular injury are known as Virchow's triad. As a general rule, arterial thrombi cause serious conditions through localized occlusive ischemia, whereas venous thrombi fragment give rise to pleural embolic complications.

Biochemical Mechanism of Blood Coagulation: The Coagulation Cascade

The formation of a blood clot is the result of an intricate and elegant cascade of biochemical events (Fig. 31.1).

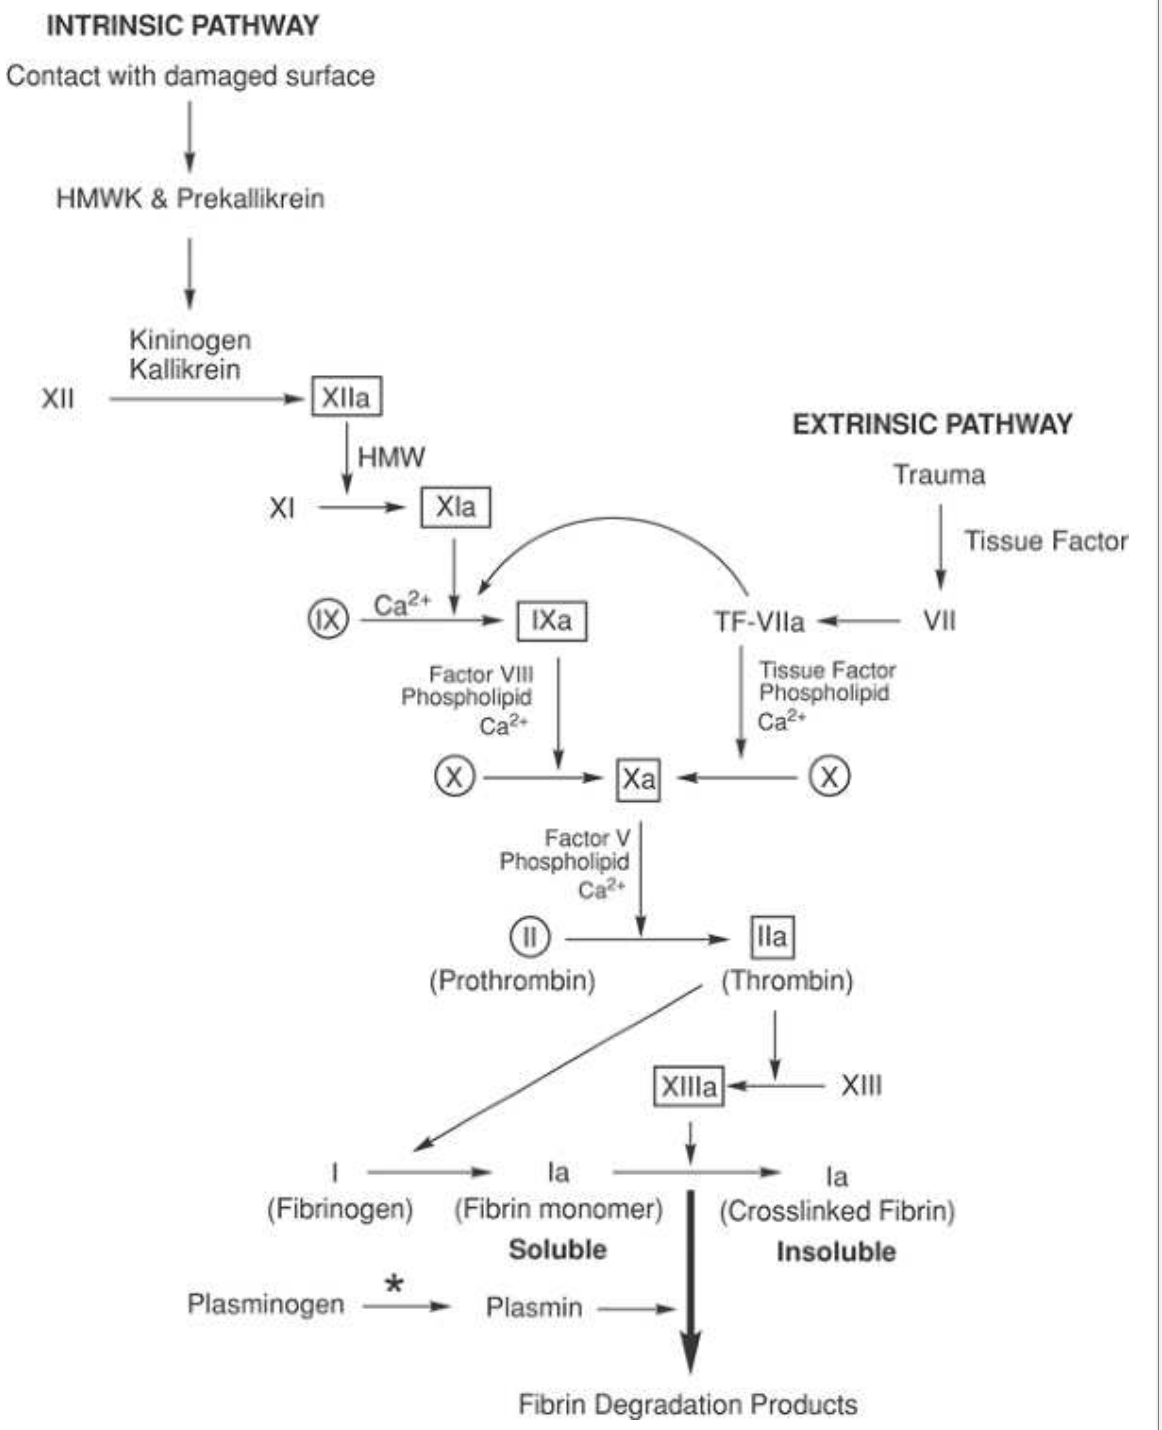

Fig. 31.1. The coagulation cascade. Circled factors are those inhibited by warfarin-like drugs; boxed factors are those affected by heparin. The star indicates the site of action of thrombolytic drugs, such as streptokinase and urokinase.

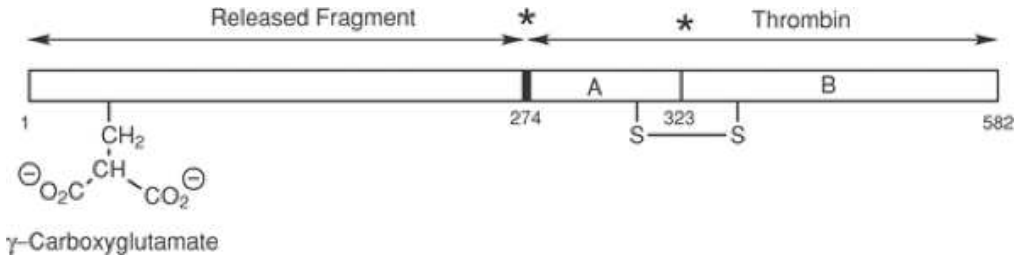

Fig. 31.2. Structure of prothrombin. Thrombin is liberated through the cleavage of the Arg 274–Thr 275 and Arg 323–Ile 324 peptide bonds (indicated by the stars). The γ-carboxyglutamate residues are in the released N-terminal portion of prothrombin and are not part of thrombin. The A and B chains of thrombin are joined by a disulfide bond.

The coagulation in arteries or veins is triggered by tissue factor (TF), a small-molecular-weight glycoprotein that initiates the extrinsic clotting cascade. The TF glycoprotein is expressed on the surface of macrophages, and TF is a major initiating factor of arterial thrombogenesis. Tissue factor binds and activates factor VII to form TF/VIIa complex, which in turn activates factor IX and factor X from either the intrinsic or extrinsic pathways shown in Figure 31.1.

Initiation of the intrinsic pathway involves the sequential activation of factors XII, XI, and IX. (The activated form of a coagulation factor is indicated by a lowercase "a.") In the presence of calcium, factor IXa binds to an activated factor VIII on the surface of activated platelets to form an intrinsic Xase complex, which initiates the activation of factor X to Xa. In addition, initiation of the extrinsic pathway involves activation of factor VII by TF to form TF/VIIa, which, like factor IXa, also catalyzes the conversion of factor X to Xa. The underlying purpose of the intrinsic pathway is maintenance of homeostasis, whereas the extrinsic pathway is activated by trauma. The intrinsic and extrinsic pathways come together with the conversion of factor X to its activated form, factor Xa. The coagulation cascade is unique in that the product of a given reaction (i.e., activated form of a specific factor) catalyzes the activation of the next factor in the cascade. The final steps in the coagulation cascade involve the conversion of prothrombin (factor II) to thrombin (factor IIa) by prothrombinase complex, consisting of factor Xa and activated factor V (Fig. 31.2). In turn, thrombin catalyzes the conversion of fibrinogen to soluble fibrin, which then becomes insoluble fibrin through the action of factor XIIIa. In its activated state, factor XIIIa actually is a transamidase enzyme. This enzyme catalyzes the formation of isopeptide bonds between lysine and glutamine side chains of distinct fibrin molecules, resulting in cross-linked (insoluble) fibrin aggregates (Fig. 31.3) (15).

Strategies for Regulating Coagulation

Coagulation can be regulated at several levels (6). These include TF pathway inhibitor (TFPI), antithrombin, and the protein C pathways. Because the design of many new anticoagulant drugs are aimed at enhancing endogenous anticoagulant or fibrinolytic mechanisms, a brief review of these pathways is warranted here.

Tissue factor pathway inhibitor is now recognized as a major physiological inhibitor of TF-initiated coagulation (16). Its main role is to modulate factor VIIa/TF catalytic activity by a two-step process. First, TFPI binds and inactivates factor Xa by forming a TFPI/factor Xa complex. Then, the inactivated factor Xa/TFPI complex binds factor VIIa within the TF/VIIa complex to modulate its catalytic activity. Additionally, TFPI potentiates the effect of heparins (i.e., TFPI is released from the vascular endothelium after injection of either unfractionated heparin or low-molecular-weight heparins [LMWHs]), which may then provide high concentrations of TFPI at sites of tissue damage

and ongoing thrombosis (17). The propagation of coagulation occurs when TFPI concentrations are low (6).

Antithrombin is a potent inhibitor of thrombin, factors IXa and Xa. It also has inhibitory actions on other activated clotting factors, including the TF/VIIa complex. In the absence of heparin, however, the action of antithrombin is slow. The action of antithrombin is enhanced 1,000-fold in the presence of heparin. It should be pointed out that even though heparin is not normally found in the blood, the vascular endothelium is rich in heparin sulfate, which contains the antithrombin-binding pentasaccharide sequence of the heparin. Drugs such as fondaparinux and idraparinux block the propagation of coagulation by inactivating factor Xa and, thereby, inhibiting the thrombin formation (6). Direct

thrombin inhibitors, such as hirudin and argatroban, work by inhibiting both the clot-bound and free thrombin and, thus, preventing fibrin formation, the final step in the coagulation cascade (6).

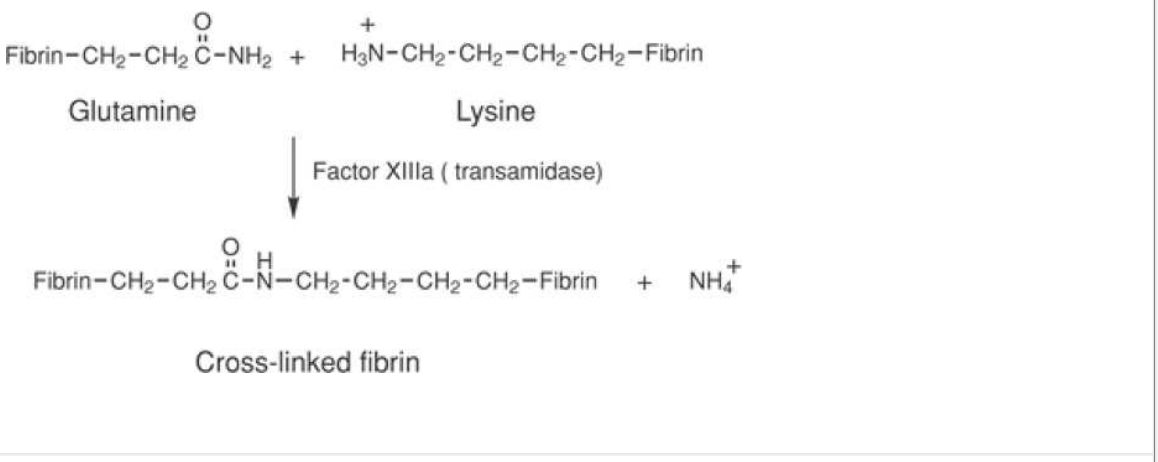

Fig. 31.3. Cross-linking of soluble fibrin monomers (factor Ia) through the activity of factor XIIIa, a transamidase enzyme.

In the protein C pathway, thrombin also is inhibited by binding to thrombomodulin, a thrombin receptor found in the endothelium. On binding to thrombomodulin, thrombin changes conformation, converting it from a procoagulant into a potent activator of protein C, a vitamin K–dependent protein, which degrades and inactivates factors Va and VIIa, thereby attenuating thrombogenesis (18).

General Approaches to Anticoagulant Therapy

Overview

Because current clinically available antithrombotic drugs target only a few specific areas within the coagulation cascade, the selection of an appropriate anticoagulant for a given patient should be based on the patient's medical and drug history, age and location of the clot, underlying diagnosis of the disease state, and ultimate goal of the therapeutic intervention. If dissolving of an existing clot is needed, activation of plasminogen with the thrombolytic agents, which degrades insoluble fibrin, is the typical approach. If the therapeutic goal is prevention of thrombus formation or extension, however, inhibition of factor activation higher in the cascade with heparin and other oral anticoagulants is the most appropriate.

An ideal anticoagulant should have reproducible pharmacodynamic and pharmacokinetic properties such that no coagulation monitoring is necessary. It also should have a wide therapeutic window, a rapid onset and offset of action, and minimal adverse effects, particularly with minimal interactions with food and other drugs.

Laboratory Assessment and Monitoring

Anticoagulant drug dosing represents a fine balance between reducing the morbidity and mortality

associated with the thrombotic condition and minimizing the risk of serious hemorrhage from excessive therapeutic anticoagulation. Because of the potentially life-threatening consequences of either inadequate or excessive anticoagulation, patients receiving antithrombotic medications, such as warfarin and unfractionated heparin, often are closely monitored with specific clinical laboratory assays. A baseline assessment of the patient's coagulation features is performed before the initiation of anticoagulant therapy. This allows detection of congenital coagulation factor deficiencies, thrombocytopenia, hepatorenal insufficiency, and vascular abnormalities, which could prove to be catastrophic if anticoagulant therapy was instituted empirically.

For monitoring oral anticoagulant therapy (i.e., vitamin K antagonists), the prothrombin time (PT) is measured (19,20). This test is used to assess the activity of the vitamin K–dependent clotting factors (II, VII, IX and X). The PT is particularly sensitive to factor VII, which is not of great clinical significance in itself but serves as a rough estimate for the ability of the liver to synthesize proteins or the extent of vitamin K depletion from warfarin therapy. The PT assay measures the time that it takes for a clot to form in citrated plasma after the addition of tissue thromboplastin and calcium. In normal (i.e., warfarin-free) plasma, this clot formation takes 10 to 13 seconds (19,20). Because of variances in commercially available thromboplastins, most clinical laboratories now report PT results in terms of international normalized ratios (INRs). Patients on warfarin therapy are optimally maintained with an INR of 2.0 to 3.0. In cases of patients who have had mechanical prosthetic heart valves placed, an INR of 2.5 to 3.5 often is recommended. At the initiation of warfarin therapy, daily PT's are performed. As the drug dosage is adjusted appropriately based on these results, the length of time between PT assessments can be extended to weekly. Finally, after warfarin therapy has been optimized and the patient's PT results have stabilized within an acceptable range, monthly or bimonthly PT checks are reasonable.

Heparin directly deactivates clotting factors II and X. Therapy with this drug is monitored based on the activated partial thromboplastin time (aPTT) assay (19,20). This assay monitors factors II and X as well as several others. Deficiencies of clotting factors that affect the aPTT result can be of little clinical significance (e.g., prekallikrein and factor XII), of potential clinical significance (e.g., factor XI), or of great clinical significance (e.g., factors VIII and IX and the hemophilic factors). In the aPTT assay, a surface activator, such as elegiac acid, kaolin, or silica, is used to activate the intrinsic pathway. When this activator comes in contact with citrated plasma in the presence of calcium and phospholipid, clot formation begins. As with the PT, the time taken for this clot to form is measured. In normal (nonheparinized) plasma, the average aPTT result is 25 to 45 seconds. A therapeutic aPTT in a patient receiving heparin typically is 70 to 140 seconds. In vivo, the platelet membrane rather than the phospholipid is the source of several clotting factors and the site of many of the coagulation reactions in the intrinsic pathway. The phospholipid used in the aPTT assay does not completely substitute for the in vivo actions of the platelets. Although this phospholipid does potentiate the intrinsic pathway, it does so without activating factor VII. This “partial activation” of the intrinsic pathway is the genesis of the name of the assay (aPTT).

Several other laboratory assays are used to assess function at various points within the clotting cascade. Quantitative levels of fibrinogen and fibrin degradation products are used to assess the extent of the effects of conditions, such as acute inflammation, disseminated intravascular coagulation (DIC), and severe liver disease. The specific clotting factors in which a given patient may be deficient also can be determined using various mixing studies (19,20). These assessments are far more specialized and performed much less frequently than the PT and aPTT.

Oral Anticoagulants

There are two different chemical classes of orally active anticoagulants, namely coumarin derivatives and 1,3-indandiones.

It has been known since 1921 that cattle eating spoiled sweet clover hay often would die from uncontrollable bleeding after suffering a very minor injury. This discovery and other subsequent findings eventually led to the isolation of bishydroxycoumarin (i.e., dicoumarol) in 1934 by Link and Campbell and its use in humans in 1954 as the first orally active anticoagulant drug (21).

Coumarin Derivatives

Warfarin and other vitamin K antagonists have been the mainstay of oral anticoagulant therapy for

more than 50 years. Although their effectiveness in the prophylaxis of thrombotic disorders has been established through many well-designed clinical trials, their usages in clinical practice are challenging because of their narrow therapeutic index, potential for drug–drug/food interactions, and patient variability that requires close assessment and drug monitoring (20).

Mechanism of Action

Vitamin K antagonists, such as warfarin, produce their effect on blood coagulation by interfering with the cyclic interconversion of vitamin K and vitamin K 2,3-epoxide (Fig. 31.4) (22). Vitamin K is an essential cofactor necessary for the posttranslational carboxylation of the glutamic acid residues on the N-terminal portions of the specific clotting factors (II, VII, IX, and X) and anticoagulant proteins, such as protein C (22). This γ-glutamyl carboxylation results in a new amino acid, γ-carboxyglutamate, which through chelation of calcium ions causes the proteins to undergo a conformational change. This change in tertiary structure allows the four vitamin K–dependent clotting factors to become activated and bind to the negatively charged phospholipid membranes during clotting cascade activation.

The specific enzyme that carboxylates vitamin K–dependent coagulation factors requires a reduced form of vitamin K (vitamin K hydroquinone [KH_2]), molecular oxygen, and carbon dioxide as cofactors. In the process of this reaction, KH_2 is oxidized to vitamin K 2,3-epoxide. The return of the epoxide to the active KH_2 form is the result of a two-step reduction. First, the epoxide is reduced to vitamin K quinone by vitamin K 2,3-epoxide reductase in the presence of NADH. This quinone intermediate is then further reduced back to KH_2 by vitamin K quinone reductase. The warfarin-like anticoagulants (i.e., vitamin K antagonists) exert their anticoagulant activity through the inhibition of vitamin K 2,3-epoxide reductase and, possibly, through inhibition of vitamin K quinone reductase, which in turn inhibits activation of the four affected coagulation factors. Unlike heparin, and as a direct result of their mechanism of action, the vitamin K antagonists only inhibit blood coagulation in vivo.

Structure–Activity Relationship of Coumarin Derivatives

All of the coumarin derivatives (Fig. 31.5) are water-insoluble lactones. Structure–activity relationship requirements typically are based on substitution of the lactone ring, specifically in positions 3 and 4. Although coumarin is a neutral compound, the clinically available derivatives are weakly acidic because of the presence of a 4-hydroxy substitution. The acidity of the proton on the 4-hydroxy group allows formation of water-soluble sodium salts for commercial preparations. Furthermore, warfarin (and, possibly,

acenocoumarol) also can exist in solution as two diastereomeric cyclic hemiketal conformers in addition to its open-chain conformer (Fig. 31.6). Because it has been suggested that vitamin K forms an active hemiketal in vivo, the cyclic hemiacetals of the vitamin K antagonists, such as warfarin, also may be the active conformers in vivo (23).

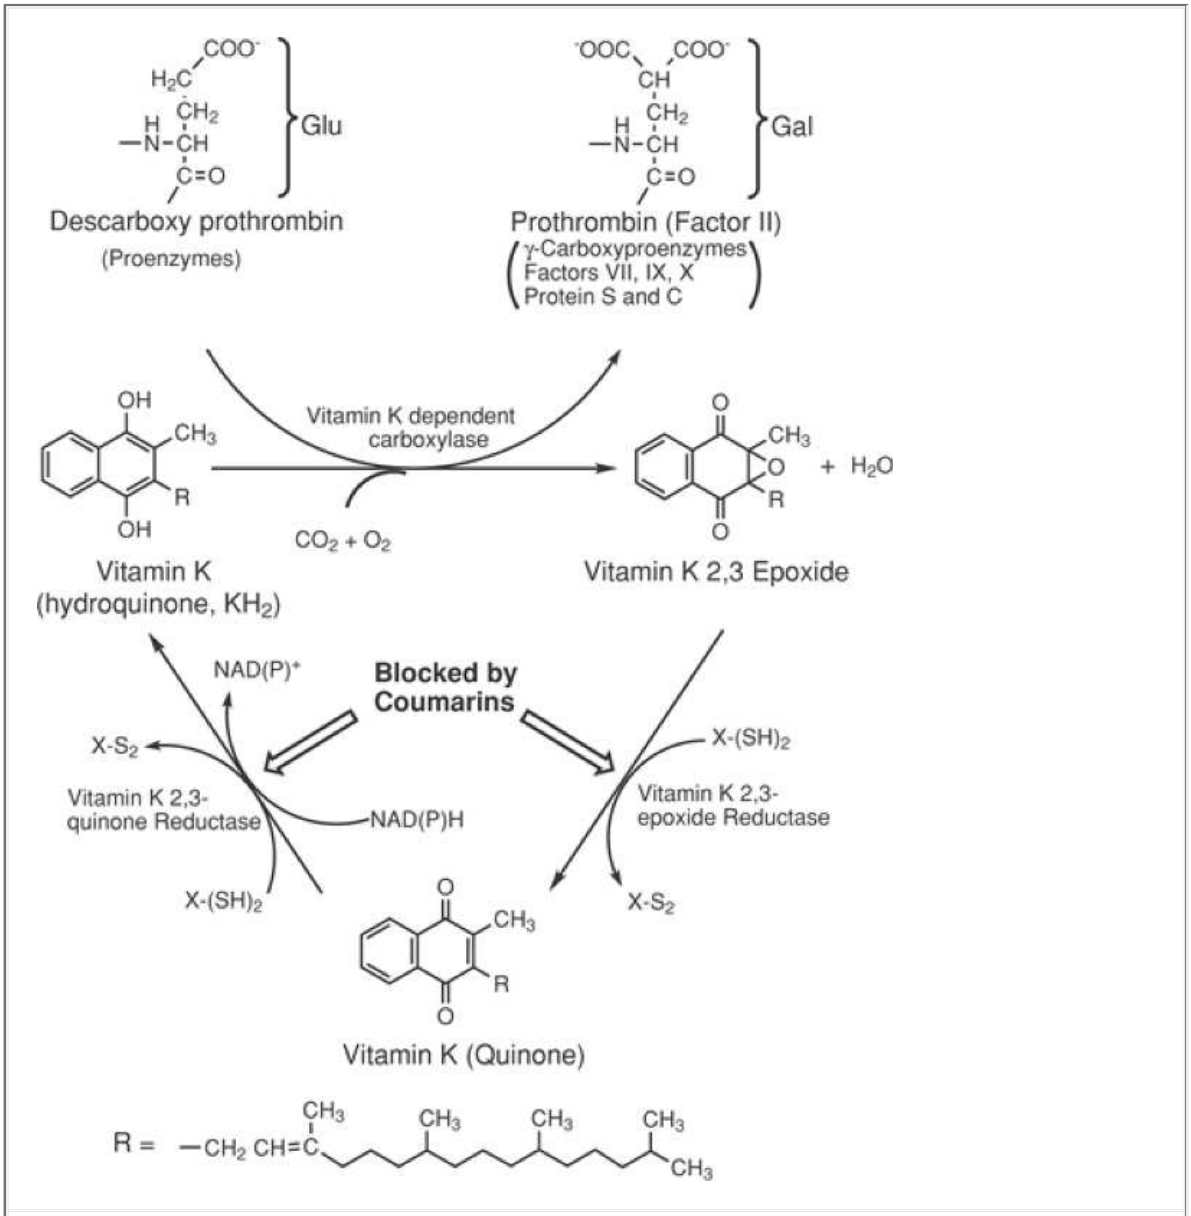

Fig. 31.4. Redox cycling of vitamin K in the activation of blood clotting, which involves conversion of glutamate residues to γ-carboxyglutamates.

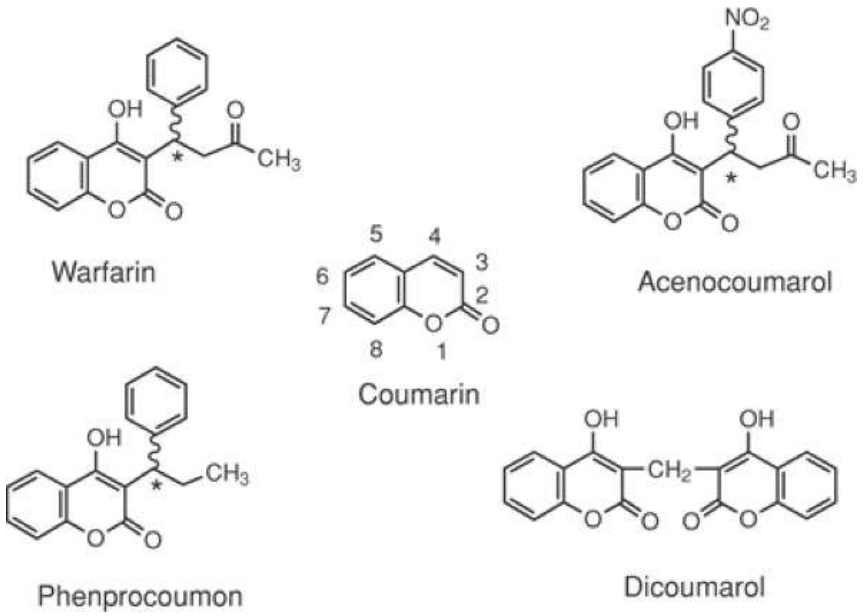

Fig. 31.5. Chemical structures of coumarin and coumarin-derived drugs.

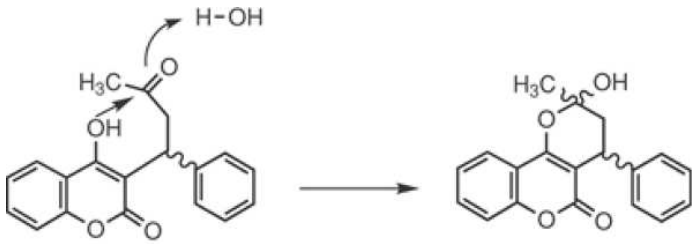

Fig. 31.6. Formation of a cyclic hemiketal of warfarin.

Pharmacokinetics

The substituents at position 3 greatly affect the pharmacokinetic and toxicological properties of warfarin and its derivatives (Table 31.1) (24). Dicoumarol is not completely absorbed in the gastrointestinal tract, often is associated with gastrointestinal discomfort, and is very rarely used clinically. Today, the only coumarin used in the United States is warfarin, but phenprocoumon and acenocomumarol are used in Europe.

Warfarin

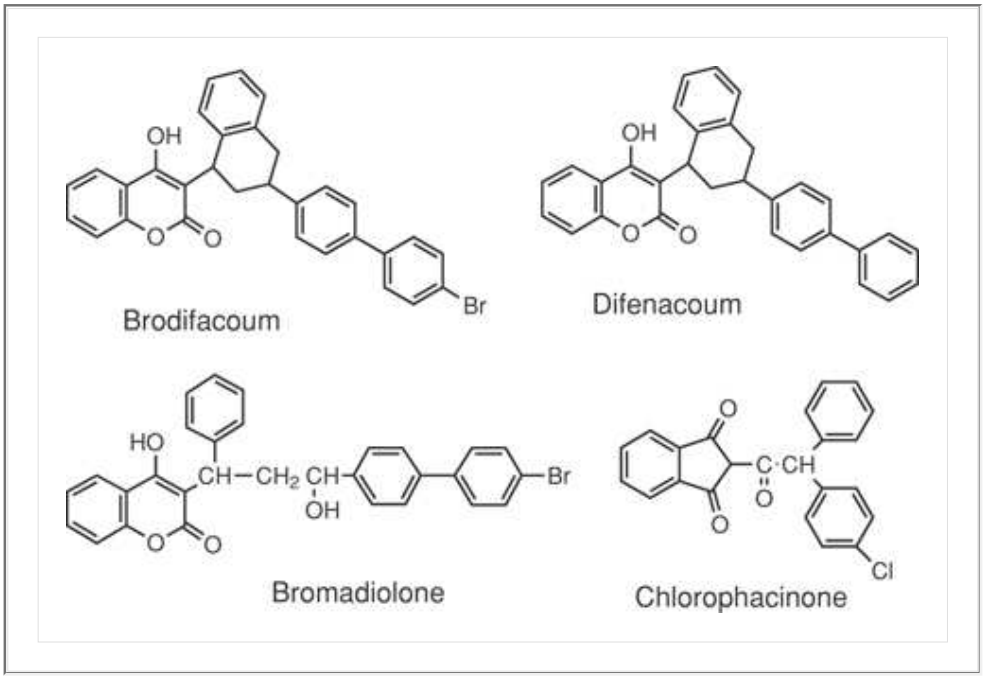
Warfarin sodium is rapidly and completely absorbed (~100% bioavailability) following oral, intramuscular, intravenous, or rectal administration. Peak plasma concentrations occur at approximately 3 hours. Its anticoagulant effect is not immediately present, however, following initiation of therapy. Instead, a delay in onset of anticoagulation occurs while the clotting factors with normal activity are cleared and those that have not been carboxylated because of the actions of warfarin reach physiologically significant levels. On average, this delay is approximately 5 hours for

factor V turnover and 2 to 3 days for factor II (thrombin). Consequently, because of the rapid decline in protein C levels, the anticoagulated state frequently is preceded by a period of hypercoagulability (25).

Warfarin also is highly protein bound (95–99%) and, as a result, has numerous interactions with other drugs. The free drug (i.e., that not bound to plasma proteins) is the active constituent. Therefore, any other substance that displaces bound drug from protein binding sites increases the levels of free drug and, as a result, can cause warfarin toxicity, which usually is manifested by hemorrhage. The volume of distribution(V_d) is quite small (0.1–0.2 L/kg), and the plasma half-life is quite long, both of which presumably result from the high degree of plasma protein binding (20,26).

"Superwarfarin" Rodenticides

Brodifacoum is a member of the second-generation anticoagulant rodenticides known as "superwarfarins" (27). This compound and others like it (e.g., bromadiolone and difenacoum) were developed to combat rodent resistance to warfarin (27).



Human ingestion of brodifacoum typically is accidental in children but usually is intentional in adults (i.e., to commit suicide) (28). In cases when large quantities are ingested, severe and potentially fatal hemorrhaging can result. Brodifacoum is readily available over-the-counter in hardware stores and supermarkets, and it is marketed under numerous trade names in North America, Europe, Australia, and New Zealand. Brodifacoum, like warfarin, is thought to exhibit its anticoagulant effects through inhibition of vitamin K epoxide reductase. Despite the similarity in mechanism of action between brodifacoum and warfarin, brodifacoum is at least fivefold more potent as an anticoagulant rodenticide (27,29). The half-life of brodifacoum in humans is approximately 24.2 days, which is roughly ninefold longer than that of warfarin (27,30,31). Brodifacoum also has a volume of distribution roughly six times that of warfarin (30). For these reasons, vitamin K therapy may be needed for weeks to months after ingestion of a superwarfarin rodenticide (32).

Table 31.1. Pharmacokinetic Properties of the Coumarins and Anisindione

Drug	Trade Name	Onset (hours)	Duration (days)	Half-life (days)	Time to Peak Plasma Concentration (hours)

Warfarin	Coumadin	1.5–3.0	2–5	0.62–2.5	4
Dicoumerol		1–5	2–10	1–4	1–9
Phenprocoumon	Marcumara		7–14	5–6	
Acenocoumarol	Sinthroma		2	0.3–1.0	1–3
Anisindione	Miradon	~6	1–3	3–5	2–3

[a]Not available in the United States but available in Europe.

P.827

The clinically used preparation of warfarin is racemic, but the enantiomers are not equipotent. In fact, (*S*)-warfarin is at least fourfold more potent as an anticoagulant than the (*R*)-warfarin. The difference in the activities and metabolism of the enantiomers is the key to understanding several stereoselective drug interactions. Similar stereochemical properties are noted for the other asymmetric coumarins (Fig. 31.5). In the case of acenocoumarol, the (*R*)-isomer is responsible for the majority of its activity.

Warfarin and other coumarin derivatives undergo extensive hepatic oxidative metabolism catalyzed by CYP2C9 isozyme to give 6- and 7-hydroxywarfarins as the major inactive metabolites. Warfarin also undergoes, to a lesser extent, reductive metabolism of the ketone on the C-3 side chain to a pair of pharmacologically active, diastereomeric 2-hydroxywarfarins (Fig. 31.7). Almost no unchanged drug is excreted in the urine. As expected, those individuals with compromised hepatic function are at greater risk for warfarin toxicity secondary to diminished clearance. Many of the drug–drug interactions are associated with enhanced or inhibited metabolism of warfarin via CYP2C9 induction or inhibition. Many additional drugs and conditions have profound effects on warfarin therapy. A partial list of these factors is shown in Table 31.2 (24).

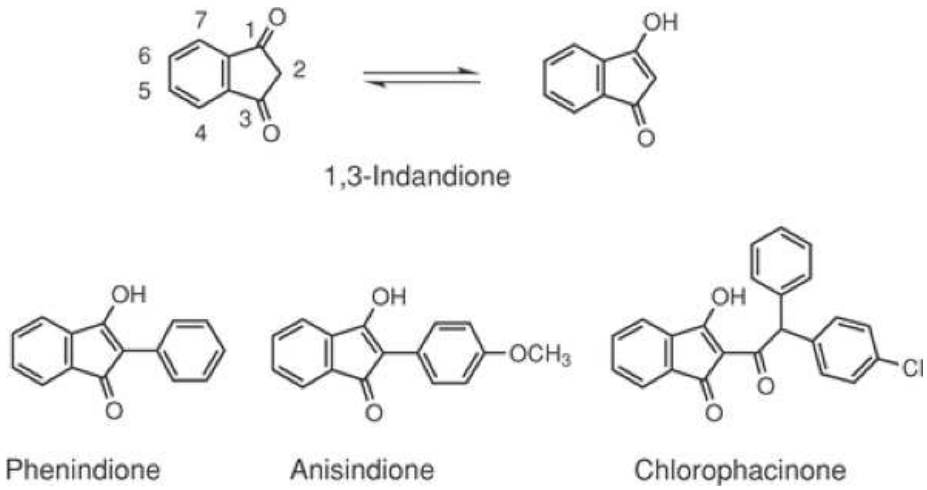

Fig. 31.8. Chemical structures of 1,3-indandione and 1,3-indandione–derived drugs.

Indandiones

Indane-1,3-dione derivatives (Fig. 31.8), such as phenindione and anisindione, are orally active anticoagulants having a similar mechanism of action to the coumarins but are rarely used clinically today because of their significant renal and hepatic toxicities. Furthermore, because of the structural similarity, patients who are allergic to warfarin will experience cross-sensitivity with anisindione and other indandione anticoagulants (33). Although anisindione reportedly has fewer significant side effects, most clinicians still prefer warfarin for oral anticoagulation. The pharmacokinetic properties also are similar to those of the coumarins (Table 31.1). Most of the newer indandione drugs, such as chlorophacinone, are marketed as potent rodenticides.

Heparin-Based Anticoagulants

Chemistry

The heparin anticoagulants are represented by a variety of structures, including the natural heparan sulfate that lines the vascular endothelium, unfractionated heparin, LWMHs, and most recently, the synthetic pentasaccharide fondaparinux. Heparin is composed of a heterogeneous mixture of straight-chain, sulfated, and negatively charged mucopolysaccharides of a molecular weight range of 5 to 30 kDa, isolated from bovine lung or porcine intestinal mucosa. Heparin, also known as heparinic acid, is an acidic molecule similar to chondroitin and hyaluronic acid. The polysaccharide polymer chains are composed of two alternating sugar units, N-acetyl-D-glucosamine and uronic acid (either D-glucuronic or L-iduronic), linked by α, 1 → 4 bonds (Fig. 31.9) (34).

These chains are called glycosaminoglycans and typically are composed of 200 to 300 monosaccharide units. In mast cells, approximately 10 to 15 of these chains are bound to a core protein to yield a proteoglycan (i.e., a protein/sugar conglomerate molecule) with a molecular weight of 750 to 1,000 kDa. Before the molecule is capable of binding to antithrombin, the proteoglycan must undergo a series of structural modifications (34). These modifications include O-sulfation and N-sulfation of the D-glucosamine residues at carbons 6 and 2, respectively; O-sulfation of the D-glucuronic acid at carbon 2; epimerization of the D-glucuronic acid at carbon 5 to form L-iduronic acid; O-sulfation at carbon 2 of the L-iduronic acid; and N-deacetylation of the glucosamine and O-sulfation of the glucosamine at position 3. None of these reactions goes to completion, so the resulting polysaccharide chains are structurally quite diverse (35,36). The heparin proteoglycan then undergoes degradation by an endo-β-glucuronidase in mast cell granules to release the active 5- to 30-kDa polysaccharide chains.

Under physiological pH conditions, heparin exists primarily as polysulfate anions and, therefore,

usually is administered as a salt. In clinical use, standard heparin most often is the sodium salt, but calcium heparin also is effective. Lithium heparin is used in blood sample collection tubes to prevent clotting of the blood samples both in vitro but not in vivo. The use of heparin salts also is important to maintain aqueous solubility, which is necessary for injection. Heparin can be administered intravenously or subcutaneously but not orally, because the polysaccharide

P.829

chains are broken down by gastric acid. Intramuscular injection of heparin is associated with a high risk of hematoma formation and is not recommended.

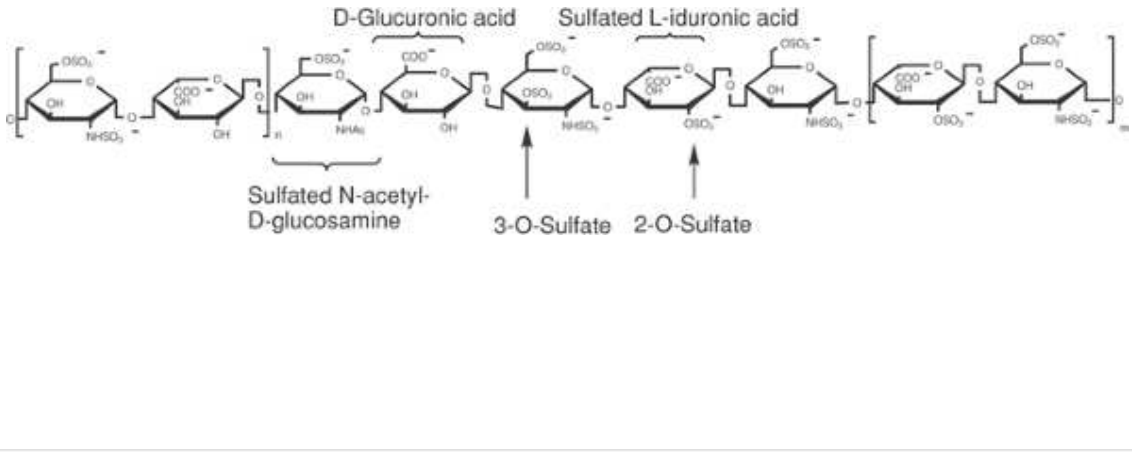

Fig. 31.9. Chemical structure of heparin polymer.

Mechanism of Action

Heparin (unfractionated heparin) was the first parenteral anticoagulant to show efficacy in the treatment of VTE and has been in use since 1937. Heparin acts at multiple sites in the coagulation cascade (34). Anticoagulation occurs when heparin binds, via a distinct pentasaccharide sequence in its molecule, to the circulating antithrombin III (a serine protease inhibitor) and potentates the antithrombin III–mediated inhibition of thrombin (factor IIa) and factor Xa, two of the key proteases in the blood coagulation cascade (Fig. 31.10) (37). The binding between heparin and antithrombin III consists of ionic bonding between sulfate and carboxylate anions in the pentasaccharide chain of heparin and arginine and lysine cations in the antithrombin III (38). Antithrombin III works by forming a stable 1:1 complex with both thrombin and factor Xa. Although the rates of these reactions (with IIa and Xa) are slow in the absence of heparin, binding is accelerated 1,000-fold when heparin is added (39). The reason for this enhancement is that when heparin binds to the antithrombin III, it induces a conformational change, resulting in increased accessibility of its active site and more rapid interaction with its protease substrates (i.e., thrombin and factor Xa). It should be noted that the ability of heparin to expose the active sites of antithrombin III is related to the large molecular size of heparin. With smaller molecules, such as LMWH and fondaparinux, the binding of antithrombin to thrombin is diminished, and the drugs become more selective (see discussions of LMWH and fondaparinux). Interestingly, the role of heparin in this process is only catalytic in nature (i.e., it is not consumed, inactivated, or degraded

P.830

by the reaction). In fact, once the complex of antithrombin and protease is formed, the heparin is released, with no loss of activity, to catalyze formation of more antithrombin/protease complexes (Fig. 31.10) (37). Additional effects of heparin on the coagulation of blood are a result of heparin's effects on plasminogen activator inhibitor, protein C inhibitor, and TFPI (17,18).

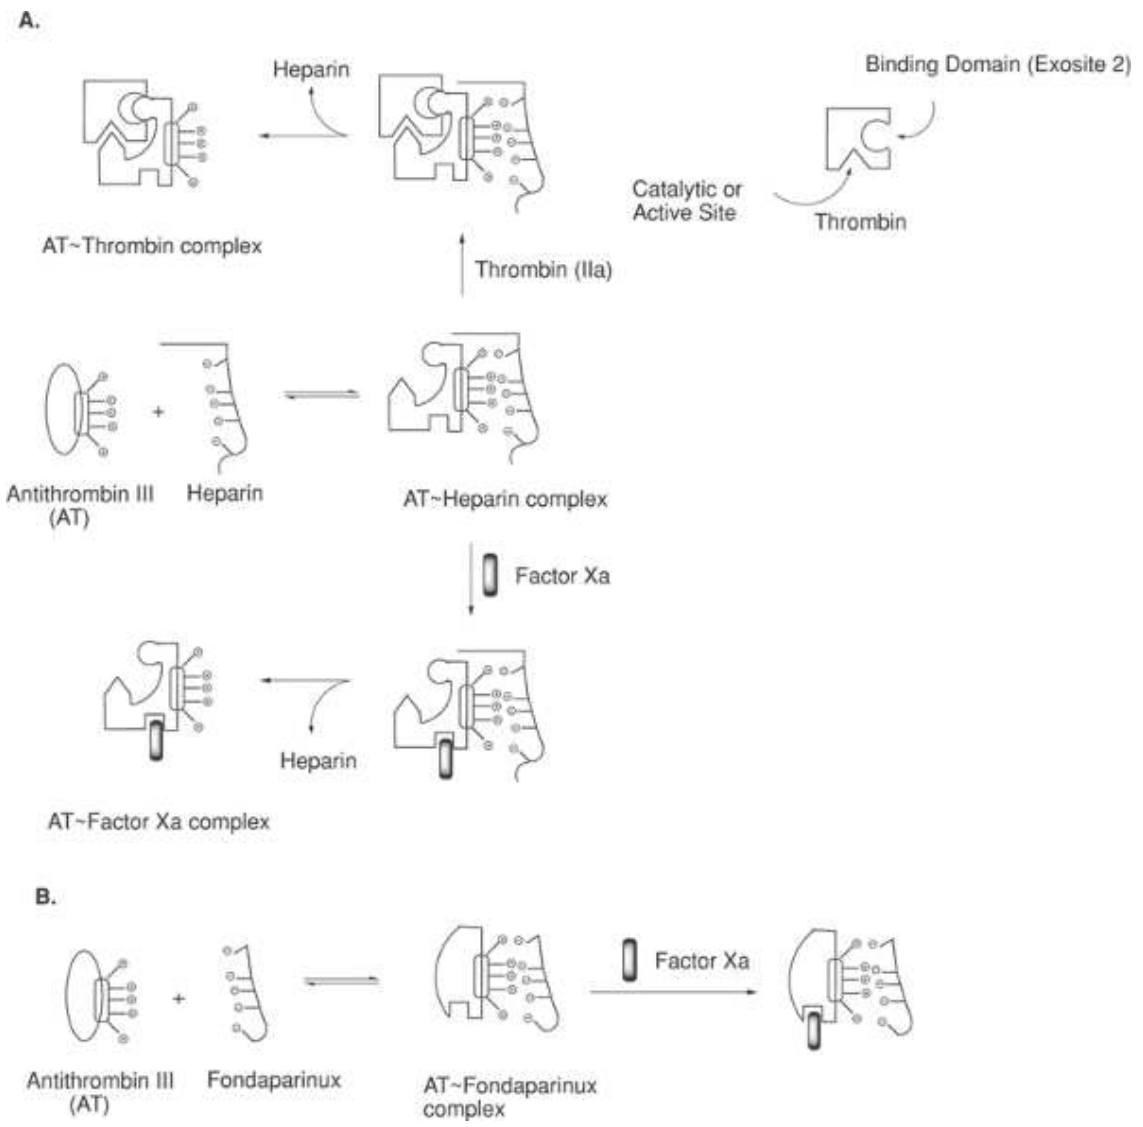

Fig. 31.10. Schematic representation of catalytic role of the heparin drugs in promoting (**A**) antithrombin–factor Xa and antithrombin–thrombin complexes and (**B**) antithrombin–fondaparinux complex.

Pharmacokinetics

The pharmacokinetic profiles of heparin and LMWHs are quite different. Whereas heparin is only 30% absorbed following subcutaneous injection, 90% of LMWH is systemically absorbed (40). The binding affinity of heparin to various protein receptors, such as those on plasma proteins, endothelial cells, platelets, platelet factor 4 (PF4), and macrophages, is very high and is related to the high negative-charged density of heparin. This high nonspecific binding decreases bioavailability and patient variability. Additionally, heparin's nonspecific binding may account for heparin's narrow therapeutic window and heparin-induced thrombocytopenia (HIT), a major limitation of heparin. These same affinities are quite low, however, in the case of LMWHs. These parameters explain several of the benefits of the LMWH's. The favorable absorption kinetics and low protein binding affinity of the LMWHs results in a greater bioavailability compared with heparin. The lowered affinity of LMWHs for PF4 seems to correlate with a reduced incidence of HIT. Heparin is subject to fast zero-order metabolism in the liver, followed by slower first-order clearance from the kidneys (41,42). The LMWHs are renally cleared and follow first-order kinetics. This makes the clearance of LMWHs more predictable as well as resulting in a prolonged half-life. Finally, the incidence of heparin-mediated osteoporosis is significantly diminished with use of LMWHs as

opposed to heparin.

Metabolism

Independent of molecular weight, the metabolic fate of the heparins is essentially the same. The distribution of the compounds is limited primarily to the circulation, but heparins also are taken up by the reticuloendothelial system (26). Once this uptake occurs, rapid depolymerization of the polysaccharide chains ensues, resulting in products that are inactive as anticoagulants. Desulfation also occurs in mononuclear phagocytes, which also produces inactive metabolites. These metabolites, as well as some of the parent compound, are then excreted in the urine (26). Because of the depolymerization of heparin in the liver and ultimate renal elimination of both metabolites and parent drug, half-life is prolonged in patients with hepatic or renal dysfunction. Another heparin-like medication is danaparoid sodium (43). The drug is composed of 84% heparan sulfate, 12% dermatan sulfate, and 4% chondroitin sulfate. The average molecular weight is 5.5 kDa, and like the LMWHs, danaparoid is dosed in terms of antifactor Xa activity. Danaparoid is completely bioavailable intravenously or subcutaneously and attains maximal antifactor Xa activity 2 to 5 hours after administration. The elimination half-life is approximately 24 hours, and clearance is through the kidneys. Coagulation assays (e.g., PT and aPTT) are not routinely monitored in patients receiving danaparoid therapy, because the drug has a very limited effect on factor II (thrombin) activity.

Specific Heparin Drugs

High-Molecular-Weight Heparin (Unfractionated Heparin)

Standard heparin is unfractionated and contains mucopolysaccharides ranging in molecular weight from 5 to 30 kDa (mean, ~15 kDa) and is referred to as high-molecular-weight heparin (Table 31.2). This group of compounds has a very high affinity for antithrombin III and causes significant in vivo anticoagulant effects. Because heparin is a heterogeneous mixture of polysaccharides with different affinities for the target receptor, dosing based on milligrams of drug is inappropriate (i.e., there frequently is a limited correlation between the concentration of heparin given and the anticoagulant effect produced). Therefore, heparin is dosed in terms of standardized activity units that must be established by bioassay. One USP unit for heparin is the quantity of heparin required to prevent 1.0 mL of citrated sheep blood from clotting for 1 hour after the addition of 0.2 mL of 1% calcium chloride (19). Commercially available heparin sodium USP must contain at least 120 USP units per milligram. Heparin therapy typically is monitored by the aPTT. A therapeutic aPTT is represented by a clotting time in the assay that is 1.5- to 2.5-fold the normal mean aPTT (19). Monitoring therapy with laboratory testing is critical.

Low-Molecular-Weight Heparins

In the past two decades, an increased interest has surfaced in a group of compounds known as LMWHs (41). The LMWHs typically are in the 4- to 6-kDa molecular weight range and are isolated as fractions from heparin using gel filtration chromatography or differential precipitation with ethanol (39). The LMWHs have more favorable pharmacokinetic and pharmacodynamic profiles relative to standard heparins (Table 31.3) (44). The mechanism of action of LMWHs is similar to conventional heparin, but the binding of LMWHs is more selective (i.e., LMWHs have more targeted activity against activated factor Xa and less against activated factor IIa [thrombin]) (Fig. 31.10). The reason for this difference is that even though LMWHs still possess the exact same specific pentasaccharide sequence as that of heparin needed for binding and potentiating the antithrombin III–mediated inhibition of activated factor Xa, most of the LMWH/antithrombin III complex is of insufficient length to bind and inhibit factor Xa and thrombin at the same time (44). Thus, although all LMWHs inactivate factor Xa, only 25 to 50% of these molecules also inactivate thrombin (41). This factor selectivity typically is defined as a higher factor Xa:thrombin (anti-Xa:anti-IIa) activity ratio. In fact, although standard (unfractionated) heparin has an anti-Xa:anti-IIa ratio of 1:1, the same ratio in the LMWHs varies from 2:1 to 4:1 (Table 31.3) (41).

Table 31.3. Properties of Heparin Derivatives

Drug	Trade Name	Dosing	Molecular Weight (daltons)	Binding Ratio
Unfractionated heparin				
Heparin	Calciparine, Calcilean	b.i.d., t.i.d.	5–30	1:1
Low-molecular-weight heparins				
Dalteparin	Fragmin	q.d.	3–8	2.2:1
Enoxaparin	Lovenox	q.d., b.i.d.	3.5–5.5	2.7–3.9:1
Tinzaparin	Innohep	q.d.	5.5–7.5	2.8:1
Pentasaccharide fondaparinux	Arixtra	q.d.	1.728	Xa only

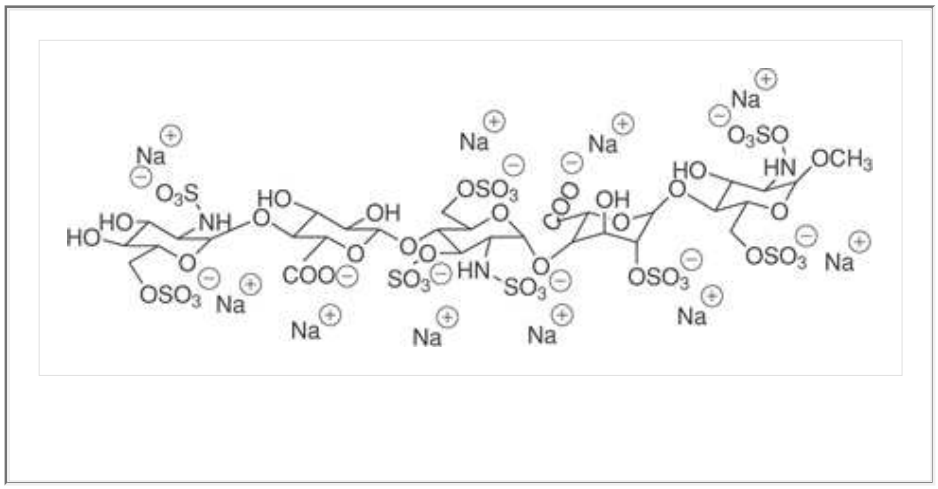
Three LWMHs are commercially available in the United States. The LWMHs are shown in Table 31.3. The three drugs differ slightly in their medical indications for use as well as in their molecular weight ranges. All three compounds are indicated for perioperative thromboembolism prevention for specific abdominal and orthopaedic surgeries. Enoxaparin and dalteparin are approved for use, in combination with aspirin, for the prophylaxis of ischemic complications of unstable angina and non-Q-wave myocardial infarction (45). Enoxaparin also is used in therapy for DVT with or without concomitant pulmonary embolism (45). Because of the increased homogeneity of enoxaparin compared to heparin, dosing of this drug is based on drug weight rather than on USP unitage. A typical dosing scheme for enoxaparin is the administration of 1 mg/kg once or twice daily. In the cases of dalteparin and ardeparin, dosage is based on antifactor Xa units (a-Xa U). Dalteparin is given as a once-daily subcutaneous injection at a dose of 2,500 to 5,000 a-Xa U. Typical dosing for tinzaparin is 175 a–Xa U/kg once daily. The LMWHs have a limited anticoagulant effect on in vitro clotting assays, such as the aPTT. In contrast to the heparin, coagulation parameters, such as aPTT, usually are not monitored in patients receiving LMWHs, nor is monitoring these assays really necessary, because the LMWHs have a highly predictable dose–response relationship (41,44).

Newer Heparin Developments

Many recent studies involving heparin have been directed toward either increasing oral bioavailability or decreasing unwanted side effects (35,46). The poor bioavailability of heparin results from its high molecular weight and high anionic charge density. These properties combined with the instability of the polysaccharides to gastric acid make penetration of biological membranes, such as the gut wall, extremely difficult for heparin. Various approaches to increase heparin absorption following oral administration have been investigated (47). Formulations of heparin including the use of amine salts in enteric-coated tablets (48), salts from organic bases such as lipophilic amines (49), oil-water emulsions (50,51), liposomes (52), and microsphere encapsulation (53,54) have been examined. Combinations of heparin with assorted calcium binding substances and non-α-amino acids (N-acylated aminoalkanoic acids) for simultaneous oral administration also have been studied (47). None of these formulations has yet been approved for clinical use. Attempts to use structural modifications to heparin to attenuate undesirable side effects also have been investigated (46). Heparin-induced thrombocytopenia is caused by the interaction of heparin with

PF4. The PF4 binding domain appears to be distinct from the thrombin binding domain. Therefore, it should be possible to use shorter oligosaccharides that bind specifically to the thrombin inhibitory sites without binding to PF4 (46). These observations were used to develop and synthetically produce a series of oligosaccharides with good thrombin binding profiles that have limited interaction with PF4. This preliminary work is quite promising, but these compounds are not yet clinically available.

Fondaparinux



Fondaparinux is a prototype of a novel class of anticoagulants with significant advantages compared to their structurally related heparin (55). Based on the active site of the heparins, fondaparinux is a synthetic, highly sulfonated pentasaccharide. The immediate advantage of fondaparinux is that as a synthetic drug, its composition will not change, which results in improved pharmacokinetics and a more selective anticoagulant action.

Mechanism of action

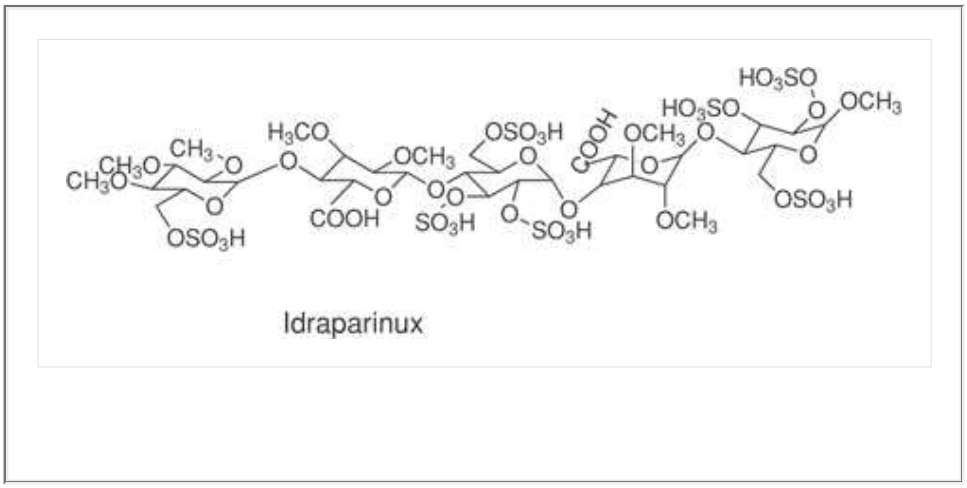
The development of fondaparinux, a synthetically derived pentasaccharide that binds specifically to and activates antithrombin III, is a further refinement on the mechanism of action of heparin (56). Fondaparinus and a related analogue, idraparinux, are specific, indirect inhibitors of activated factor Xa via their activation of antithrombin (Fig. 31.10). Fondaparinux has strategically located sulfonates that bind to antithrombin. Fondaparinux is structurally related to the antithrombotic binding site of heparin (57,58). Unlike heparin or LMWHs, however, these inhibitors have no effect on thrombin, because they lack the longer saccharide chains required for binding to thrombin. The highly sulfated heparins exhibit nonselective binding to a number of additional proteins, resulting in decreased bioavailability and significant variation in activity.

Therapeutic application

Fondaparinux is the first selective factor Xa inhibitor that is approved for the prophylaxis of DVT, which may occur in patients undergoing hip fracture surgery or hip or knee replacement surgery

(59). The most common side effect is major and minor bleeding, and the patient must be carefully monitored. The drug is not to be used when spinal anesthesia or spinal puncture is employed because of the potential for developing a blood clot in the spine. Fondaparinux has not been reported to cause thrombocytopenia, a condition seen with heparin (56,59,60). It is 100% bioavailable, with little or no protein binding.

Idraparinux is a polymethylated derivative of fondaparinux that may soon be marketed. Like fondaparinux, this drug is an indirect inhibitor of factor Xa, which binds to antithrombin with high affinity (62). The drug has a plasma half-life of 80 hours and can be administered once a week. Idraparinux is administered subcutaneously, is 100% bioavailable, and does not bind to other plasma proteins.



Pharmacokinetics

Fondaparinux is administered via subcutaneous injection with a single daily dose and shows complete absorption. The drug is highly bound to antithrombin III (~94%), with no significant binding to other plasma proteins. Because of the predictable anticoagulant effect, the drug does not require routine coagulation monitoring (61). The drug is not metabolized and is excreted in the urine unchanged within 72 hours in patients with normal renal function. Fondaparinux has an elimination half-life of 17 hours. Presently, no clinically significant drug interactions have been reported.

Direct Thrombin Inhibitors

In the last 10 years, with a better understanding of the molecular mechanisms of blood coagulation, the availability of molecular modeling and recombinant technologies, and the structure-based drug design strategies, many new anticoagulants that target almost every step in the coagulation pathway have been developed (6,63). Among these, five direct thrombin inhibitors (DTIs; hirudin, bibalirudin, lepirudin, argatroban, and ximelagatran) have been approved for clinical use in recent years (Table 31.4). Many other anticoagulants that act on the endogenous anticoagulation mechanisms, such as activated protein C pathway, TFPI, as well as additional orally active DTIs, currently are undergoing clinical trials (63,64).

Discovery and Design of Direct Thrombin Inhibitors

Hirudin, the lead compound for the design of DTIs, is a small protein (65 amino acids) that was originally isolated from the salivary glands of the medicinal leech, *Hirudo medicinalis* (65). This protein has potent and specific inhibitory effects on thrombin through the formation of a 1:1 complex with the clotting factor. The anticoagulant activity of hirudin seems to be contained within its highly anionic C-terminus. Several clinical studies have compared hirudin and a small peptidomimetic analogue, hirulog, with heparin in the treatment of several thrombotic disorders. In many cases, hirudin seems to be more efficacious and the responses to it more predictable. Furthermore, some of the studies also indicate a lower incidence of bleeding complications with hirudin compared with heparin. Hirudin is now produced by recombinant technology, and many hirulogs continue to be screened (66,67). Significant progress in the design and development of direct thrombin inhibition has been achieved. The recent emergence of orally active DTIs may simplify the prevention and treatment of various thrombotic disorders (68,69,70).

Mechanism of Action

The DTIs bind and inactivate both free thrombin and thrombin bound to fibrin. Unlike heparin, DTIs, such as lepirudin, bivalirudin, argatroban, and ximelagatran, bind directly and reversibly to the active site of thrombin. Unlike the heparins, these inhibitors do not require an activated antithrombin III as a cofactor for their anticoagulant activity. Furthermore, contrary to the heparins,

these agents inhibit only the activity of thrombin, whereas heparin indirectly inhibits factors IIa (thrombin), IXa, Xa, XIa, and XIIa (64). There are three different domains where DTIs bind to and

block the action of thrombin: the active site (or catalytic site, CS) as well as two additional exosites. Exosite-1 acts as a dock for substrates such as fibrin and, thereby, orients the appropriate peptide bonds in the active site for its biotransformation. Exosite-2 is the heparin binding domain. Bivalent DTIs, such as lepirudin and bivalirudin, block thrombin at the active site and exosite-1, whereas argatroban, melagatran, and dabigatran are univalent DTIs and, thus, bind only to the active site of the thrombin.

Table 31.4. Direct Thrombin Inhibitors (DTIs)

Drug	Trade Name	Route of Administration	Site of Binding	Reversibility	Half-life (minutes)
Hirudin		IV	CS, exosite-1	Irreversible	
Lepirudin	Refludan	IV	CS, exosite-1	Irreversible	80
Desiruden	Iprivask	SC	CS, exosite-1	Irreversible	120–18
Bivalirudin	Angiomax	IV	CS, exosite-1	Reversible	25
Argatroban	Novastan	IV	CS	Reversible	39–51
Melagatran		SC, IV	CS	Reversible	150
Ximelagatran	Exantaa	PO	CS	Reversible	180–22

CS, catalytic site; IV, intravenous, PO, oral; SC, subcutaneous.
[a]AstraZeneca announced the withdrawal of Exanta from the market on February.

Specific Drugs

Recombinant Hirudin Derivatives: Lepirudin and Desirudin

Lepirudin and desirudin have been approved for the treatment of HIT and of HIT with thrombotic syndrome (71). Both lepirudin and desirudin are recombinant hirudin derivatives that consists of a 65-amino-acid protein (72,73). Lepirudin is related to the recombinant product desirudin differing in the two N-terminal amino acids. The N-terminal amino acids in lepirudin are leucine-1 and threonine-2, whereas in desirudin, the N-terminal amino acids are valine-1 and valine-2. Additionally, desirudin lacks a sulfated tyrosine at amino acid 63. The antithrombin activity of the two drugs is slightly different.

Lepirudin and desirudin are both bivalent DTI that bind to both the active site and the exosite-1 of thrombin. The result of this binding is that they create a nearly irreversible inhibition of thrombin. Lepirudin and desirudin inhibit both free thrombin and thrombin bound to fibrin (74).

Lepirudin is administered via intravenous bolus injection, followed by continuous infusion, whereas desirudin is administered subcutaneously twice daily (Table 31.4) (73,75). The drugs are cleared via the kidneys. Lepirudin is nearly totally degraded before excretion (~90%), whereas desirudin is

excreted 50% unchanged. Lepirudin has immunogenic properties, and a significant number of patients develop antihirudin antibodies. In addition, hemorrhages may occur in patients treated with lepirudin. The drug half-life is approximately 1.3 hours (76).

Bivalirudin

Bivalirudin, a 20-amino-acid peptide, has been approved for use in patients with unstable angina undergoing percutaneous coronary intervention (Fig. 31.11) (77).

Bivalirudin is a rapid-onset, short-acting DTI that binds to both the active site and the exosite-1 of thrombin. Unlike lepirudin, bivalirudin is a reversible inhibitor of both free thrombin and thrombin bound to fibrin. This reversibility is possible because the bound bivalirudin undergoes cleavage at the second N-terminal proline to release the portion of the drug bound to the active site. The carboxyl-terminal portion of bivalirudin dissociates from thrombin to regenerate thrombin (Fig. 31.11) (76). Bivalirudin does not bind to plasma protein.

Bivalirudin is administered via intravenous bolus injection, followed by continuous infusion (Table 31.4). The drug exhibits a rapid onset and a short duration of action. Bivalirudin is eliminated by renal excretion. It has been suggested that dosage adjustments be made in patients with severe renal impairment and in patients undergoing dialysis. Approximately 30% is eliminated unchanged along with proteolytic cleavage products. Because of the reversible nature of bivalirudin the drug exhibits less risk of bleeding than other antithrombotics, and there have been no reported cases of antibody formation to bivalirudin (78).

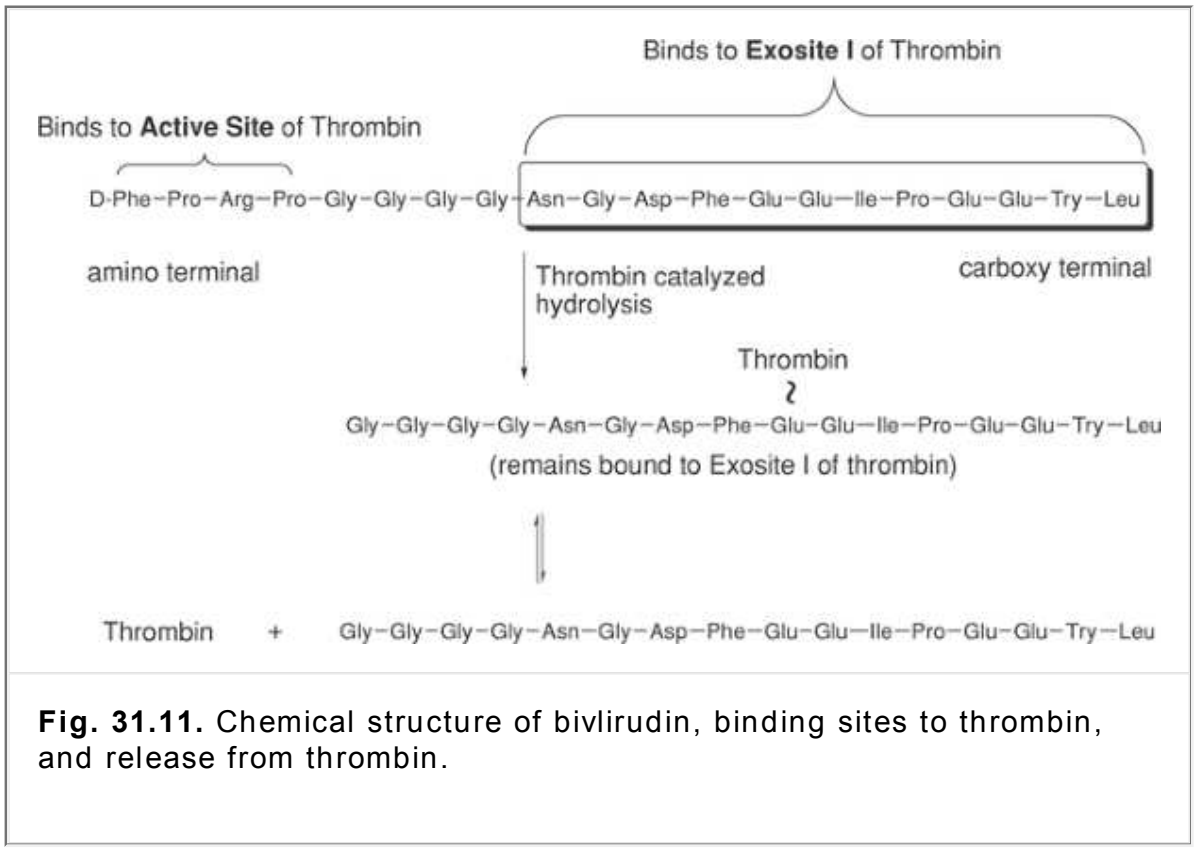


Fig. 31.11. Chemical structure of bivlirudin, binding sites to thrombin, and release from thrombin.

P.834

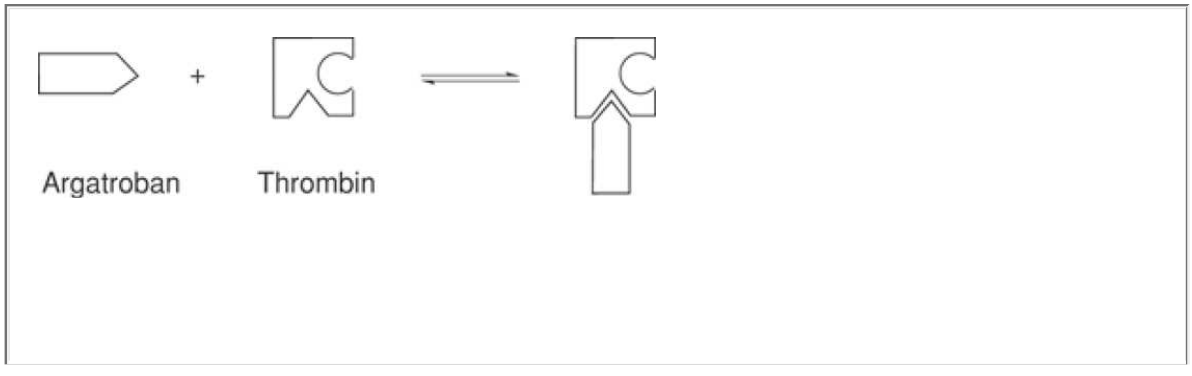

Fig. 31.12. Schematic representation of mechanism of action of argatroban.

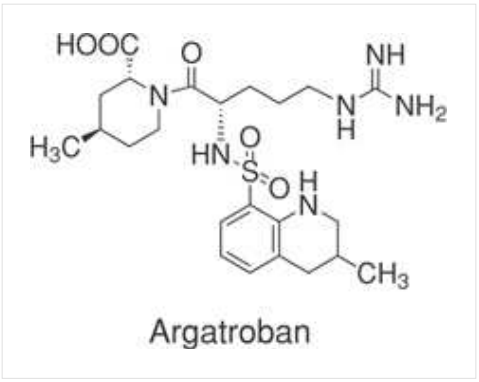
Argatroban



Argatroban has been approved for the prophylaxis and treatment of thrombosis in patients with HIT (79). Argatroban is a peptidomimetic that binds selectively to the catalytic site of thrombin as a univalent competitive DTI (Fig. 31.12). Argatroban is available as a mixture of 21-*R* and 21-*S* diastereomers (64:36), with the *S*-isomer approximately twice as potent as the *R*-isomer (80). The drug is a reversible inhibitor of both free thrombin as well as clot-bound thrombin.

Pharmacokinetics (Table 31.4)

Argatroban is administered subcutaneously because of the low lipophilicity of the drug. The drug is bound to plasma protein and is metabolized via CYP3A4/5 to the aromatized metabolite and the two hydroxylated metabolites (Fig. 31.13). The M-1 metabolite retains 20 to 30% of the antithrombotic activity. Coadministration of argatroban with inhibitors of CYP3A4 does not appear to produce clinically significant effects. Argatroban is eliminated via biliary secretion into the feces (81).

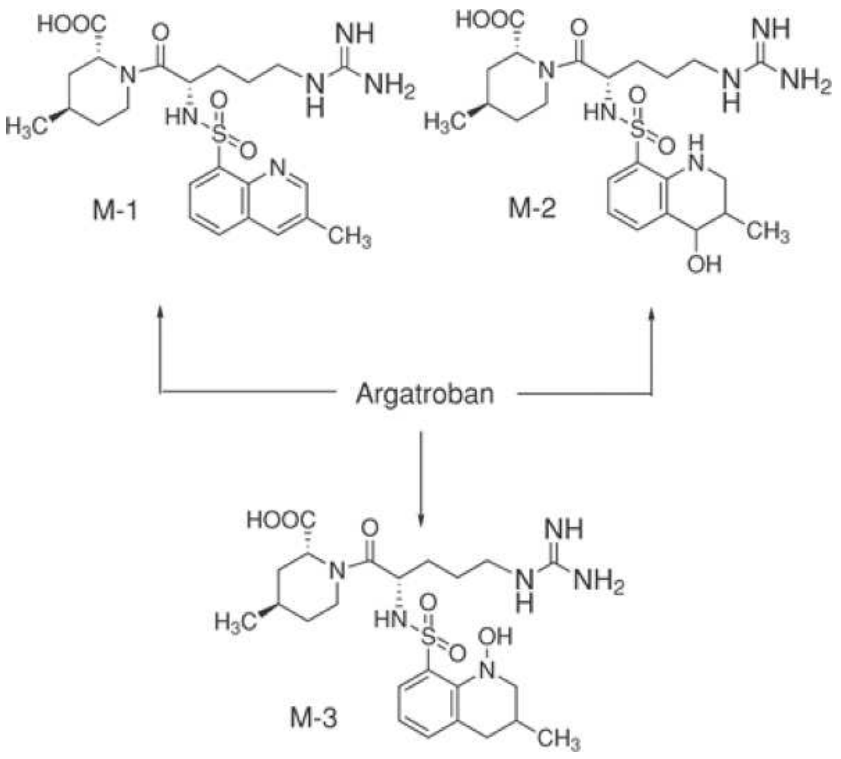


Fig. 31.13. Metabolism of argatroban.

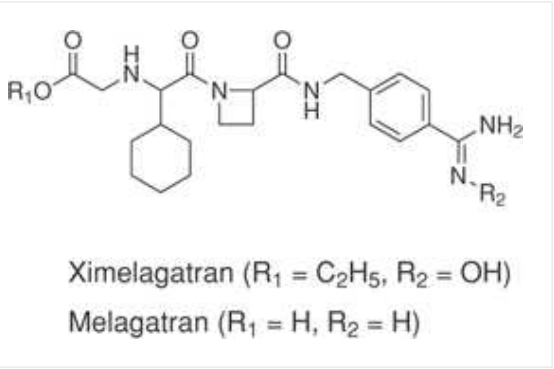
Ximelagatran was the first orally active DTI, approved in 2004 for the prevention of venous thromboembolism for patients undergoing total knee replacement surgery and in patients with atrial fibrillation (82,83). Ximelagatran is a pro-drug that, following metabolism, gives rise to the DTI melagatran. Melagatran inhibits both free thrombin and thrombin bound to fibrin by reversibly binding to a single site in thrombin; thus, it is referred to as a univalent DTI. This is in contrast to lepirudin and bivalirudin, which bind nearly irreversibly to two sites in thrombin. Melagatran also inhibits platelet activation and cleavage of protease-activated receptor-1 in a dose-dependent manner (84,85).



Ximelagatran was reported to be well tolerated, with a low incidence of adverse effects. It had been reported, however, that the drug caused liver toxicity, although studies have indicated that this is a rare event (86).

On February 14, 2006, AstraZeneca announced that the company had decided to withdraw melagatran/ximelagatran from the market and terminate its development because of a potential risk of severe liver injury when the drug was used beyond the approved 11 days.

Previous studies had reported elevated liver transaminases in 7.9% of the patients and suggested monitoring with long-term use of the drug. This effect appeared after 1.5 to 4.0 months.

Antiplatelet Drugs

Another site for regulating blood coagulation and subsequent thrombus formation is at the level of the platelets (87). Antiplatelet drugs work by inhibiting platelet activation via a number of different mechanisms (87,88). The major role of antiplatelet drugs is in the prevention of ischemic complications in patients with coronary diseases (89). These drugs also are effective in combination with moderate-intensity anticoagulants for patients with atrial fibrillation.

Pathophysiology of Arterial Thrombosis

The pivotal role of platelets in thrombus formation and potential sites for drug interventions is illustrated in Figure 31.14 (89). Normal endothelial cells in the vascular wall synthesize and release prostacyclin (PGI_2), which

stimulates the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), thus preventing platelet aggregation and degranulation. In the case of an injury to the vascular wall, glycoprotein (GP) receptors (i.e., GPI_a and GPI_b) bind substances such as von Willebrand factor (vWf) and collagen from the exposed subendothelial surface, thereby activating the platelets. The $GPII_b/III_a$ receptors (also known as the fibrinogen receptor or integrin αIIbβ3 receptor) then mediate the final step of platelet aggregation by binding to fibrinogen or vWf, thus cross-linking platelets to form aggregates (Fig. 31.14).

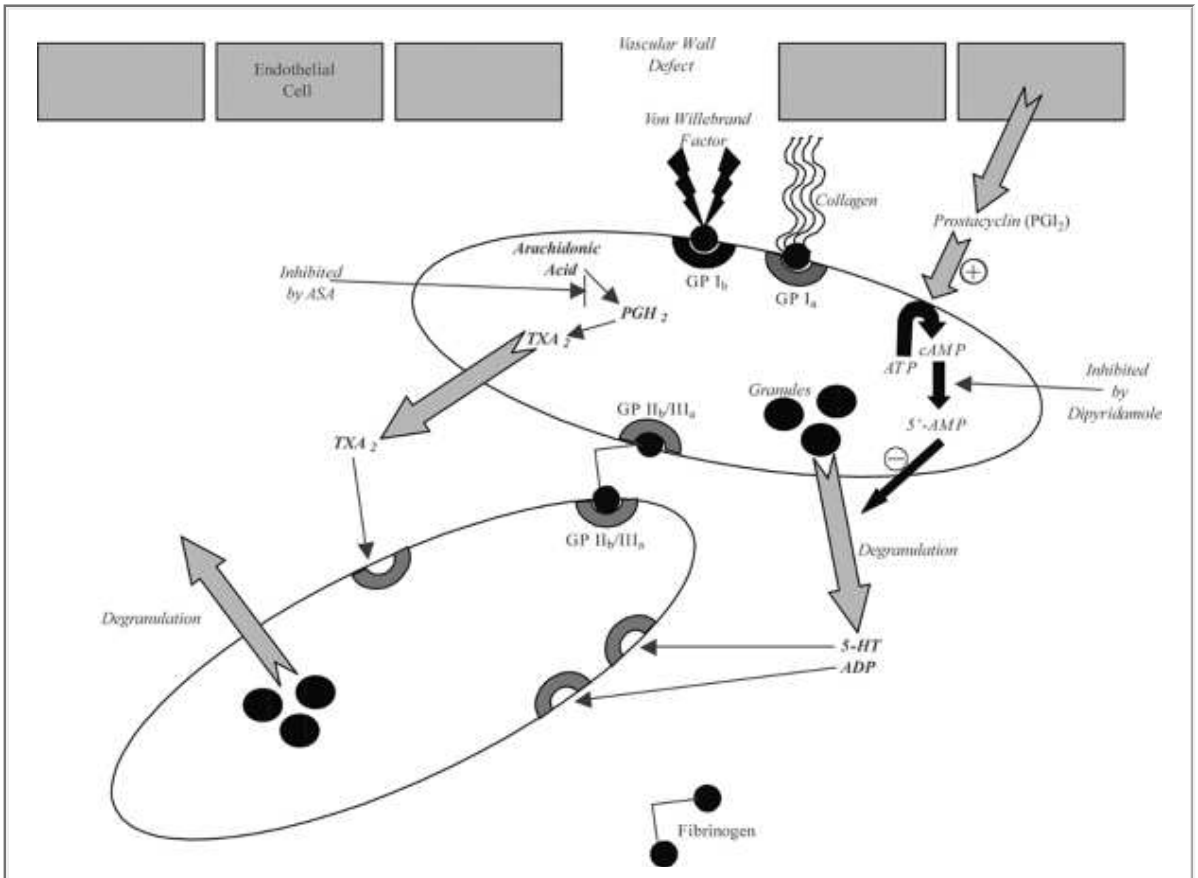


Fig. 31.14. Scheme describing platelet activation as it relates to blood clot formation. The thrombus is formed at the site of a damaged wall in the vasculature. Normal endothelial cells in vascular wall provide prostacyclin, which stimulates the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), preventing platelet

aggregation. In injury, glycoprotein (GP) receptors bind substances such as von Willebrand factor and collagen, activating the platelet. The GPIIb/IIIa receptors cross-link platelets via fibrinogen binding. As the platelet degranulates, additional aggregating substances including thromboxane A_2 (TXA_2), serotonin (5-HT), and adenine diphosphate (ADP) are released. The substances bind to other platelets, activating them and resulting in a cascade effect. Also shown are the sites of inhibition of platelet aggregation.

The adherent platelets degranulate and release additional aggregating substances, such as thromboxane A_2 (TXA_2), serotonin (5-HT), and adenosine diphosphate (ADP). These substances serve as secondary chemical messengers to recruit more platelets to the site of vascular injury and, thereby, amplify platelet aggregation. For example, thrombin production releases ADP, which is a potent inducer of platelet aggregation and stimulates prostaglandin synthesis from arachidonic acid in the platelet. The prostaglandins synthesized, PGI_2 and TXA_2, have opposite effects on thrombogenesis. The PGI_2 is synthesized in the walls of the vasculature and inhibits thrombus formation. Conversely, TXA_2, which is synthesized in the platelets, induces vasoconstriction and thrombogenesis. Serotonin, which also is released from the platelets, has similar and additive effects to those of TXA_2.

This rapid platelet aggregation and thrombus formation at the site of vascular injury is the main mechanism of hemostasis (stoppage of bleeding, a normal process of wound healing). When platelets are activated on the ruptured atherosclerotic plaques or in regions of restricted blood flow, however, it can lead to thromboembolic

complications that contribute to common diseases, such as myocardial infarction or ischemic stroke.

Mechanism of Action of Antiplatelet Drugs

Most of the current available antiplatelet drugs, such as aspirin, dipyridamole, ticlopidine, and sulfinpyrazone, exert their actions by affecting only the secondary platelet aggregation pathways (87). For example, aspirin and sulfinpyrazone work by inhibiting the biosynthesis of TXA_2 in the platelets (see Fig. 36.4). Aspirin works by irreversibly and permanently inactivating cyclooxygenase (COX) through covalent acetylation of a serine residue in close proximity to the active site of the enzyme. A cumulative inactivation effect occurs on platelets with long-term therapy, because platelets do not synthesize new COX (i.e., platelets are unable to synthesize, via de novo pathway, COX-1, because they are anucleated cells). Therefore, the effects of aspirin last for the lifetime of the platelet (7–10 days). Sulfinpyrazone also is a potent but reversible COX inhibitor that does not affect PGI_2 synthesis in endothelial cells. Like nonsteroidal anti-inflammatory agents (NSAIDs), such as aspirin, this action inhibits the aggregation of platelets into thrombi. Dipyridamole interrupts platelet function through its effect of increasing cellular concentration of cAMP by inhibiting phosphodiesterase, an enzyme needed for degradation of cAMP. Dipyridamole also may stimulate PGI_2 release and inhibits TXA_2 formation. Ticlopidine and clopidogrel selectively inhibit ADP-induced platelet aggregation with no direct action on prostaglandin production. New and more selective antiplatelet drugs, such as integrin αIIbβ3 receptor antagonists (GPIIa/IIIb blockers), thromboxane synthase inhibitor, and TXA_2 receptor antagonists, are currently being developed (88).

COX-1 Inhibitors

Because TXA_2 is a potent vasoconstrictor as well as a labile platelet aggregation inducer, inhibition of production of TXA_2 effectively blocks platelet aggregation. Aspirin and related analogues (Fig. 31.15) exhibit their effectiveness through such a blocking mechanism.

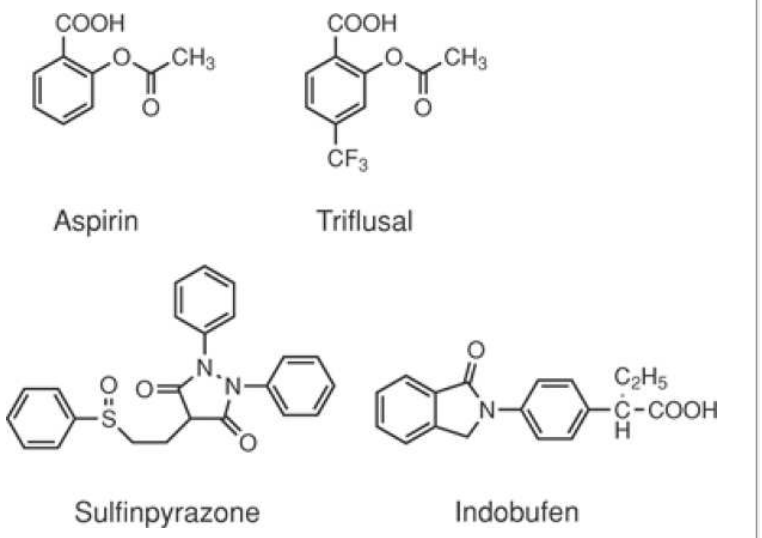

Fig. 31.15. Cyclooxygenase (COX)-1 inhibitors.

Aspirin

Aspirin is a well-established antiplatelet drug in the treatment of atherothrombotic vascular disease (87,88,89). As stated earlier, aspirin works by its ability to acetylate and irreversibly deactivate platelet COX (COX-1), and its antithrombotic effect remains for the life span of the platelet (7–10 days). Aspirin also has been shown to have other antithrombotic effects that are unrelated to its action on COX-1 (87). These effects include the dose-dependent inhibition of platelet function, the enhancement of fibrinolysis, and the suppression of blood coagulation.

Aspirin is rapidly absorbed in the stomach and quickly degraded by plasma cholinesterases (half-life, 15–20 min). A once-daily dose of 160 mg of aspirin, which is much lower than dosages needed for its anti-inflammatory/analgesic actions, is sufficient to completely inactivate platelet COX-1 irreversibly (90). Higher doses of aspirin only contribute to its side effects, especially internal bleeding and upper gastrointestinal irritations.

In recent years, the term “aspirin resistance” has been used to denote those situations in which the use of aspirin is unable to protect a patient from thrombotic complications, to cause a prolongation of the bleeding time, or to produce an anticipated effect on one or more in vitro tests of platelet function (87,90,91). One possible explanation for aspirin-resistant TXA_2 biosynthesis is the transient expression of COX-2 in newly formed platelets (92). Many other clinical, pharmacodynamic, biological, and genetic factors, however, such as tobacco use, drug interaction, alternate pathways for platelet activation, and genetic polymorphism or mutations of the COX-1 gene, may be involved (93). Currently, many questions regarding the biochemical mechanism, diagnosis, prevalence, clinical relevance, and optimal therapeutic intervention for aspirin resistance remain unanswered (93).

Triflusal

Triflusal (2-acetoxy-4-trifluoromethyl benzoic acid) is an antiplatelet drug that despite its structural similarity to aspirin (Fig. 31.15) exhibits quite different pharmacological and pharmacokinetic properties (94). Unlike aspirin, 2-hydroxy-4-trifluoromethylbenzoic acid (HTB), the deacetylated metabolite of triflusal, retains significant antiplatelet activity. Triflusal is rapidly absorbed and metabolized. The area under the concentration–time curve for triflusal is 20.26 mg/L/hour after a 900-mg dose, whereas that for HTB is 42.27 mg/L/hour. Much of the pharmacokinetic data for triflusal activity is associated with HTB. The inhibition of COX, as measured by reduced production of thromboxane B_2, is 25% after 2 hours and 85% after 7 days with triflusal, whereas the effects of aspirin on thromboxane B_2 is more than 90% reduction after 2 hours and is maintained at this level after 7 days (95). It would appear that the presence of a 4-trifluoromethyl group also greatly

enhances triflusal's ability to inhibit the activation of nuclear factor κB, which in turn regulates the expression of the mRNA of vascular

cell adhesion molecule-1 (96) needed for platelet aggregation. In addition, triflusal increases nitric oxide synthesis in neutrophils, which results in an increased vasodilatory potential (97). Finally, an additional site of action for triflusal/HTB is the inhibition of cAMP phosphodiesterase, leading to increased levels of cAMP. Elevated cAMP levels decrease platelet aggregation through decreased mobilization of calcium. Aspirin and salicylic acid do not significantly increase cAMP levels.

Although recent trials comparing triflusal and aspirin for the prevention of vascular events in patients following a stroke revealed no significant differences between these two antiplatelet drugs, triflusal's use was associated with a significantly lower rate of hemorrhagic complications (94).

Sulfinpyrazone (Anturane)

Sulfinpyrazone is a structural derivative of the anti-inflammatory drug phenylbutazone. Unlike phenylbutazone, however, sulfinpyrazone does not have significant anti-inflammatory activity. It does have potent uricosuric effects and frequently is used in the treatment of gout. At least four metabolites of sulfinpyrazone have been identified, including the sulfide, sulfone, *p*-hydroxysulfide, and *p*-hydroxysulfinpyrazone derivatives (Fig. 31.16) (24). Only the parent sulfinpyrazone and its reduced sulfide metabolite, however, are active as COX inhibitors (98). Because these compounds are reversible inhibitors, the antithrombotic activity lasts only as long as blood levels of the drug and metabolite persist (half-life, 4–6 hours for parent sulfinpyrazone, 11–14 hours for the sulfide metabolite). Sulfinpyrazone is not yet approved in the United States for use in acute myocardial infarction or for transient ischemic attack prophylaxis.

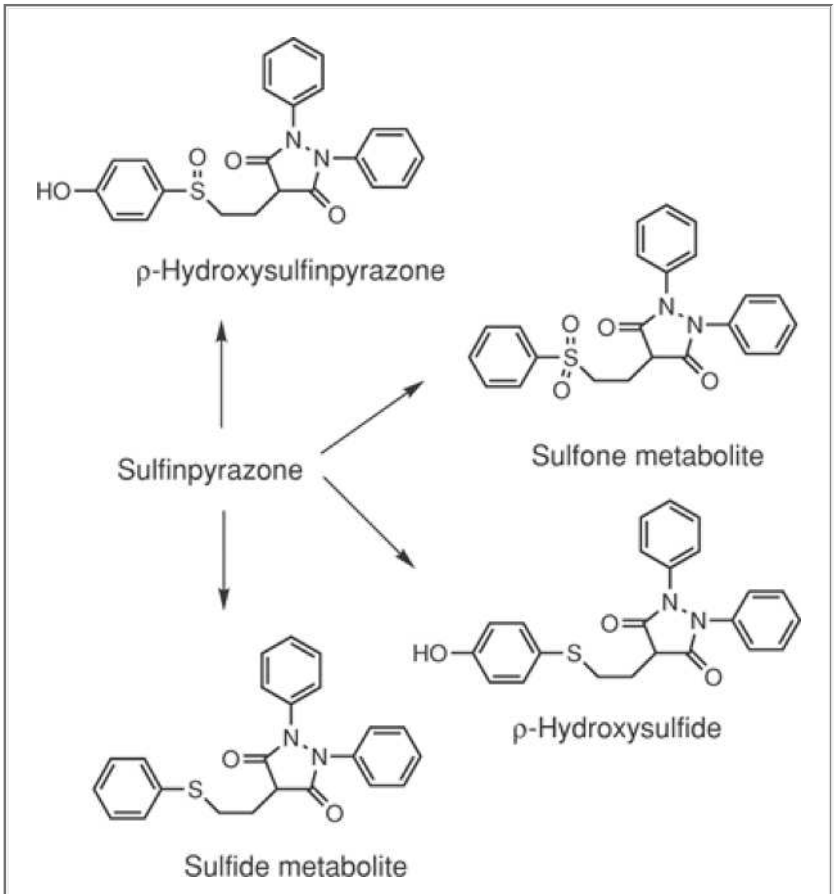

Fig. 31.16. Metabolism of sulfinpyrazone.

Indobufen

Many NSAIDs also inhibit TXA_2-dependent platelet function through a competitive, reversible

inhibition of COX-1 (see Chapter 36 for their structures). At a conventional analgesic dosage, these drugs only inhibit COX-1 activity by 70 to 90%, which is inadequate for controlling platelet aggregation. Thus, unlike aspirin, most of the clinically available NSAIDs are not used clinically for their antithrombotic properties.

In contrast, indobufen (Fig. 31.15), a reversible but very potent inhibitor of platelet COX-1 activity, was shown to have comparable clinical efficacy to that of aspirin in prevention of DVT after myocardial infarction and in blocking exercise-induced increase in platelet aggregation (99). In the secondary prevention of thromboembolic events, 100 or 200 mg of indobufen twice daily is as effective as warfarin or aspirin in patients with or without atrial fibrillation (100). Currently, indobufen is only available for routine clinical use in Europe.

Phosphodiesterase Inhibitors

Phosphodiesterase-3 (PDE3) is an enzyme responsible for degradation of cAMP to AMP in platelets and blood vessels. Selective cAMP PDE3 inhibitors, such as dipyridamole and cilostazol (Fig. 31.17), inhibit the degradation of cAMP, thereby increasing cellular concentration of cAMP and leading to inhibition of platelet aggregation and vasodilation (see Chapter 17 for additional information) (101).

Dipyridamole (Aggrenox)

Dipyridamole is a pyrimidopyrimidine derivative with vasodilatory and antiplatelet properties (Fig. 31.17). Dipyridamole exerts its antiplatelet function by increasing cellular concentrations of cAMP via its inhibition of the degradating enzyme, cyclic nucleotide PDE3. It also blocks adenosine uptake, which acts at A_2 adenosine receptors to stimulate platelet adenyl cyclase. Less common uses for this drug include inhibition of embolization from prosthetic heart valves when used in combination with warfarin (the only currently recommended use) and reduction of thrombosis in patients with thrombotic disease when used in combination with aspirin. Alone, dipyridamole has little, if any, benefit in the treatment of thrombotic conditions (102).

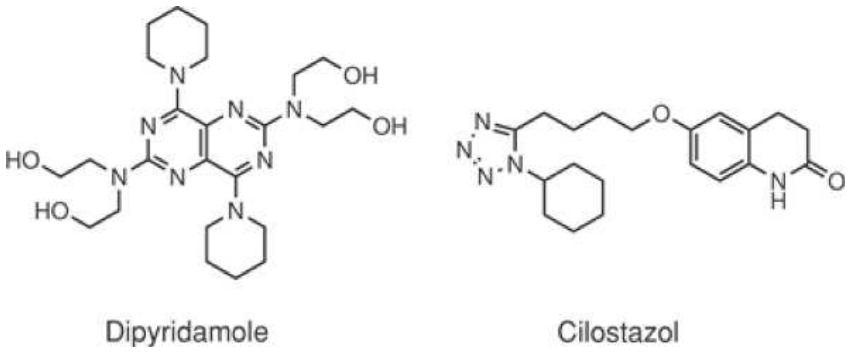

Fig. 31.17. Chemical structures of phosphodiesterase inhibitors.

Cilostazol (Pletal)

Cilostazol, a quinolinone derivative, is a potent orally active antiplatelet drug approved for the treatment of intermittent claudication (a peripheral artery disease resulting from blockage of blood vessels in the limbs). Cilostazol exhibits greater selectivity than dipyridamole as an inhibitor of PDE3A (Fig. 31.18) (102). The drug does not affect the other PDEs (PDEs 1, 2, or 4). Cilostazol reversibly inhibit platelet aggregation induced by a number of stimuli, such as thrombin, ADP, collagen, or stress from exercise (103,104). Additionally, cilostazol inhibits adenosine uptake, leading to increased activity of adenosine at A_1 and A_2 receptors. Adenosine's action on A_2 receptors in platelets increase cAMP levels, which, as previously indicated, leads to decreased

platelet aggregation (105).

Cilostazol is rapidly absorbed after oral administration, particularly with a high-fat meal, which greatly increases its bioavailability to approximately 90%. It is extensively metabolized in the liver by various cytochromes. The most important cytochromes appear to be CYP3A4 and, to lesser extent, by CYP2C19, with an elimination half-life of approximately 11 to 13 hours. Among the various metabolites produced (11 metabolites are known), the two major metabolites are 3,4-dehydrocilostazol and 4′-trans-hydroxycliostazol (Fig. 31.19). These two metabolites are pharmacologically active. Studies indicate that the concomitant administration of cilostazol with CYP3A inhibitors can greatly increase cilostazol blood concentrations, and a dose reduction may be required (106). Similar results are seen when CYP2C19 is inhibited, leading to decreased formation of 4-trans-hydroxycliostazol and significant increases in cilostazol and 3,4-dehydrocilostazol (107).

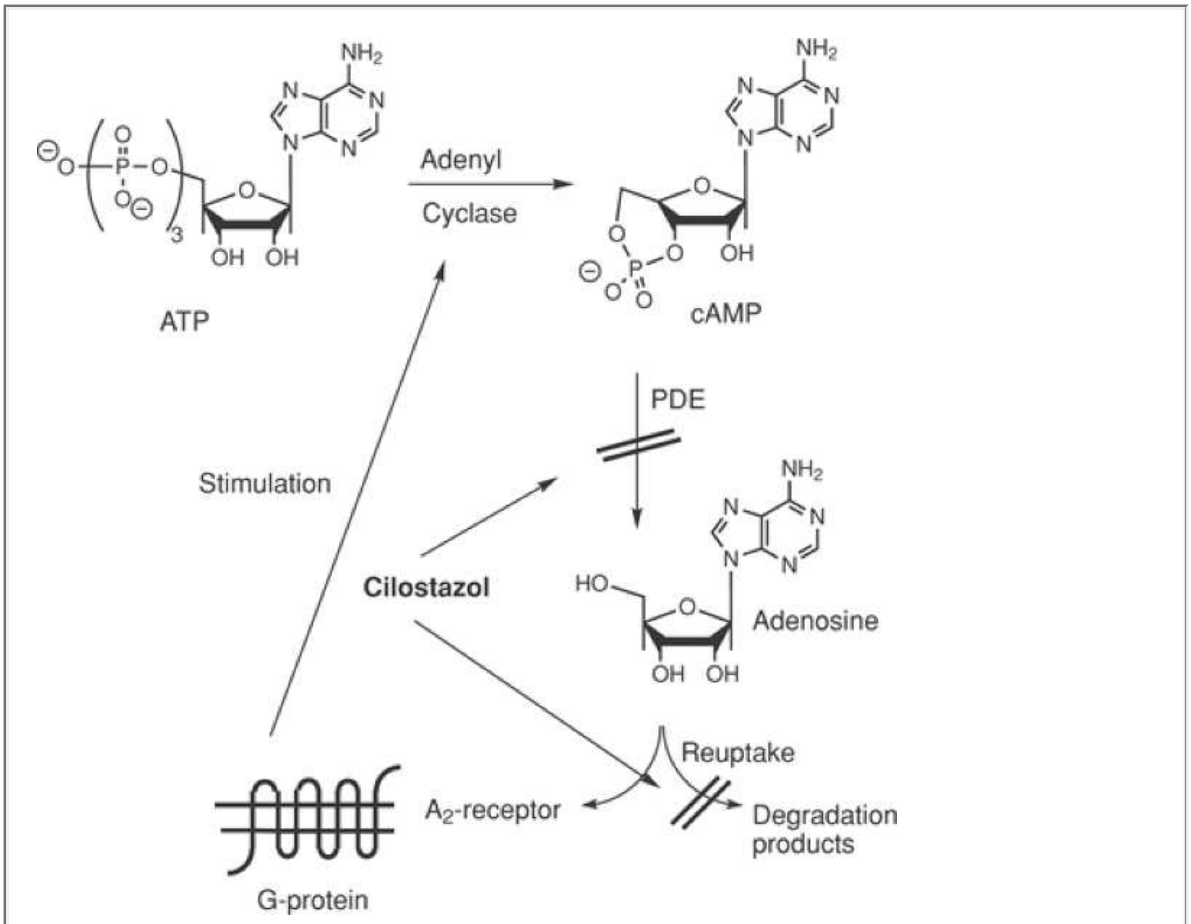

Fig. 31.18. Sites of action of cilostazol, blocking phosphodiesterase 3A (PDE) and adenosine uptake, leading to increased levels of cyclic adenosine monophosphate (cAMP) directly by inhibition of cAMP breakdown and indirectly through adenosine binding to adenosine 2 receptors (A_2-receptor), which through G-protein coupling stimulates adenyl cyclase.

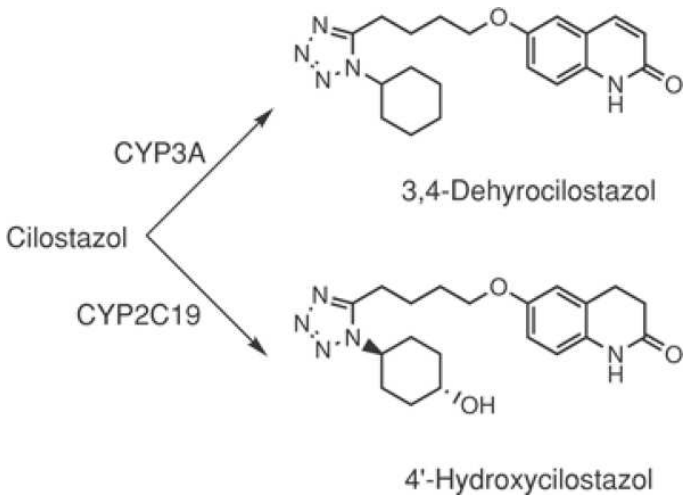

Fig. 31.19. Metabolism of cilostazol.

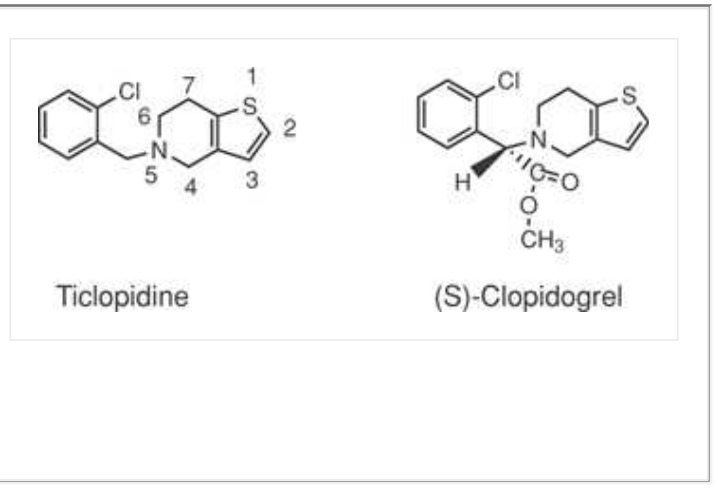
Platelet P2Y Purinergic Receptor

The crucial role that ADP plays in platelet activation and aggregation has been extensively investigated (108). The molecular targets of ADP in the platelet are G protein–coupled P2Y purinergic receptors. There are three nucleotide receptors: $P2X_1$, a cation channel receptor activated by ATP, and purinergic receptors $P2Y_1$ and $P2Y_{12}$, both of which are activated by ADP. Initial binding of ADP to the $P2Y_1$ purinergic receptor (373-amino-acid protein) induces platelet shape changes, causes intracellular calcium mobilization, and initiates aggregation. Subsequent binding of ADP to the $P2Y_{12}$ purinergic receptors (342 amino acids) leads to sustained platelet aggregation by inhibiting adenylate cyclase and, thereby, decreasing cellular cAMP levels (109). The $P2Y_{12}$ receptor is coupled to the $G\alpha_{i2}$ G protein. The antithrombotic drugs ticlopidine and clopidogrel are irreversible antagonists of this $P2Y_{12}$ purinergic receptor (108). The clinical relevance of this $P2Y_{12}$ receptor as a new target for antiplatelet drug development of novel reversible antagonists has been extensively reviewed (109,110,111).

Ticlopidine (Ticlid) and Clopidogrel (Plavix)



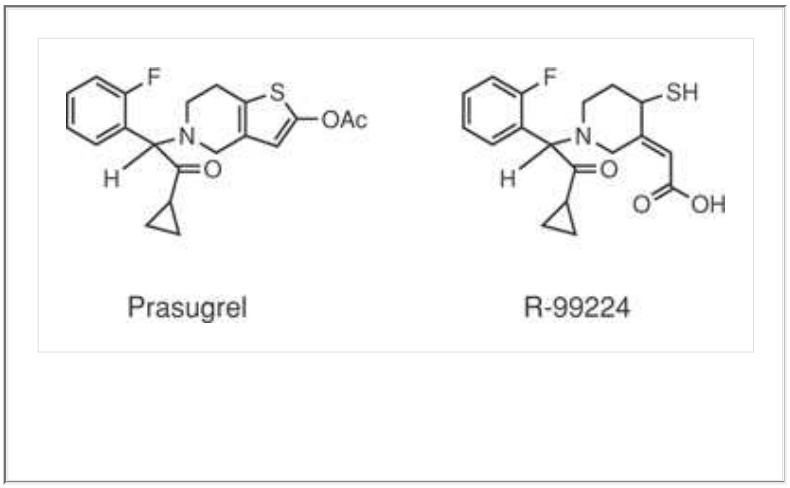
P.839

Ticlopidine and clopidogrel are thienopyridines, which through inhibition of platelet aggregation prolong bleeding time and delay clot retraction. The thienopyridines are prescribed for reduction of myocardial infarction and stroke, for treatment of peripheral arterial disease, and in combination with aspirin for acute coronary syndromes. This latter utility appears to result from the fact that both aspirin and the thienopyridines block major amplification pathways, leading to platelet aggregation

and, thus, producing enhanced effectiveness. Triclopidine has major safety concerns in that in a small population (1–2%), neutropenia occurs that is potentially fatal, may cause thrombotic thrombocytopenic purpura, and is largely replaced with clopidogrel. These same side effects are rare with clopidogrel. Additional side effects include diarrhea, nausea, vomiting, and skin rash (112).

The thienopyridine class exhibit selective inhibition of ADP-induced platelet aggregation. The action of ticlopidine and clopidogrel appear to be irreversible in that there is still antiplatelet activity for 7 to 10 days after discontinuation of the medications (despite the fact that the elimination half-life of ticlopidine is only 24–36 hours after a single dose) (24). Support of the theory of irreversible inhibition of $P2Y_{12}$ is provided by the observation that ticlopidine is not effective in blocking platelet aggregation in vitro when compared to the effect of the drug on the platelets of people taking ticlopidine. The thienopyridines both function as pro-drugs requiring cytochrome P450 activation. The thienopyridines are rapidly absorbed and extensively metabolized in the liver. The most significant metabolites of clopidogrel are shown in Figure 31.20. An inactive carboxylic acid represents the major circulating metabolite, which through oxidation by CYP3A4 gives rise to the 2-oxo derivative, which in turn is hydrolyzed to the thiol. The thiol is thought to bind irreversibly to $P2Y_{12}$ by forming a disulfide bridge to a cysteine in $P2Y_{12}$ (113,114,115). Specially, clopidogrel is thought to bind to Cys17 or Cys270 and, thus, block the binding of the agonist. In the case of ticlopidine, additional metabolites have been identified, dihydrothienopyridinium (M5) and thienodihydropyridinium metabolites (M6). These short-lived metabolites may be responsible for the toxic adverse reactions (116).

In light of various limitations posed by clopidogrel, such as patient variability, resistance, and bleeding events, newer compounds continue to be developed. One such agent is parsugrel, which presently is in Phase II/III clinical studies. Prasugrel and its active metabolite R-99224 exhibit a more rapid onset, a higher potency, and a low rate of bleeding (117).



Glycoprotein II_b/III_a Receptor Antagonists

One of the newest groups of antithrombotic agents is the platelet receptor $GPII_b/III_a$ antagonists (87). This novel class of compounds has been shown to provide more comprehensive inhibition of platelet aggregation than the usual combination of aspirin and heparin. The final common pathway in platelet aggregation is the expression of functional $GPII_b/III_a$ (integrin αIIbβ3) receptors. These protein receptors are expressed regardless

of the origin of the stimulus initiating the clotting cascade. The normal substrate for the $GPII_b/III_a$ receptor is fibrinogen. One fibrinogen molecule acts to cross-link two platelets via binding to the $GPII_b/III_a$ receptors on the platelet surfaces (Fig. 31.14). If the platelet surface receptors are occupied by another substrate that prevents fibrinogen binding and cross-linking, platelet aggregation will not occur. To this end, a number of novel compounds representing diverse structural groups have been prepared as $GPII_b/III_a$ receptor antagonists (Fig. 31.21) (118). Included

in this list of antagonists are monoclonal antibodies against the natural $GPII_b/III_a$ receptor, naturally occurring peptides isolated from snake venom that contain the Arg-Gly-Asp (RGD) sequence, synthetic peptides containing either the RGD or Lys-Gly-Asp (KGD) sequences, and peptidomimetic and nonpeptide RGD mimetics that compete with fibrinogen and other ligands for occupancy of the receptor (87). The natural binding ligands, such as vWf and fibronectin, contain the natural RGD sequence.

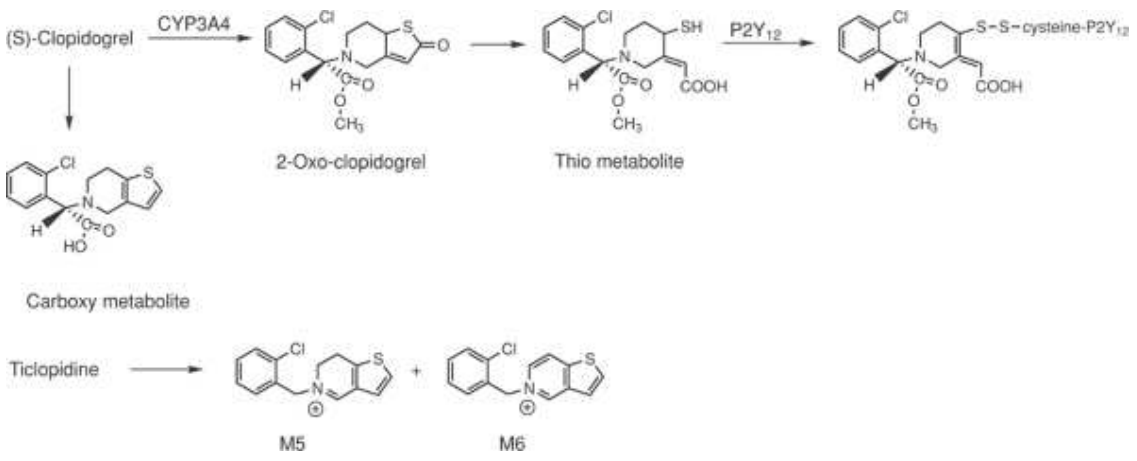


Fig. 31.20. Metabolism of clopidogrel and ticlopidine.

The $GPII_b/III_a$ receptor antagonists are indicated in therapy for unstable angina, non-Q-wave myocardial infarction, and percutaneous coronary procedures. Like other antithrombotic agents, the main concern associated with $GPII_b/III_a$ receptor antagonists is bleeding. Additionally, these drugs have been suggested to possibly increase the risk of thrombocytopenia (87). Although a number of orally active $GPII_b/III_a$ receptor antagonists have been prepared and evaluated, their clinical efficacy in acute treatment of patients with unstable angina and in those undergoing angioplasty has not been fully established (118).

Abciximab

The initial antibodies against the $GPII_b/III_a$ receptor were murine in origin. Because of concerns about the antigenicity of a pure murine antibody, a chimeric human–mouse 7E3 Fab was developed (119). This chimera, marketed as abciximab, is the clinically available form of the antibody (120). For an adult patient, the usual dosing scheme is 0.25 mg/kg as an intravenous bolus given 10 to 60 minutes before percutaneous coronary intervention, followed by the continuous infusion of 0.125 µg/kg/minute for 12 hours to a maximum of 10 µg/kg. Elimination of abciximab is biphasic. The initial phase has a half-life of 10 minutes, whereas the half-life of the second phase is approximately 30 minutes and results from platelet binding. Platelet function returns to normal within 48 hours after infusion, even though abciximab is bound to circulating platelets for approximately 2 weeks (Table 31.5) (42).

Eptifibatide

Eptifibatide is a cyclic heptapeptide composed of six amino acids and one mercaptopropionyl residue. The cyclization is completed via a disulfide linkage between the cysteine and the mercaptopropionyl moieties. The lysine-glycine-aspartate component of eptifibatide is highly specific for the $GPII_b/III_a$ receptor, with low

binding affinity, as indicated by the rapid dissociation constant (Table 31.5). Because of this, eptifibatide is a reversible, parenterally administered antagonist of platelet aggregation.

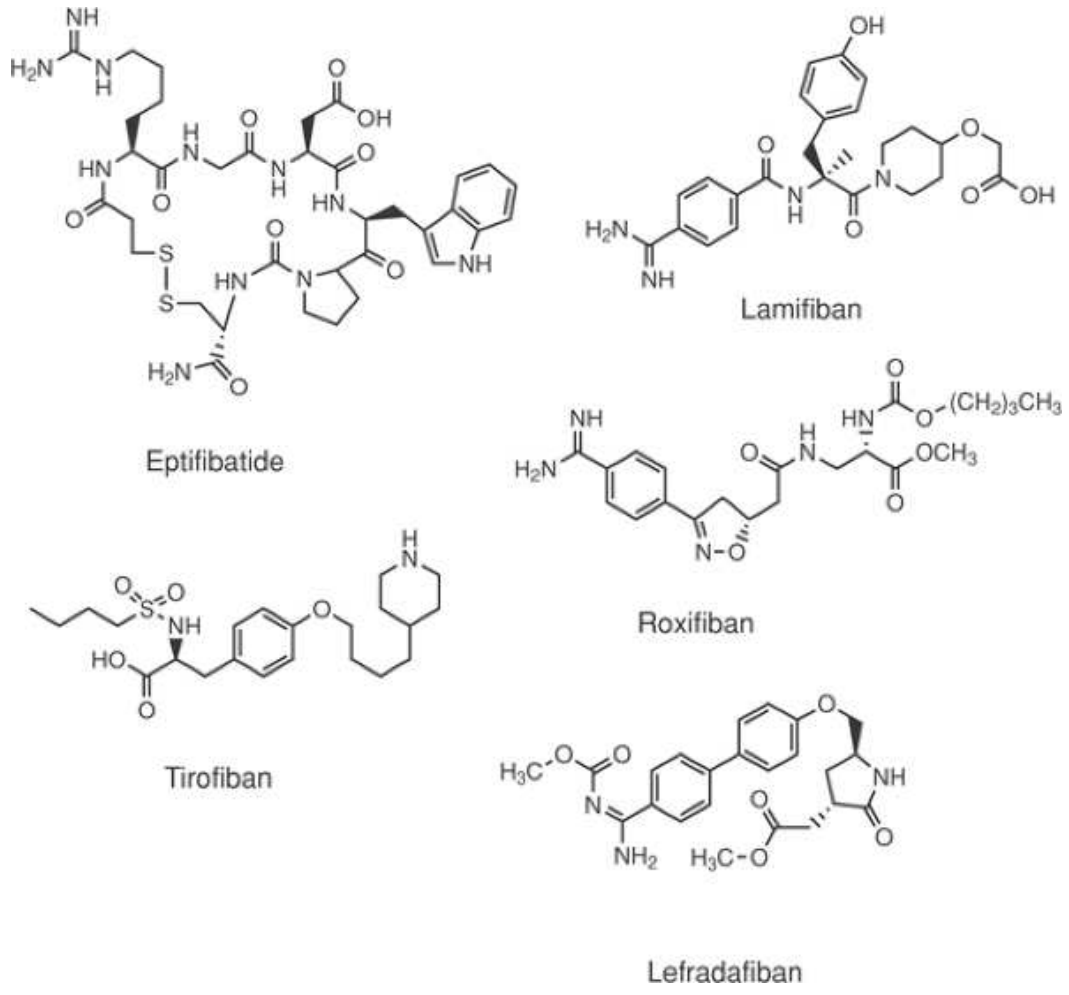

Fig. 31.21. Structures of selected glycoprotein (GP) $IIb/IIIa$ receptor antagonists.

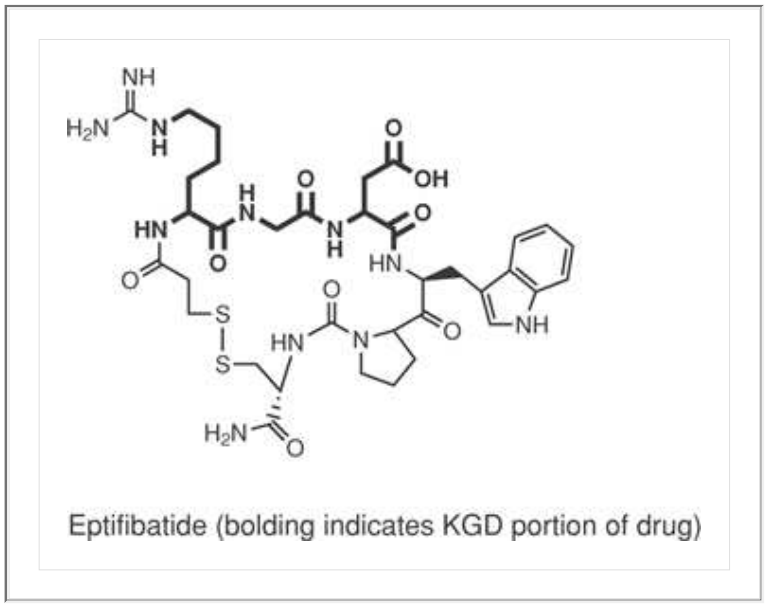
Table 31.5. Pharmacokinetic Properties of the Glycoprotein IIb/IIIa Receptor Antagonists

Drug	Trade Name	Molecular Weight (daltons)	Dissociation Constant (nmol/L)	Plasma Half-Life (hours)	Protein Binding (%)
Abciximab	ReoPro	47,615	5	72	
Eptifibatide	Integrelin	800	120	4	25
Tirofibin	Aggrastat	495	15	3–4	65



The drug is eliminated primarily via renal mechanisms as eptifibatide and deaminated eptifibatide. The clinical importance of eptifibatide and its benefits in comparison with other therapeutic agents used in the treatment of acute coronary syndromes and percutaneous coronary intervention have recently been reviewed by Curran and Keating (121).

Tirofiban

Tirofiban is a member of a new class of antithrombotic agents known as the "fibans" (Fig. 31.21). These compounds have a structural similarity to disintegrin, which was originally isolated from snake venoms. The location of the $-COO^-$ and NH_3^+ in the fibans is identical to the distance between the same functional groups of the RGD loop of disintegrin, and as a result, the fibans are able to effectively block the binding of fibrinogen to the GPIIb/IIIa receptor in an reversible manor. Tirofiban, like eptifibatide, has a rapid dissociation constant (Table 31.5). Tirofiban is a peptidomimetic (nonpeptide) that is parenterally administered and exhibits a reduced risk of bleeding because of its shorter biological half-life than abciximab. Additionally, it is less costly than other GPIIb/IIIa receptor antagonists. The remaining fibans shown in Figure 31.21 are in various stages of development. Lamifiban is administered parenterally, whereas roxifiban and lefradafiban are used orally.

New Developments in Antiplatelet Drugs

Several newer approaches to antiplatelet drug development have been recently discovered (122). These include inhibitions of the vWf/GPIb interaction, the platelet/collagen interaction, and the thrombin-induced platelet activation. Other approaches to platelet inhibition include the use of serotonin antagonists (because serotonin induces platelet aggregation), nitric oxide–donating antiplatelet agents, phosphodiesterase inhibitors, and inducers of adenyl cyclase.

Specific inhibitors of thromboxane synthase have been tested for their ability to block this enzyme without inhibiting the entrie acachidonic acid cascade (123). This allows an accumulation of prostaglandin G (PGG_2) and Prostaglandin H_2 (PGH_2) which can then be channeled into an increased production of prostacyclin (PGI_2) which also has antithrombotic activity.

Thrombolytic Drugs

Early application of reperfusion therapy with thrombolytic agents has significantly improved the outcomes of acute myocardial infarction and other conditions, such as pulmonary embolism, DVT, arterial thrombosis, acute thrombosis of retinal vessel, extensive coronary emboli, and peripheral vascular thromboembolism (124).

Although, the beneficial effect of the thrombolytic drugs, such as streptokinase and urokinase, for dissolving

newly formed thrombus in patients with acute myocardial infarction were first reported in 1958, their full acceptance into clinical practice was not realized until the early 1980s as a result of several prospective, randomized, controlled trials. Today, with the approval of many second- and third-generation thrombolytic drugs, thrombolytic therapy has become a standard treatment for patients presenting with acute myocardial infarction or stroke (124,125).

Snake Venom–Induced Coagulopathy

The venom of snakes of the Crotalinae family, which includes rattlesnakes, produces a state of impaired coagulation. This can lead to both local and systemic hemorrhagic events. Venom consists of many components, including phospholipases and hemolysins, which cause cell lysis by disrupting platelet and red blood cell membranes. The venoms also contain procoagulant components that induce the formation of intravascular clots as well as hemorrhagins that destroy vascular integrity. Typically, both PT and aPTT are elevated with total fibrin levels being lowered and fibrin degradation products being increased. All of the findings are consistent with a consumptive coagulopathy. Because of the multiple mechanisms affecting coagulation, coagulopathies caused by snake venom are best managed using antivenin.

Mechanism of Action

Normally, newly formed blood clots (fibrin) are dissolved by the actions of the fibrinolytic system. the purpose of which is the removal of unwanted clots without damaging the integrity of the vascular system. This system works via a relatively nonspecific protease enzyme called plasmin, the function of which is to digest fibrin (the very last step of the coagulation cascade) (Fig. 31.1). The lack of substrate specificity of plasmin is illustrated by the fact that it degrades fibrin clots as well as some plasma proteins and coagulation factors.

The fibrinolytically active plasmin is produced from the circulating inactive “proenzyme” plasminogen following the cleavage of a single peptide bond by a group of trypsin-like serine proteases known as the plasminogen activators. The principal activator, tissue-type plasminogen activator (tPA), is released from the vascular endothelium. Thrombolytic drugs, such as streptokinase and urokinase, act like a plasminogen activator that converts this proenzyme to the active plasmin. Endogenously, plasmin activity is regulated by two specific inactivators known as tPA inhibitors 1 and 2.

First-Generation Thrombolytic Agents

Streptokinase (Streptase)

Streptokinase is a drug of choice for thrombolytic therapy based on its cost-effectiveness consideration, and it is the only thrombolytic drug approved by the U.S. Food and Drug Administration (FDA) for peripheral vascular disease (126). The drug is approved for treatment of myocardial infarction but rarely is used for this condition today, having been replaced with the fibrin-specific agents discussed below (127).

Mechanism of action

Streptokinase is a protein purified from culture broths of group C β-hemolytic streptococci bacteria. Streptokinase contains a single polypeptide chain of 414-amino-acid residues with a molecular weight of 47 kDa (126). Streptokinase by itself has no intrinsic enzymatic activity. To be active, it must bind with plasminogen to form an activator complex (1:1 complex). This complex then acts to convert uncomplexed plasminogen to the active fibrinolytic enzyme, plasmin. The streptokinase/plasminogen complex not only degrades fibrin clots but also catalyzes the breakdown of fibrinogen and factors V and VII (124,126). As a result, streptokinase is considered to be a fibrin-nonspecific drug.

Pharmacokinetics

Unfortunately, the half-life of the activator complex is less than 30 minutes, which frequently is too short to completely lyse a thrombus. Anistreplase (APSAC; Eminase) is a 1:1 streptokinase/lysine-plasminogen complex that has been acylated with an anisoyl group at the active-site serine within

the lysine-plasminogen. Anistreplase is inactive as such, but following complexation with fibrin, the anisoyl group is slowly cleaved, exposing the active site and, thus, leading to degradation of fibrin. The pro-drug nature of anistreplase exhibits an improved pharmacokinetic profile, with anistreplase acting as a semiselective lysis agent at the clot site. The inactivity of the circulating anistreplase also allows this drug to be given as a very rapid intravenous infusion (typically, 30 U over 3–5 minutes). Tissue reperfusion following anistreplase therapy compares favorably to streptokinase because of the extended half-life (90 minutes).

Side effects

Because it is a foreign protein, streptokinase is associated with significant hypersensitivity reactions. Most people have, at some point in their lives, had a streptococcal infection and, therefore, have developed circulating antistreptococcal antibodies. These antibodies frequently are active against streptokinase as well. The response of the streptokinase to these antibodies can vary widely, from inactivation of the fibrinolytic properties of the protein to rash, fever, and rarely, anaphylaxis. Significant allergic reactions to streptokinase occur in approximately 3% of patients.

Urokinase (Abbokinase)

Urokinase is an enzyme with the ability to directly degrade fibrin and fibrinogen. It is now isolated from cultures of human fetal kidney cells and is composed of two polypeptide chains with molecular weights of 32 and 54 kDa. This method of isolation is much more efficient than the original isolation of urokinase from human urine (128). Because of its source, the human body does not see urokinase as a foreign protein. Therefore, it lacks the antigenicity associated with streptokinase and frequently is used for patients with a known hypersensitivity to streptokinase (129). Plasmin cannot be used directly because of the presence of naturally occurring plasmin antagonists in plasma. No such inhibitors of urokinase exist in the plasma, however, allowing this enzyme to have clinical utility. Even so, urokinase is much more expensive (threefold the price of streptokinase) and has an even shorter half-life (15 minutes). Urokinase also has other fibrin-nonspecific actions similar to streptokinase.

Currently, urokinase is only approved for treatment of pulmonary embolism.

Second-Generation Thrombolytic Agents

Alteplase (Activase)

Alteplase (tPA) is a serine protease with a low affinity for free plasminogen but a very high affinity for the

plasminogen bound to fibrin in a thrombus (fibrin-specific agent) (Fig. 31.22). Both streptokinase and urokinase lack this specificity (i.e., are nonspecific) and act on free plasminogen, inducing a generalized thrombolytic state. Alteplase also has a greater specificity for older clots compared with newer clots relative to streptokinase and urokinase. Alteplase was originally isolated from cultures of human melanoma cells but is now produced commercially using recombinant DNA technology. Alteplase is unmodified human tPA, whereas reteplase (see below) is human tPA that has had several specific amino acid sequences removed (130). At low doses, alteplase is quite selective for degrading fibrin without concomitant lysis of other proteins, such as fibrinogen. At the higher doses currently used therapeutically, however, alteplase activates free plasminogen to some extent and, therefore, can cause hemorrhage. Many of the therapeutic indications for the other thrombolytic agents also are indications for alteplase (i.e., myocardial infarction, massive pulmonary embolism, and acute ischemic stroke). The half-life of alteplase is very short (~5 minutes), necessitating its administration as a 15-mg intravenous bolus, followed by a 85-mg intravenous infusion over 90 minutes, or as 60 mg infused over the first hour, with the remaining 40 mg given at a rate of 20 mg/hour.

Prourokinase (scuPA, r-ProUK)

Prourokinase is a single-chain, urokinase-like plasminogen activator of 411 amino acids that displays clot-lysis activity yet does not interfere with hemostasis (131). It is nonimmunogenic and has a more favorable dose-related safety and efficacy profile than both urokinase and

streptokinase. Thus, it is a potentially useful thrombolytic drug in the treatment of peripheral vascular occlusion (132).

Third-Generation Thrombolytic Agents

Many third-generation thrombolytic agents currently are under clinical trials. These agents are derived from

structural modifications of the basic plasminogen activators (tPA or other tPA of animal origins) using technologies such as mutations, conjugation with monoclonal antibodies, or hybridization with another thrombolytic agent. Some of these agents are amediplase (hybrid of tPA and prourokinase), lanoteplase (mutant tPA), staphylokinase (from bacterial tPA) (125).

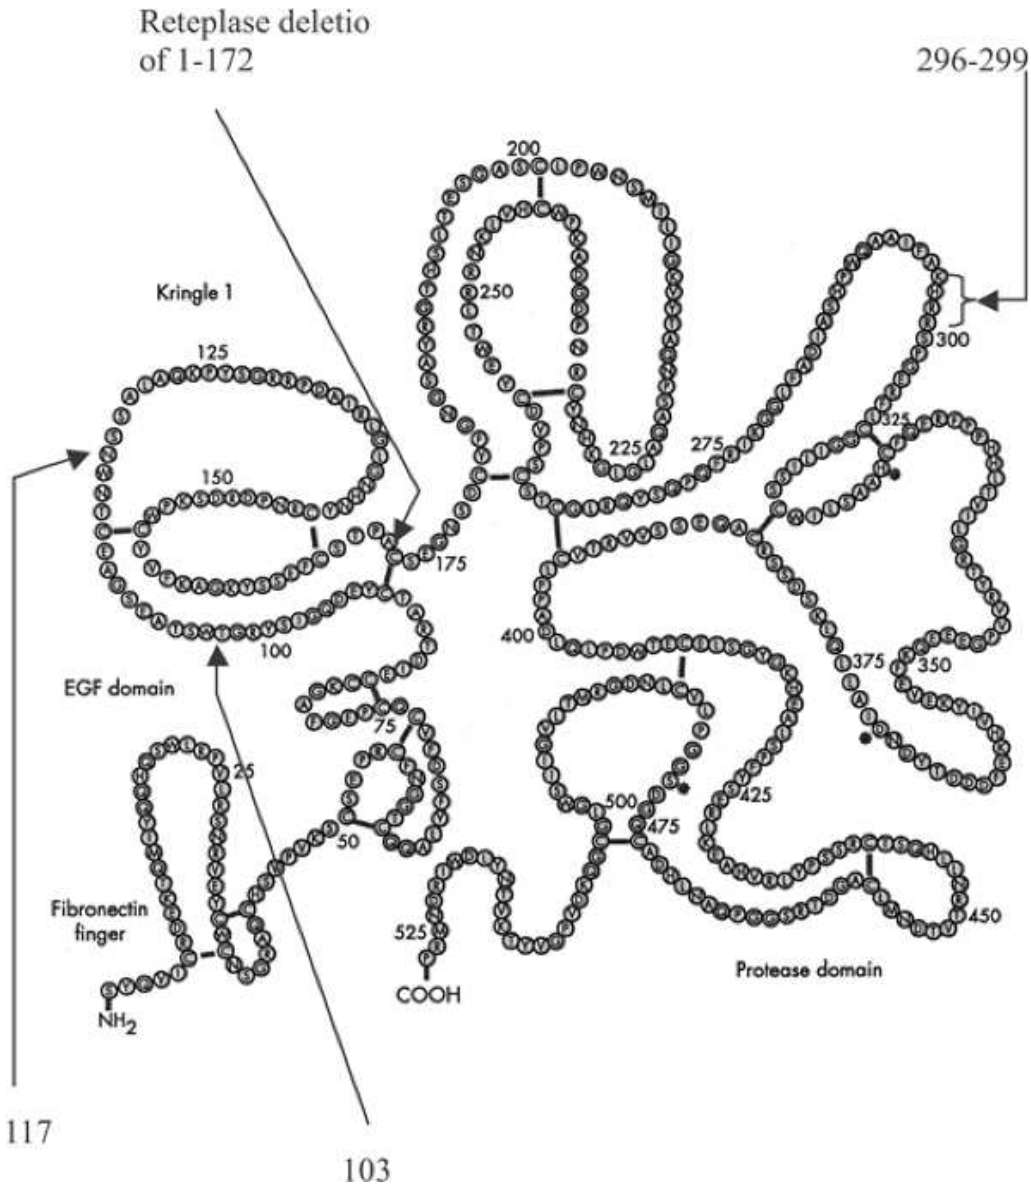


Fig. 31.22. Schematic diagram of alteplase, reteplase (removal of amino acids 1–172), and tenecteplase in which threonine (T) at position 103 is replaced with asparagines, asparagine (N) at position 117 is replaced with glutamine, and lysine (K)-histadine-arginine-asparagine at positions 296 to 299 are replaced with four alanines. (Adapted from Nordt TK. Bode C. Thrombolysis: Newer thrombolytic agents and their role in clinical medicine. Heart 2003;89: 1358–1362; with permission.)

Reteplase (Retavase)

Reteplase is a recombinant deletion mutant of tPA lacking the finger, epidermal growth factor, kringle 1 domain, and carbohydrate side chain (Fig. 31.22) (133). As a highly fibrin-specific thrombolytic agent, reteplase is missing the first 172 amino acids that are present in alteplase and has 355 amino acids with a molecular weight of 39 kDa. Because of the removal of the finger kringle 1 domain, reteplase binding to fibrin is reduced from that of alteplase, and reteplase has reduced fibrin selectivity. In addition, the structural modification reduces hepatic elimination, leading to a longer half-life (reteplase, 14–18 minutes; alteplase, 3–4 minutes).

Administered as a double bolus of 10 U every 30 minutes, reteplase is approved for use in acute myocardial infarction.

Tenecteplase (TNKase)

Tenecteplase is composed of 527 amino acids with 17 disulfide bridges. It differs structurally from anteplase by three point mutations (Fig. 31.22). The mutations were bioengineered to occur at amino acid 103, where threonine (T) is replaced by asparagine; at amino acid 117, where asparagine (N) is replaced by glutamine; and at amino acids 296 to 299, where lysine (K)-histidine-arginine-arginine are replaced with four alanines. Thus, the name TNK is derived from the mutations. The replacement of these amino acids along with their attached carbohydrate side chains results in a prolonged half-life (~17 minutes) and allows a single bolus application (133). These point-mutation changes also change the binding of tenecteplase to plasminogen activator inhibitor-1 (PAI-1) by 80-fold, thus improving activity. A physiological enzyme, PAI-1 inhibits fibrinolysis. Finally, tenecteplase shows a 15-fold higher fibrin specificity. The drug is still eliminated via hepatic mechanisms.

Toxicity of Antithrombotics and Thrombolytics

Antithrombotic Toxicity

Recall that warfarin exhibits its anticoagulation effects by preventing γ-carboxylation of specific glutamate residues necessary for vitamin K–dependent coagulation (Fig. 31.4). However, γ-carboxyglutamate proteins are not unique to coagulation factors. These types of proteins are synthesized in bone as well. As would be expected, warfarin also interferes with the carboxylation of these proteins, resulting in an inhibition of the effects of vitamin K on osteoblast development. It has been suggested that this is the mechanism responsible for bone abnormalities in neonates born to mothers who were treated with warfarin while pregnant (134). No evidence suggests that bone metabolism or development is affected by warfarin when the drug is administered to children or adults. Because of the mechanism of action of the warfarin-like drugs, the management of their toxicity is based largely on vitamin K therapy (see Coagulants below).

Unlike warfarin, heparin is safe for anticoagulant therapy during pregnancy (134). Although warfarin is known to cause serious fetal malformations when used in pregnancy, heparin does not cross the placental barrier and has shown no tendency to induce fetal damage. Furthermore, heparin does not increase fetal mortality or prematurity. To minimize the risk of postpartum hemorrhage, it is recommended that heparin therapy be withdrawn 24 hours before delivery.

Despite its safety in pregnancy, several potential problems are associated with heparin therapy. Because heparins (high-molecular-weight heparins and LMWHs) are isolated from animal sources, the chance of antigenic hypersensitivity exists but is rarely observed. Heparin competitively binds many other plasma proteins (i.e., vitronectin and PF4) in addition to the antithrombin, resulting in inactivation of the heparin as an anticoagulant (36). This may be the reason for heparin resistance and for a serious condition known as HIT. Typically, this condition occurs 7 to 14 days after initiation of heparin therapy, but it may occur earlier in some patients who have had previous exposures to heparin. In these cases, heparin-induced platelet aggregation occurs and may result in the production of antiplatelet antibodies. Development of this condition necessitates termination of heparin therapy and institution of antiplatelet drugs or oral anticoagulants. On withdrawal of heparin, the thrombocytopenia usually is reversible. Mild increases in liver function tests frequently are associated with heparin therapy. Long-term use of full therapeutic doses of heparin (>20,000 U/day for 3–6 months) has been associated with osteoporosis, and spontaneous vertebral fractures

have been infrequently reported (36).

Hemorrhagic complications of heparin therapy are managed, in part, with the specific antagonist protamine sulfate (36). This agent is discussed in greater detail in the *Coagulants* section of this chapter.

The structural and mechanistic diversity of the antiplatelet drugs disallows a cohesive description of their toxicities. Hemorrhage is certainly a concern, but other, more drug-specific toxicities may be of greater immediate concern. It is suggested that toxicity information for antiplatelet medications be obtained from

appropriate references for the specific agent in question and from the most recent reviews of antiplatelet agents (87).

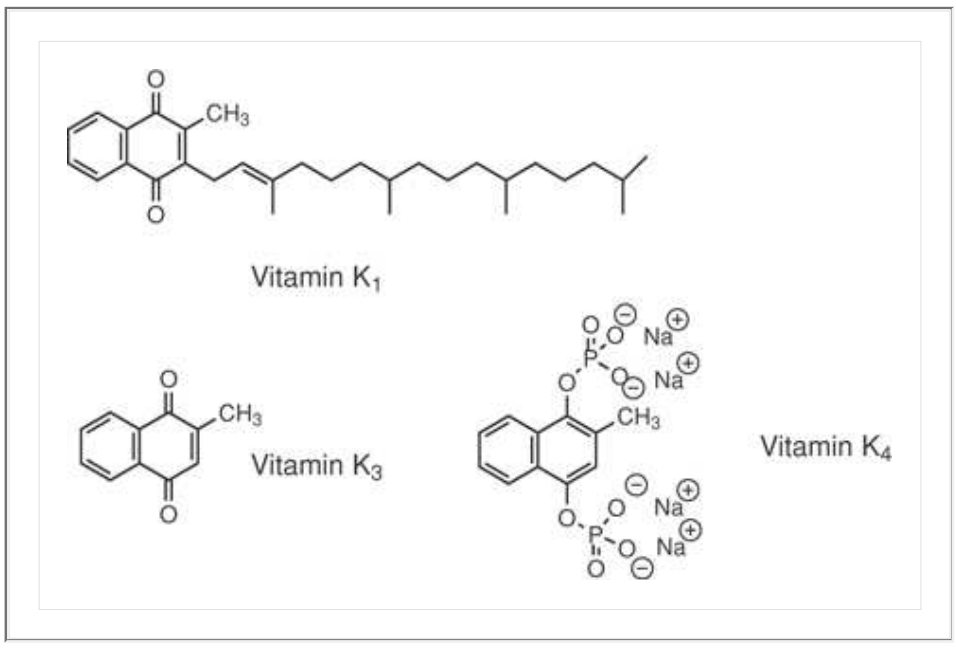
Thrombolytic Toxicities

As discussed earlier, plasmin, because of its lack of specificity, not only digests fibrin but also degrades many other plasma proteins, including several coagulation factors and the anticoagulating factor, activated protein C. Thus, as expected, most thrombolytic drugs not only attack pathological clots but also exert their actions on any other site of compromised vascular integrity. The dissolution of necessary clots results in the principal side effect of thrombolytic therapy, hemorrhage. Its action on the activated protein C also may be responsible for their neurovascular toxicities (135).

Multiple studies have examined the incidence of life-threatening hemorrhage (i.e., intracranial hemorrhage) with the various thrombolytic medications. These studies indicate that the rate of significant hemorrhagic complication is essentially the same (0.1–0.7%) regardless of the specific therapeutic agent used. Supportive care is indicated in cases of thrombolytic toxicity. No specific antagonist exists to manage thrombolytic medication-induced hemorrhage, but antifibrinolytic drugs, such as aminocaproic acid and tranexamic acid, often are used. These compounds are described in detail in the *Coagulants* section of this chapter.

Coagulants

A variety of pathological and toxicological conditions can result in excessive bleeding from inadequate coagulation. Depending on the etiology and severity of the hemorrhagic episode, several possible blood coagulation inducers can be therapeutically employed.



Vitamin K

Because the orally active anticoagulants, such as warfarin and the indandiones, act through interruption of the normal actions of vitamin K, it stands to reason that vitamin K should be effective

in the treatment of bleeding induced by these agents (122). Vitamin K_1 (phytonadione, Mephyton) is the form of vitamin K most often used therapeutically. Vitamin K_1 is safe for use in infants, pregnant women, and patients with glucose-6-phosphate deficiency. Furthermore, phytonadione, being more lipid soluble, has a faster onset than other vitamin K preparations and requires smaller doses than vitamin K_3 (menadione) or vitamin K_4 (menadiol sodium diphosphate). Both vitamins K_3 and K_4 may produce hyperbilirubinemia and kernicterus in neonates as well as hemolysis in neonates and glucose-6-phosphate–deficient patients. In fact, the only advantage of vitamins K_3 and K_4 over vitamin K_1 is that whereas absorption of vitamin K_1 requires the presence of bile, absorption of vitamins K_3 and K_4 does not, because they are absorbed via a passive process directly from the intestine (122). This may be a slight advantage for patients with cholestasis or severe pancreatic dysfunction. Only vitamin K_1, however, is appropriate therapy for bleeding associated with warfarin and superwarfarin anticoagulation. Vitamin K_2 is not used therapeutically.

Vitamin K_1 is effective at inducing coagulation when administered orally, subcutaneously, intramuscularly, or intravenously. Although the oral route is preferred, it is not always practical in a patient who is critically hemorrhaging. The other routes of administration, though used clinically, all have significant potential drawbacks. Larger doses (e.g., volume >5 mL) are not appropriate for subcutaneous administration, and intramuscular injection generally is avoided in patients who are at risk for significant hematoma formation (e.g., hemophiliacs). Intravenous dosing of vitamin K has been associated with severe anaphylactoid reactions (including death) presumably secondary to colloidal formulation.

The half-life of vitamin K_1 is quite short—only 1.7 hours via the intravenous route and 3–5 hours via the oral route. When given orally, vitamin K_1 is absorbed directly from the proximal small intestine in an energy-dependent and saturable process that requires the presence of bile salts. These kinetic features argue for administration in divided doses rather than larger, single daily doses. The typical starting point for adults with drug-induced hypoprothrombinemia is 2.5 to 10 mg of vitamin K_1 orally, repeating in 12 to 48 hours if needed. In cases of ingestion of long-acting superwarfarin rodenticides (e.g., brodifacoum), therapy may be 125 mg/day for weeks or months. Practically speaking, because vitamin K_1 is dispensed as 5-mg tablets, superwarfarin-poisoned patients may require 10 to 30 tablets every 6 hours.

Because of the short half-life of vitamin K_1, dosing must be repeated two to four times per day for the duration of treatment. Furthermore, regardless of the route of administration, coagulant effects are not evident for up to 24 hours. Because of this delay in onset, severe

acute hemorrhage is better managed initially with intravenous infusion of fresh-frozen plasma, followed by vitamin K therapy.

Protamine

Mechanism of Action

Protamine sulfate has been approved in the United States as a specific antagonist to heparin since 1968 (134). Protamines are an arginine-rich, highly basic group of simple proteins derived from salmon sperm. The highly acidic heparin polysaccharides exhibit their anticoagulant activity through binding to antithrombin III. Because of the basicity of protamine, heparin has an increased affinity for protamine relative to antithrombin III. In fact, its binding affinity for protamine is so much greater than that of antithrombin III that protamine actually will induce dissociation of the heparin/antithrombin III complex. If protamine is administered in the absence of heparin, it can have marked effects on coagulation. Protamine is not completely selective for heparin and, in vivo, also interacts with fibrinogen, platelets, and other plasma proteins causing anticoagulation. For this reason, use of the minimal amount of protamine necessary to antagonize heparin-associated bleeding should be employed (usually 1 mg of protamine intravenously for every 100 U of heparin remaining in the patient).

Side Effects

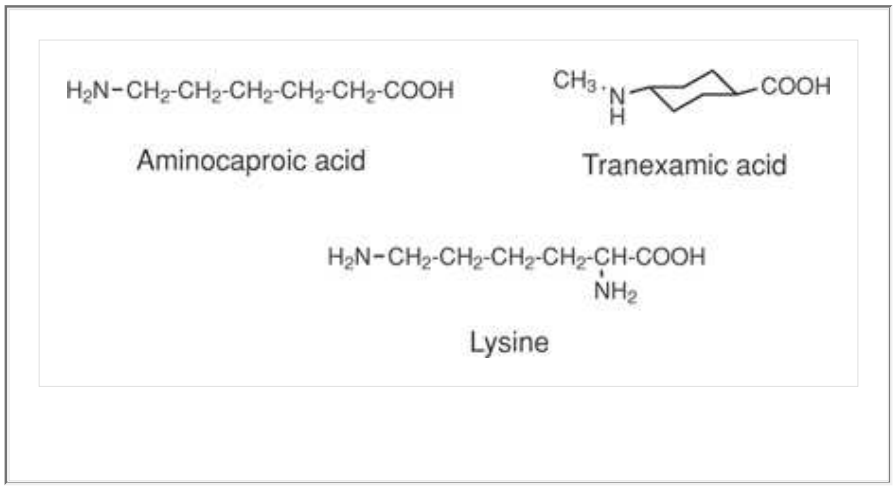
Anaphylaxis also has been associated with the use of protamine. Although development of protamine anaphylaxis is not limited to diabetics, those patients with diabetes that have used protamine-containing insulin (NPH or protamine zinc) do have a slightly increased risk of anaphylaxis. Some

less common reactions to protamine include pulmonary vasoconstriction, hypotension, and thrombus formation.

Antifibrinolytic Agents

Mechanism of Action

Control of a variety of fibrinolytic states can be achieved using a number of synthetic antifibrinolytic agents, such as tranexamic acid (Cyklokapron) and ε-aminocaproic acid (Amicar), that completely inhibit plasminogen activation. Plasmin binds to fibrin through a lysine binding site to activate the final stages of fibrinolysis (Fig. 31.1). Aminocaproic acid, a lysine analogue, and tranexamic acid are antifibrinolytic agents with high affinity for the five lysine binding sites of plasminogen, thus effectively competing and preventing the binding of plasmin to fibrin.



Pharmacokinetics

Both ε-aminocaproic acid and tranexamic acid are readily absorbed when administered orally. They also can be given intravenously, although significant hypotension can result if the infusion is given too quickly. Elimination of the drugs is primarily renal, with little metabolism taking place. The half-lives of ε-aminocaproic acid and tranexamic acid are each approximately 2 hours.

Therapeutic Use

These drugs find clinical utility in settings such as prevention of rebleeding in intracranial hemorrhages, as adjunctive therapy in hemophilia, and of course, in treatment of bleeding associated with fibrinolytic therapy. In most bleeding conditions, however, ε-aminocaproic acid therapy has not been shown to be of definitive benefit. In recent trials, tranexamic acid was found to reduce red cell transfusion better than ε-aminocaproic acid or placebo in patients undergoing liver transplantation (136).

Side Effects

The major risk associated with ε-aminocaproic or tranexamic acid therapy is intravascular thrombosis as a direct result of the inhibition of plasminogen activator. Thrombi that form during therapy are not easily lysed and, therefore, can have additional ischemic consequences. Additional possible complications include hypotension, abdominal discomfort, and rarely, myopathy and muscle necrosis.

Aprotinin (Traysylol)

Operative procedures, such as heart valve replacement, frequently have effects on platelet function and endogenous coagulation factors (137). These effects may result in significant peri- or postoperative bleeding. Aprotinin is a serine protease inhibitor that blocks kallikrein and plasmin and provides some protection to platelets from mechanical injury. The inhibition of fibrinolysis results in profound antihemorrhagic effects (137). Side effects of aprotinin therapy usually are minor, but anaphylaxis has possibly been implicated in a small population (<0.5%). For this reason,

it is suggested that a small test dose be given before initiation of the therapeutic infusion.

Plasma Fractions

Spontaneous bleeding can result from dysfunction or deficiencies of specific coagulation factors. A list of coagulation factors and deficiency states is given in Table 31.6.

Spontaneous bleeding usually occurs when the activity of coagulation factors falls below 5% of normal. Typically, these deficiencies are the result of a chronic disease state, such as von Willebrand's disease or hemophilia. Management of an acute hemorrhagic event in a coagulation factor–deficient patient includes administration of the appropriate factors in concentrated form. The most

common inherited clotting factor deficiencies involve factor VIII (classic hemophilia A) and factor IX (hemophilia B, or Christmas disease).

Table 31.6. Clotting Factors

Factor	Common Name	Deficiency State	Source	Half-Life of Infused Factor (days)	Target for Action of
I	Fibrinogen	Afibrinogenemia, defibrination syndrome	Liver	4	
II	Prothrombin	Prothrombin deficiency	Liver (requires vitamin K)	3	Heparin (IIa) warfarin (synthesis)
III	Tissue thromboplastin, thrombokinase, tissue factor		Liver (may require vitamin K)		
IV	Calcium (Ca^{2+})				
V	Proaccelerin, labile factor	Factor V deficiency	Liver	1	
VI	Deleted factor				
VII	Proconvertin, stable factor	Factor VII deficiency	Liver (requires vitamin K)	0.25	Heparin (VIIa); warfarin (synthesis)
VIII	Antihemophilic A factor (AHF), antihemophilic globulin (AHG)	Hemophilia A (classic) Von Willebrand's	Liver	0.5 Unknown	

		disease			
IX	Antihemophilic B factor, plasma thromboplastin component (PTC), Christmas factor	Hemophilia B (Christmas disease)	Liver (requires vitamin K)	1	Heparin (IXa); warfarin (synthesis)
X	Stuart or Stuart-Prower factor	Stuart-Prower defect	Liver (requires vitamin K)	1.5	Heparin (IXa); warfarin (synthesis)

Two forms of factor VIII concentrate are clinically available, cryoprecipitate and lyophilized factor VIII concentrate. Cryoprecipitate is a factor VIII–rich plasma protein fraction (PPF) prepared from whole blood that also contains approximately 300 mg of fibrinogen per unit. Immediately before

infusion, the required number of cryoprecipitate units are thawed in a sterile saline/citrate solution and pooled. The lyophilized factor VIII concentrates are prepared from large plasma pools and also are rich in fibrinogen. Lyophilized factor VIII concentrates are not useful in therapy for von Willebrand's disease, because during the extraction and lyophilization process, the polymeric structure of factor VIII in the von Willebrand protein that supports platelet adhesion is destroyed, rendering the preparation inactive. Because of the pooling of blood from multiple donors in the preparation of lyophilized factor VIII concentrates, it generally is held that cryoprecipitate, which is isolated from a single donor, is safer.

The major concern associated with the use of concentrated clotting factors is the risk of viral transmission (primarily HIV and hepatitis B). This fear has somewhat attenuated the use of concentrated plasma fractions, even in diseases such as hemophilia. Ultrapure factor VIII concentrates produced using recombinant DNA technology have been approved for use. Frequently, however, the expense of these recombinant agents is the reason why the more traditional plasma isolates are used—despite the possibility of viral transmission.

Lyophilized preparations of prothrombin, factor IX, and factor X also are available. The manufacturing process involves plasma extraction with solvents and detergents that renders the preparations virally inactive but still able to activate clotting factors. To prevent excessive thrombus formation in these situations, heparin often is added to the therapeutic regimen.

At times, a hemorrhagic event is possible but the patient does not require immediate coagulation therapy. For example, if a patient with mild hemophilia A needs to have a dental extraction performed, the potential for hemorrhage exists. In these cases, it is possible to increase the activity of the endogenous factor VIII through pretreatment with desmopressin acetate. This preoperative measure may alleviate the need for clotting factor replacement.

Plasma Extenders and Blood Substitutes

Maintenance of circulation is secondary only to airway and breathing in the American Heart Association chain of survival (138). Circulation is governed by the three components of the Fick Principle: 1) on-loading of oxygen onto the erythrocytes (red blood cells), 2) delivery of oxygen-laden erythrocytes to the various cells and tissues, and 3) off-loading of the oxygen from the erythrocytes to the tissue cells (139). Interruption of any of these three components results in physiologic compromise. Inadequate blood volume (i.e., a loss of red blood cells) will disallow the transport of oxygen to tissues.

Severe anemia, such as that secondary to major hemorrhage, is a complicated condition to manage. Simply replacing lost blood with new blood may not always be practical—or even beneficial to the patient. Numerous approaches and theories exist that attempt to define the best method of emergently managing severe blood loss. Two basic types of fluid infusion are used for the resuscitation of severely anemic patients. These are sanguinous (blood-containing) infusions, in which fluids (e.g., whole blood and fractionated blood products) are used, and asanguinous (i.e., nonblood-containing) infusions, in which various crystalloids, colloids, blood substitutes, and plasma expanders are employed.

Sanguinous Resuscitation

It seems intuitive that resuscitation following severe blood loss would be best accomplished by replacing lost blood with fresh blood (i.e., sanguinous resuscitation); however, this is not always in the best interest of the resuscitation. Nonetheless, infusion of blood and blood products is recommended in certain hypovolemic circumstances. Generally, if hemodynamic instability exists in a hypovolemic adult following the infusion of 2 L of crystalloid (three successive 20 mL/kg body weight infusions in a child), addition of blood to the resuscitative regimen is recommended (140). The most significant advantage of sanguinous resuscitation is that infusion of red blood cells can replace both volume and oxygen-carrying capacity. Significant disadvantages of sanguinous resuscitation include limited supply, risk of transfusion reaction, expense, and possible transmission of bloodborne diseases.

At one time, a significant controversy existed regarding whether survivability was increased with the use of whole-blood transfusion or infusion of packed red blood cells (known as component therapy).

Traditionally, this decision was based on cost and the fact that few hospitals actually stored whole blood. Fortunately, however, scientists reached the same decision as the fiscal experts (140). The three major conclusions drawn from the scientific community were as follows:

1. "Whole blood out" does not require "whole blood in." Banked whole blood stored at 4°C lacks functional platelets and also suffers a progressive deterioration in the activities of various clotting factors. There is little difference in these parameters between banked whole blood and packed red blood cells. Because trauma patients require red blood cells, clotting factors, and platelets to varying degrees, it makes more sense to use functional components to replace what is specifically needed at that time.
2. Whole blood is not infused more rapidly than packed red blood cells. In fact, infusion technology exists that allows replacement of packed red blood cells suspended in normal saline as fast as 1,600 mL/min.
3. The overall risk of antigenic hypersensitivity reactions is greatly increased when using whole blood as opposed to specific components. The standard of care at this time is judicious use of the individual components with crystalloid infusion to maintain volume while the defect resulting in the blood loss is repaired.

Asanguinous Resuscitation

Crystalloids are aqueous electrolyte-containing solutions without proteins or large molecules. Examples of crystalloids are normal saline (0.9% NaCl) and lactated Ringer's solution. Colloids are aqueous solutions that contain various proteins or other larger molecules as well as electrolytes. Protein-containing colloids include albumin and PPF. Nonproteinaceous colloids include the dextrans and hetastarch. A list detailing the compositions of several common crystalloids and colloids is given in Table 31.7.

Crystalloids

Crystalloids have several advantages, including being inexpensive and free of risk of transferring bloodborne pathogens or inducing anaphylaxis. Furthermore, they largely are compatible with drugs and undergo rapid

renal clearance. The crystalloids, however, have a very short resident time in the intravascular space—only 30% remains in the vasculature within a few minutes following infusion. These fluids rapidly leak out of the vasculature into the interstitial space and can result in significant extravascular fluid accumulations ("third spacing"). Furthermore, crystalloids do not have any oxygen-carrying capacity.

Table 31.7. Composition of Common Intravenous Flui

Solution	Common/Trade Name	Concentration Solute	Ionic Concentration g/dL	mEq/L	Indicatic

*TCA OD, Tricyclic antidepressant overdose

Attempts at lengthening intravascular resident time of the solution and limit third spacing have resulted in the development of “hypertonic” crystalloid solutions. An example of a hypertonic solution is 3% NaCl (“hypertonic saline”). It has been suggested that the increased electrolyte

concentration will result in an osmotic gradient pulling fluid from the interstitial and intracellular spaces into the vasculature. These fluid shifts therefore would require less total volume to be infused. As expected, the possibility of severe hypernatremia and hyperchloremia, among other electrolyte disturbances, exists.

Protein Colloids

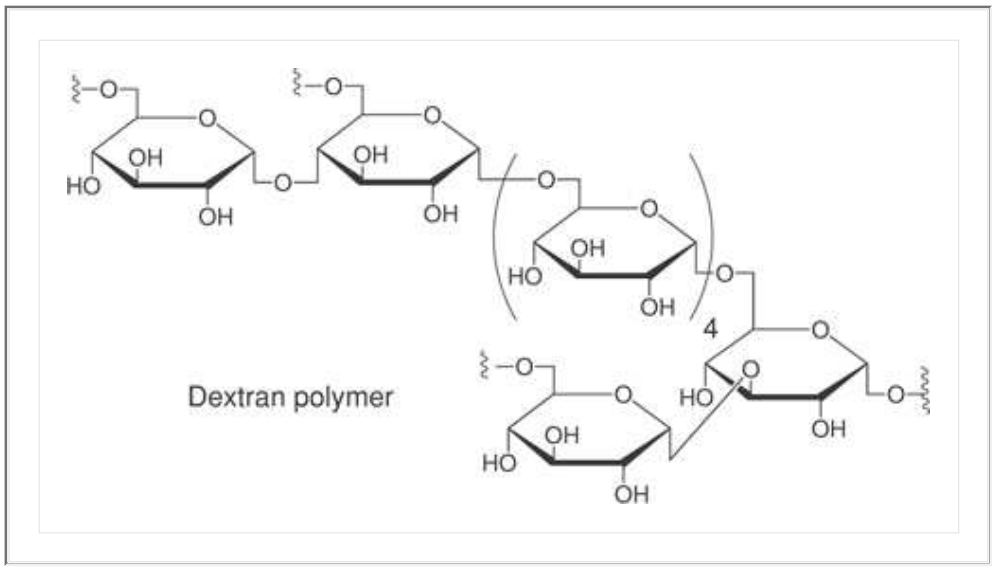
Protein colloids contain larger molecules and have a longer intravascular residence time than crystalloids, but eventual fluid loss to the extravascular space does occur. Protein colloids, such as albumin and PPF, are prepared from pooled human blood and, therefore, carry with them a risk of transmission of viral infection or induction of anaphylaxis. The PPF is a 5% mixture (5 g of protein in 100 ml of 0.9% NaCl solution) of proteins that is osmotically equivalent to human plasma. The composition of the protein mixture is 83 to 90% albumin. Albumin typically is administered as either a 5 or 25% solution. By definition, albumin preparations must be composed of a protein mixture that is more than 90% albumin. Generally, PPF is favored over albumin for fluid resuscitation, because albumin appears to cause more interstitial edema.

Nonproteinaceous Colloids

Dextrans

Nonproteinaceous colloids also are used in fluid resuscitation. These compounds generally are complex mixtures of sugar polymers. Dextrans are glucose polymers produced by bacteria linked in an α-1,6 chain and having an α-1,3 or α-1,4 branch about every fifth residue. The specific positioning of the branching varies by the bacterium producing it. The molecular weights of these chains generally are 40 or 70 kDa (dextran-40 and dextran-70, respectively), and the compounds work via an osmotic gradient similar to the colloids and hypertonic crystalloid solutions. Dextran-70 is a 4% solution, whereas dextran-40 is a 10% preparation. Dextrans have a longer intravascular residence time

than albumin, which limits interstitial edema. As with the crystalloids and other colloids, the dextrans have no oxygen-carrying capacity. Furthermore, because they are bacterial products, the dextrans have the potential to be potent antigens and induce anaphylaxis. The incidence of serious antigenic response seems to increase if the dextran used has a significant fraction of components with a molecular weight of greater than 100 kDa. In these cases, administration of dextran-1 (molecular weight, 1 kDa) before the higher-molecular-weight dextrans minimizes formulation of the very large immunogenic complexes. This approach has been shown to decrease sensitivity responses to high-molecular-weight dextrans by as much as 15- to 20-fold. This is particularly important in a number of European countries, where dextran-150 (molecular weight, ~150 kDa) is routinely used.



Hetastarch

Hetastarch, another nonproteinaceous colloid, is a complex mixture of ethoxylated amylopectins

ranging in molecular weight from 10 to 1,000 kDa (average molecular weight, ~450 kDa). When infused as a 6% solution, hetastarch approximates the activity of human albumin. The larger molecular weights, however, increase its intravascular residence time as well as its plasma expansion effects relative to albumin. Hetastarch is synthetically produced, so it is degraded more slowly and is less antigenic than other colloids. Despite these advantages, hetastarch is quite expensive and also has no oxygen-carrying capacity.

Plasma substitutes, such as dextrans and hetastarch, have some additional unusual disadvantages specific to the various classes. High-molecular-weight (70-kDa) dextran coats erythrocytes, making subsequent blood typing and cross-matching difficult. On the other hand, low-molecular-weight (40-kDa) dextran coats platelets, which can induce a bleeding disorder. Hetastarch has a dilutional effect on factor VIII and, therefore, should not be used to treat patients with factor VIII deficiency (e.g., hemophilia)–related hemorrhage.

Combination use of hypertonic crystalloids with nonproteinaceous colloids has been investigated. For example, 7.5% NaCl in 6% dextran-70 (hypertonic saline–dextrose) has been studied in a variety of animal models and in human trauma patients with some success. Particularly promising are animal studies of closed head injury, which suggest not only a hemodynamic benefit but also a sustained decrease in intracranial pressure. Studies in this system as well as in burn and trauma patients are ongoing.

Red-Cell Substitutes ("Synthetic Blood")

Concerns about the safety and adequacy of the blood supply and the increasing need to rigorously screened human blood because of HIV and hepatitis B and C virus have stimulated extensive search for "blood substitutes" (or, more accurately "red-cell substitutes") for resuscitation of trauma patients (140,141). Three different classes of materials have been evaluated clinically as potential blood substitutes (140). They are perfluorocarbon (PFC)-based emulsion, hemoglobin-based oxygen carriers (HBOCs), and liposome-enclosed hemoglobin. Thus far, only the PFCs and HBOCs have reached various phases of their clinical trials, whereas liposome-enclosed hemoglobin is still in the preclinical stage of development. Several excellent reviews have been published in recent years summarizing the clinical progress, efficacy, and toxicity of these agents (142,143,144,145,146).

Perfluorocarbon-Based Oxygen Carriers

Some of the common ingredients of the synthetic blood substitutes are shown in Fig. 31.23. The most significant benefit of PFCs is their ability to transport oxygen to the body tissues via the circulatory system and their in vivo metabolic stability (145). This ability results from the high solubility of gases, such as oxygen and carbon dioxide, in the PFC preparations. Red blood cells with fully functional hemoglobin have an oxygen solubility of 17 to 20 mL/dL. Red blood cells without hemoglobin can only dissolve approximately 0.3 mL/dL of oxygen. The oxygen solubility of PFC preparations is approximately 7 mL/dL.

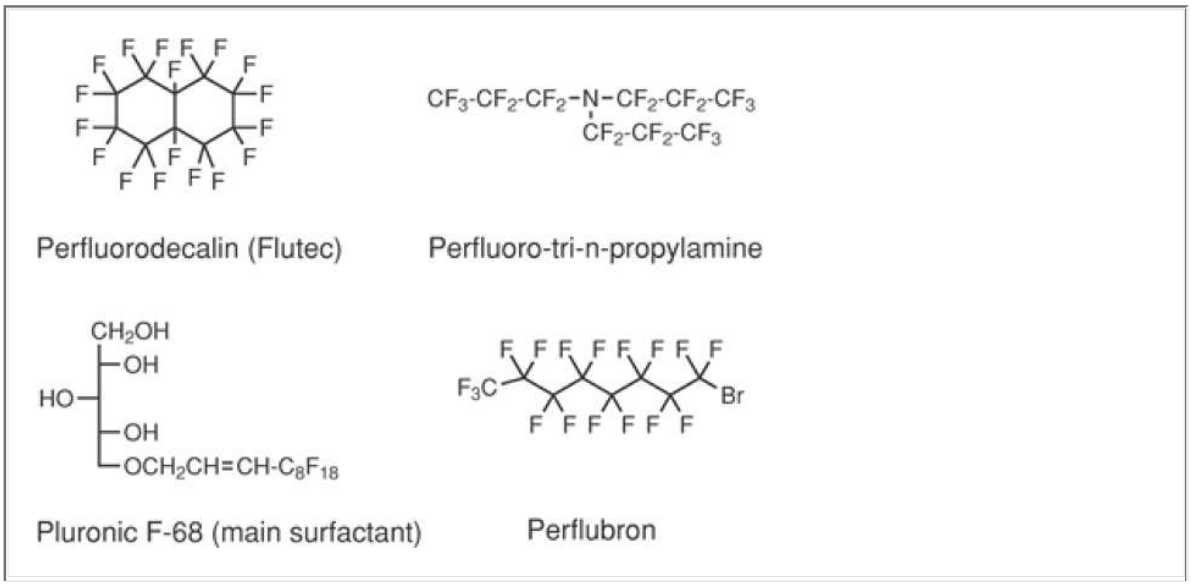


Fig. 31.23. Chemical structures of perfluorocarbon-based blood substitutes.

The PFCs are formulated as stable aqueous emulsions with dextrose, egg yolk phospholipids, and physiologic electrolytes. These emulsions are somewhat less viscous than whole blood at 37°C. The PFCs have a dose-dependent half-live of 8 to 24 hours. Normal doses are 10 mL/kg, but short-term doses of up to 30 mL/kg have been reported. The PFCs are not metabolized and are eliminated unchanged in expired respiratory gases. Because they are highly lipophilic, multiple doses can cause PFC accumulation in the liver and spleen. Therefore, it is recommended that these compounds not be administered more than once in a 6-month period.

During the early 1980s, PFC emulsions, such as Fluosol (a 20% emulsion of perfluorodecalin and perfluoro-tri-n-propylamine), were used as an oxygen carrier in the preoperative treatment of severely anemic patients, but often with significant toxicities, high incidence of hypertension, and potential to cause anaphylaxis reactions (143,147).

Another use for PFC emulsions is decreasing or preventing myocardial ischemia during percutaneous transluminal coronary angioplasty in high-risk patients. The emulsion is preoxygenated and injected transluminally through the coronary angioplasty balloon to deliver the oxygenated emulsion to areas distal to the point of balloon inflation. Less common but also investigated uses of PFC emulsions include therapy for carbon monoxide intoxication, oxygenation in cases of cerebral hypoxia, autoimmune hemolytic anemia, and nonavailability of compatible blood products. Newer PFCs, such as perflubron, that are less toxic have been used with some success in limited clinical trials during orthopaedic surgery (148).

Genetically Engineered and Chimeric Hemoglobin-Based Oxygen Carriers

Stroma-free hemoglobin appears to hold significant promise as a potential acellular oxygen transporter. These preparations have no effect on colloid osmotic pressure and are not effective as plasma expanders. A number of potential advantages exist with this technology. For example, stroma-free hemoglobin can be prepared from bovine or outdated human erythrocytes, no cross-match is necessary, it is lyophilized for convenient and space-efficient storage, and it is reconstituted in normal saline (149).

Two major problems that are currently being addressed are large-scale production of the material and the fact that stroma-free hemoglobin does not readily release oxygen to the tissues at normal oxygen tensions. Recombinant DNA technology has allowed the production of large amounts of hemoglobin through synthetic gene expression in *Escherichia coli* and *Saccharomyces cerevisiae*. New developments in hemoglobin polymerization also show promise (142,149).

Another approach to stroma-free hemoglobin technology is the development of chimeric hemoglobins. Human hemoglobin stripped from red blood cells is not functional. Diphosphoglycerate (DPG) is required for oxygen release from hemoglobin, and insufficient DPG is available outside the red cell to induce oxygen release (i.e., oxygen affinity for hemoglobin is too high in the absence of DPG). Tetrameric human hemoglobin decomposes into dimers when infused into the bloodstream. These dimers precipitate in the kidneys, potentially causing severe renal damage. In native red cell–bound hemoglobin, this decomposition is prevented by the high concentration of proteins inside the red blood cells. Interestingly, not all species require ATP and DPG to diminish oxygen affinity for hemoglobin. The crocodile is one such animal in which red blood cells do not contain DPG, and this phosphate has no effect on oxygen affinity to their hemoglobin. Crocodile hemoglobin cannot be used directly in humans, because certain features of human hemoglobin are necessary for recognition and signaling. Genetic engineering technology has allowed the creation of a chimeric hemoglobin that is part human and part crocodile and that is useful in humans (149). It has the advantage of providing hemoglobin oxygen-carrying capacity without transmitting human bloodborne diseases. One major disadvantage is that the chimeric hemoglobins are not endogenous proteins and, therefore, may be potent antigens. A great deal of investigation is still necessary before chimeric hemoglobins will see any clinical usage.

The most successful HBOCs clinically are polymerized hemoglobin solution (142). Among these, Hemolink, Hemopure, and PolyHeme are undergoing U.S. FDA–approved phase III clinical trials. Hemolink is a product consisting of human hemoglobin polymerized using an oxidized trisaccharide, O-raffinose, followed by a reduction. Hemopure and PolyHeme, on the other hand, are produced by using glutaraldehyde as the polymerizing agent and with either bovine hemoglobin (Hemopure) or human hemoglobin (PolyHeme) as the source of hemoglobins.

Newer HBOCs without the nitric oxide–scavenging properties of the first-generation HBOCs have been prepared and are being investigated as red-cell substitutes (150,151,152,153).

Liposome-Encapsulated Hemoglobin

The successful use of liposomes as drug-delivery vehicles has prompted the preparations of liposome-encapsulated hemoglobins as artificial red-cell substitutes (154). This represents a promising approach for the design of longer storage half-life red-cell substitutes, because it has no blood group antigens on its surface and, thus, could be stored for long period of times (154). The circulatory half-life of liposome-encapsulated hemoglobin is further improved with the design of cellular-based red-cell substitutes with an actin matrix underlying the lipid bilayer as a structure support (155).

Case Study

Victoria F. Roche

S. William Zito

DF is a 24-year-old Hispanic man who appeared in the emergency department with a chief complaint of right leg swelling and pain. He reports that he received a severe trauma to his right calf 5 days ago from the crush of people at a protest rally in support of equal rights for immigrant farm workers. A review of DF's patient history reveals him to be a healthy male except for a previous HIT that resulted from low-dose heparin prophylaxis associated with a laparoscopic repair of an inguinal hernia several years ago. On examination, the physician observes the classic signs of DVT, including pain when asked to pull his foot up toward himself against resistance, tenderness, swelling, and warmth. The presence of DVT was confirmed by Doppler ultrasonography, and the physician wants to begin anticoagulation treatment and asks your opinion of the following choices

1. Identify the therapeutic problem(s) where the pharmacist's intervention may benefit the patient.
2. Identify and prioritize the patient-specific factors that must be considered to achieve the desired therapeutic outcomes.
3. Conduct a thorough and mechanistically oriented structure–activity analysis of all therapeutic alternatives provided in the case.
4. Evaluate the structure–activity relationship findings against the patient-specific factors and desired therapeutic outcomes, and make a therapeutic decision.
5. Counsel your patient.
